A LIVING BOOK

Antonio Alfaiate

AI in Education

The State of the Art

EDITION 2026.11

Grows as the field learns.

Living Book — Monograph

Generated 2026-10-25T22:48:09.913Z · Latest edition 120 (2026-10-25T23:00:00Z) · Total editions 120 · Questions in monograph 238

21 chapters · 238 questions · 3306 citations · 2541 unique sources · 1190 cross-references

Table of Contents

- Cover
- Preamble
- Chapter 1: Philosophical Foundations — Why Do We Educate? (16 questions)
  - Q001 — What is the purpose of education in a world where machines can know, reason, and create?
  - Q002 — If AI can answer any question, what does it mean to "learn" something?
  - Q003 — Does human knowledge lose or change its value when it is no longer scarce?
  - Q004 — What is the difference between knowledge, understanding, and wisdom — and which of these can AI possess or transmit?
  - Q005 — How does the human relationship with truth change when answers are generated rather than discovered?
  - Q006 — What is irreducibly human in the act of teaching, and what is irreducibly human in the act of learning?
  - Q007 — Should education aim to make humans complementary to AI, resistant to it, or independent of it?
  - Q008 — How does AI reshape our concept of intelligence itself — and the way schools measure and reward it?
  - Q009 — What happens to intellectual struggle, effort, and "productive failure" when friction can always be removed?
  - Q010 — Is there a moral difference between learning with AI, learning from AI, and outsourcing learning to AI?
  - Q102 — If a machine can produce an original-seeming idea, what remains of the concept of authorship in student work?
  - Q103 — Does AI change what it means to be educated, as distinct from being skilled or informed?
  - Q104 — What obligations does a society have toward knowledge that no human any longer holds unaided?
  - Q105 — Is curiosity a trainable capacity, and what does current evidence say about whether answer-on-demand technology weakens or strengthens it?
  - Q106 — Can a machine participate in a tradition of inquiry, or only imitate its outputs?
  - Q258 — What does classical virtue ethics contribute to the question of how much AI assistance is compatible with the intellectual and moral development education is meant to cultivate?
- Chapter 2: Ethical Dimensions (13 questions)
  - Q011 — Who is responsible when an AI teaches something false, biased, or harmful to a student?

- Q012 — How should student data collected by AI systems be governed, and who owns the learning profile of a child?
- Q013 — Does personalized AI tutoring risk creating algorithmic determinism — locking students into predicted trajectories?
- Q014 — How do we prevent AI from amplifying existing inequalities of class, language, geography, and disability in education?
- Q016 — What consent can a minor meaningfully give to AI-mediated education?
- Q017 — How do we preserve academic integrity when the boundary between assistance and authorship dissolves?
- Q018 — Should there be a "right to a human teacher," analogous to a right to human medical care?
- Q019 — How do we address the cultural and ideological biases embedded in models trained predominantly on certain languages and worldviews?
- Q020 — What ethical obligations do AI companies have toward education systems they disrupt but do not serve?
- Q109 — Is it defensible for a school to require AI use when families object on religious or philosophical grounds?
- Q111 — What duties do educators have toward students who cannot or will not use AI?
- Q101 — Should teachers be required to disclose their own classroom use of AI, as the EU AI Act requires of AI systems, even when disclosure weakens the exercise?
- Q259 — What obligations do AI developers and companies owe specifically to the education sector, and what regulatory or market mechanisms might enforce those obligations?

- Chapter 3: AI's Role in Teaching (15 questions)
  - Q021 — What can AI tutors do better than human teachers, and where do they fall short?
  - Q022 — How should the teacher's role be redefined — from transmitter of knowledge to what, exactly?
  - Q023 — What pedagogical models (Socratic, constructivist, mastery-based) does AI enable at scale for the first time?
  - Q024 — How can AI support teachers (planning, assessment, feedback) without deskilling or replacing them?
  - Q025 — What does effective human–AI co-teaching look like in a real classroom?
  - Q026 — How should teacher training change so educators can critically use, evaluate, and challenge AI tools?
  - Q027 — Can AI meaningfully teach non-cognitive skills — empathy, collaboration, resilience, character?
  - Q028 — How do we assess learning authentically when AI can complete any traditional assessment?

- Q030 — How do we design AI systems that strengthen rather than substitute students' thinking (avoiding cognitive offloading)?
- Q114 — What happens to teacher expertise and professional identity when curriculum materials are machine-generated?
- Q116 — What effect does AI support have on novice, substitute, and under-qualified teachers specifically?
- Q227 — How is generative AI changing pedagogy, authorship, and assessment in creative arts education?
- Q230 — How can educators design formative assessment with AI that strengthens feedback, self-regulation, and learning rather than task substitution?
- Q260 — How do teachers maintain instructional authority, pedagogical presence, and classroom trust when AI systems are simultaneously delivering competing explanations to students?
- Q274 — Now that the same generative model can act as a personal tutor, a whole-class assistant, or a teacher's planning copilot, how should schools balance one-on-one AI tutoring with AI support for classrooms and teachers?

- Chapter 4: The Learner's Experience (12 questions)
  - Q031 — How does constant AI availability change motivation, curiosity, and the desire to learn?
  - Q032 — What are the effects of AI companionship on students' social development and human relationships?
  - Q033 — How do we cultivate critical thinking in students who grow up trusting AI-generated answers?
  - Q034 — What new literacies (AI literacy, prompt literacy, epistemic hygiene) become as fundamental as reading and writing?
  - Q035 — What is the promise and the peril of AI-driven accessibility for learners with disabilities, neurodivergence, or language barriers, from the learner's own perspective?
  - Q036 — What does self-directed, lifelong learning look like when everyone has a personal AI mentor?
  - Q037 — How do we protect and develop memory, attention, and deep reading in an AI-saturated environment?
  - Q118 — How does always-available tutoring change help-seeking behaviour and peer learning?
  - Q120 — What does AI assistance do to students' self-assessment accuracy and metacognition?
  - Q121 — How is AI reshaping collaboration, peer help, and cheating norms within student cultures?
  - Q233 — What are the specific opportunities and risks of AI-powered personalisation for gifted and high-ability learners?
  - Q261 — What evidence, if any, links a student's AI usage patterns in early adolescence to their academic independence, metacognition, and critical thinking in later years?

- Chapter 5: Institutions and Systems (12 questions)
  - Q038 — Is the industrial-era school model (grades, classrooms, standardized curricula) still viable, and what replaces it?
  - Q039 — How should curricula be redesigned when factual content is instantly accessible and rapidly obsolete?
  - Q040 — What is the future of universities, credentials, and degrees when skills can be learned and demonstrated outside institutions?
  - Q041 — How can public education systems keep pace with private AI development without surrendering governance to tech companies?
  - Q042 — Who has legitimate authority to govern AI in education — states, markets, professions, or communities — and on what principles?
  - Q043 — How do developing nations avoid a new "AI colonialism" in education while leapfrogging infrastructure gaps?
  - Q122 — What is the total cost of AI to a school system, including licences, infrastructure, training, and staff time?
  - Q124 — What happens to a school when its AI vendor raises prices, is acquired, or ceases operation?
  - Q126 — What organisational conditions distinguish institutions that adopt AI successfully from those that do not?
  - Q234 — What data-protection and contractual clauses should every school-AI vendor agreement contain to safeguard student data and institutional interests?
  - Q235 — What governance structures give teachers, students, and parents meaningful input into a school's AI adoption decisions?
  - Q279 — How are leading universities building institution-wide AI strategies — including campus-wide generative-AI licences — that balance innovation, governance, and academic freedom?
- Chapter 6: Work, Economy, and Society (13 questions)
  - Q044 — Which capabilities do labour-market forecasts expect to reward, how reliable have such forecasts been, and how should schools teach for an unpredictable future?
  - Q045 — How should education respond to the possible decoupling of learning from employment (if AI displaces large categories of work)?
  - Q046 — What is the role of education in a society where economic productivity no longer requires most human labor — education for meaning rather than for jobs?
  - Q047 — How do we manage the transition for current workers whose skills are being obsoleted faster than retraining systems can respond?
  - Q048 — How does AI in education affect democracy — the formation of citizens capable of judgment, deliberation, and resistance to manipulation?

- Q049 — What shared human culture and values should education transmit when AI fragments information into personalized realities?
- Q050 — Which current decisions about AI in education do researchers and policymakers identify as most consequential, and on what grounds?
- Q127 — Which educational credentials are losing labour-market signalling value because of AI, and which are gaining it?
- Q128 — How is AI changing entry-level work, and what does that mean for the school-to-work transition?
- Q129 — What is happening to the economics of private tutoring, test preparation, and supplementary education?
- Q130 — How is AI affecting adult retraining and mid-career education systems?
- Q131 — Who profits from AI in education, and what business models are emerging around students?
- Q262 — What micro-credentials, digital badges, and AI-verified competency records are emerging as alternatives or supplements to traditional degrees, and what is their current labour-market traction?

- Chapter 7: The Evidence Base — What Research Actually Shows (13 questions)
  - Q051 — What does current peer-reviewed evidence show about the effects of AI tutoring systems on learning outcomes, and how strong is that evidence?
  - Q052 — What does research reveal about how students actually use generative AI when unsupervised — as distinct from how they report using it?
  - Q053 — What is currently known from cognitive science about AI's effects on memory formation, retention, and transfer of learning?
  - Q054 — What does the evidence show about AI's impact on writing skill development, from early literacy through academic and professional writing?
  - Q055 — What have studies found about AI feedback compared with human feedback — in accuracy, usefulness, and student receptivity?
  - Q056 — What does research show about the reliability of AI-detection tools, and what have institutions learned from relying on them?
  - Q057 — What evidence exists on how AI use affects different learner profiles — high vs. low performers, younger vs. older students, novices vs. experts?
  - Q058 — What do studies reveal about teachers' actual adoption patterns, workload effects, and attitudes toward AI tools?
  - Q059 — What does current evidence show about AI's effects on student motivation, engagement, and persistence — and how do these findings differ from marketing claims?

- Q060 — Which widely repeated claims about AI in education lack solid evidence, and which early findings have failed to replicate?
- Q136 — What are the recurring methodological weaknesses in this literature, and how should a reader discount for them?
- Q263 — What systematic reviews and meta-analyses of AI-in-education interventions exist as of 2025–2026, and what do they collectively conclude about effect sizes and methodological quality?
- Q273 — Do generative-AI tutors (2023–) improve durable learning, or mainly boost short-term task performance that fades once the tool is removed?

- Chapter 8: Field Experiences — Case Studies from Real Classrooms (10 questions)
  - Q061 — What have large-scale national AI-in-education initiatives (across different countries and income levels) achieved, and what have they abandoned?
  - Q062 — What lessons emerge from schools and universities that banned AI, then reversed course — or embraced it, then restricted it?
  - Q063 — What do documented deployments of AI tutors in low-resource and developing-world contexts show about what transfers and what fails?
  - Q064 — How have universities restructured courses, assessments, and honor codes in response to generative AI, and with what results?
  - Q065 — What have K–12 schools learned from integrating AI into daily instruction — the successes, failures, and unexpected consequences?
  - Q066 — What experiences have emerged from AI use in vocational, technical, and professional training (medicine, law, engineering, trades)?
  - Q067 — What can be learned from teachers who have become exemplary AI practitioners — what do they do differently?
  - Q068 — What documented harms — from data breaches to well-being incidents to learning setbacks — have occurred in real AI deployments, and what changed as a result?
  - Q236 — What do documented AI implementations for neurodivergent and special-needs learners show about benefits, limitations, and potential harms?
  - Q237 — What do higher-education early adopters report about long-term student outcomes three or more years after systematic AI integration?
- Chapter 9: Policy and Governance in Practice (13 questions)
  - Q069 — Which national and regional AI-in-education regulations currently exist, and how do their approaches compare?
  - Q070 — What guidance have major international bodies (UNESCO, OECD, EU, and others) issued on AI in education, and how is it being implemented?
  - Q071 — What does an effective institutional AI policy contain, and what distinguishes policies that work from those ignored in practice?

- Q072 — How are education systems regulating student data privacy in AI tools, and which legal frameworks apply to minors?
- Q073 — How should institutions handle procurement of AI tools — evaluation criteria, vendor accountability, contract terms, and exit strategies?
- Q074 — How are examination and credentialing bodies redesigning high-stakes assessment for the AI era?
- Q075 — What academic-integrity frameworks have institutions adopted to replace binary "cheating/not cheating" models, and how are they working?
- Q076 — How are teacher unions, professional bodies, and accreditation agencies responding to AI, and what standards are they setting?
- Q077 — What funding models and public investments in AI for education exist, and what do early returns suggest about their effectiveness?
- Q144 — What liability rules apply when an AI system harms a pupil's academic record or wellbeing?
- Q145 — How are age limits and child-safety requirements for AI products enforced, if at all?
- Q264 — What transparency, explainability, and audit obligations are being imposed on AI vendors supplying education systems, and how can schools enforce them contractually?
- Q277 — How should governments and universities regulate AI systems used for admissions, grading, proctoring, and other high-stakes educational decisions now that frameworks such as the EU AI Act classify them as high-risk?

- Chapter 10: Practical Navigation — Guides for Teachers, Students, and Leaders (14 questions)
  - Q078 — How should a teacher decide, lesson by lesson, when AI use helps learning and when it undermines it — is there a practical decision framework?
  - Q079 — What are the current best practices for designing AI-resilient and AI-inclusive assignments and assessments?
  - Q081 — How should students use AI as a study partner in ways that demonstrably strengthen rather than weaken their learning?
  - Q082 — What should students know about the limits, failure modes, and biases of AI systems before trusting their outputs?
  - Q083 — How should students disclose and document their AI use in academic work, and how can they build integrity habits that also serve them professionally?
  - Q084 — What practical steps allow school and university leaders to move from prohibition or paralysis to structured adoption — a realistic implementation roadmap?
  - Q085 — How should institutions structure professional development so teachers gain real AI competence rather than one-off training?
  - Q086 — How can schools communicate with and involve parents and communities in decisions about AI use?

- Q087 — What technical and organizational safeguards (age gates, data controls, human oversight, escalation paths) should any classroom AI deployment include?
- Q088 — How can educators and institutions with minimal budgets or infrastructure still give students equitable access to AI-supported learning?
- Q147 — What should a teacher do on first encountering AI-written student work?
- Q150 — What guidance exists for parents deciding which AI use is appropriate at home, by age?
- Q231 — What classroom-level governance practices enable teachers to implement AI policy consistently and pedagogically?
- Q265 — How should a school write, implement, and keep current an AI acceptable-use policy that remains meaningful as technology and institutional practice evolve?

- Chapter 11: Measurement and Evaluation (10 questions)
  - Q089 — How should the effectiveness of an AI intervention in education be measured — what outcomes, over what timescales, against what baselines?
  - Q090 — What standards of evidence should decision makers demand from edtech vendors before adopting AI products at scale?
  - Q091 — How can institutions monitor for unintended effects of AI — skill atrophy, dependency, equity gaps — that standard metrics miss?
  - Q092 — What is known about the longitudinal effects of sustained AI use on learners, and how should long-term studies be designed and tracked?
  - Q093 — How should learning analytics generated by AI systems be interpreted, validated, and protected from misuse in student evaluation?
  - Q094 — What benchmarks and audits exist for evaluating the pedagogical quality, safety, and bias of educational AI models themselves?
  - Q154 — How can learning gains from AI be measured without relying on the tool that produced them?
  - Q155 — What does it mean, methodologically, to assess a human-AI pair rather than an individual?
  - Q238 — How reliable are AI-generated assessments and grades compared to human marking, and under what conditions do they diverge?
  - Q239 — What methodological standards should peer reviewers apply to studies of AI educational interventions to identify industry-funded bias and weak designs?
- Chapter 12: Frontiers — Emerging Territories (11 questions)
  - Q095 — How are multimodal and voice-based AI changing learning beyond text — in languages, arts, sciences, and physical skills?
  - Q096 — What roles are autonomous AI agents beginning to play in education — as persistent tutors, course designers, or student proxies — and what new questions do they raise?

- Q097 — What is known and unknown about AI in early childhood education, where developmental stakes are highest?
- Q098 — How is AI reshaping special education and individualized support plans in practice, beyond its general accessibility promise?
- Q099 — How is AI transforming informal and out-of-school learning — self-teaching, homeschooling, communities of practice, and family learning?
- Q100 — What weak signals today — in research labs, startups, and experimental schools — most plausibly indicate what AI in education will look like in ten years?
- Q159 — What is the realistic near-term prospect for AI in embodied, laboratory, and practical subjects?
- Q160 — What would it mean for education if AI capability plateaus rather than continues to accelerate?
- Q161 — What emerging risks — model collapse, synthetic-content saturation, data exhaustion — bear directly on education?
- Q226 — How should AI-mediated laboratory simulation and coding assistants be designed and evaluated in STEM education?
- Q232 — How is AI transforming physical education and sports science pedagogy in schools and universities?

- Chapter 13: Knowledge Integrity and the Information Environment (11 questions)
  - Q162 — How can schools establish the provenance of the teaching materials they use, now that AI-generated content is indistinguishable in form from authored content?
  - Q163 — To what extent are textbooks, worksheets, and reference works used in schools now AI-generated, and is this disclosed?
  - Q164 — What documented cases exist of AI-generated misinformation entering curricula or classroom materials?
  - Q165 — How are school librarians and media specialists adapting their role to synthetic information environments?
  - Q166 — What verification and source-evaluation skills should now be taught explicitly, and at what ages?
  - Q167 — What happens to citation practice in schools when the cited source may itself be machine-written?
  - Q168 — What technical provenance standards — watermarking, content credentials, signed provenance — exist, and do they work in educational settings?
  - Q169 — How should a school decide whether a claim delivered by an AI system is reliable enough to teach?

- Q240 — How do AI systems trained predominantly on older data handle rapidly evolving topics, and how should educators communicate this temporal limitation to students?
- Q241 — What is the epistemic status of AI-generated summaries and syntheses — when, if ever, can they serve as academically citable sources?
- Q272 — Since GPT-4-class large language models (2023–) made drafting a mixed human–machine workflow, how has the practical meaning of writing, revision, and originality changed in classrooms?

- Chapter 14: Language, Culture, and Global Asymmetry (9 questions)
  - Q170 — Which languages do current AI systems serve well in educational use, and which do they serve poorly?
  - Q171 — How is AI being used in multilingual and newcomer classrooms, and with what measured results?
  - Q174 — How is AI being applied in indigenous and minority-language education, and who controls those projects?
  - Q175 — Is there evidence that AI use accelerates linguistic homogenisation in student writing and speech?
  - Q176 — What does AI translation change about the case for learning a foreign language at school?
  - Q228 — What does evidence show about AI-supported second-language acquisition, and what linguistic inequities does it create?
  - Q242 — What does research say about AI translation's role in foreign-language learning — does it support or substitute genuine language acquisition?
  - Q243 — How do cultural assumptions embedded in dominant AI language models affect the teaching of history, social studies, and humanities in non-Western educational contexts?
  - Q244 — What happens to language-minority communities when AI educational systems default to dominant languages — documented cases and proposed remedies?
- Chapter 15: Human Development, Wellbeing, and Mental Health (10 questions)
  - Q178 — What does developmental research say about age-appropriate exposure to conversational AI?
  - Q180 — How is AI being used in school counselling and crisis detection, and how accurate are those systems?
  - Q182 — What safeguarding duties arise when a student discloses harm to an AI system rather than to an adult?
  - Q183 — Is there evidence that AI use affects student anxiety, academic pressure, or perfectionism?
  - Q185 — What design features make an educational AI system engaging rather than compulsive, and are any enforced?
  - Q229 — How do educational AI systems affect student mental health, social isolation, and identity beyond anxiety?

- Q245 — What developmental-psychology evidence addresses the long-term effects of AI mentorship and tutoring on children's sense of agency, identity, and self-efficacy?
- Q246 — How should schools identify and respond when a student develops an unhealthy emotional dependency on an AI companion or tutor?
- Q247 — What do children and adolescents themselves report about how AI affects their motivation, confidence, and experience of learning?
- Q015 — What is known and unknown about long-term cognitive and emotional effects of AI on children, and how do ethicists weigh acting under that uncertainty?

- Chapter 16: Equity, Access, and the New Digital Divide (9 questions)
  - Q186 — What are the current gaps in device, connectivity, and AI-tool access between and within school systems?
  - Q187 — How large is the quality gap between free and paid AI tiers, and how does it map onto student wealth?
  - Q188 — Does measured evidence show AI narrowing or widening achievement gaps?
  - Q190 — How are rural and remote schools faring with AI relative to urban ones?
  - Q191 — Are there gendered differences in student AI adoption, confidence, and outcomes?
  - Q192 — How does AI-assisted homework interact with differences in home support and parental capacity?
  - Q193 — What interventions have demonstrably reduced AI-related inequity in schools?
  - Q248 — How are students with disabilities being helped or harmed by mainstream AI educational tools not specifically designed for their needs?
  - Q249 — What does the evidence show about AI's effect on first-generation and low-income college students — does it level or steepen the playing field?
- Chapter 17: Environmental and Material Costs (10 questions)
  - Q194 — What is the estimated energy and water footprint of typical AI use in a school, per student per year?
  - Q195 — How do AI's environmental costs in education compare with those of the technologies it displaces?
  - Q196 — Do education AI vendors disclose environmental data, and is any of it independently verified?
  - Q197 — Should schools account for AI emissions in their sustainability reporting, and do any currently do so?
  - Q198 — What device-lifecycle and e-waste consequences follow from AI-driven hardware requirements in schools?
  - Q199 — How should the contradiction between teaching sustainability and operating energy-intensive AI be handled?

- Q200 — What practical measures reduce the environmental cost of AI use in education without abandoning it?
- Q201 — Are data-centre siting decisions affecting the communities whose schools use these systems?
- Q250 — How should schools account for the full lifecycle carbon and water footprint of AI infrastructure, from hardware manufacture through data-centre operation to device disposal?
- Q251 — What evidence exists that smaller, locally deployed AI models can achieve comparable educational outcomes at significantly lower energy cost?

- Chapter 18: Higher Education and Research (10 questions)
  - Q202 — What is happening to the undergraduate essay as an assessment instrument?
  - Q203 — How is AI changing doctoral supervision and research training?
  - Q204 — What is AI doing to peer review and scholarly publishing, and how are journals responding?
  - Q205 — What research-integrity failures attributable to AI have been documented, and at what rate?
  - Q206 — How are admissions systems responding to AI-written applications and personal statements?
  - Q207 — What are the economic consequences of AI for universities' teaching-revenue models?
  - Q208 — How is AI changing the value and delivery of graduate professional programmes?
  - Q209 — What is AI doing to the academic labour market, including adjunct and teaching-assistant work?
  - Q252 — What is AI doing to the academic conference system, preprint culture, and peer review — and are hallucinated citations appearing in published literature?
  - Q253 — How are universities restructuring research data management and open-science policies in response to AI tools that can process, summarise, and generate research outputs?
- Chapter 19: Teacher Formation and the Profession (9 questions)
  - Q210 — What must initial teacher education now include about AI, and what do programmes actually teach?
  - Q211 — How is AI being used in teacher recruitment, evaluation, and classroom surveillance?
  - Q212 — What measured effect does AI have on teacher workload and burnout?
  - Q214 — How does mandated AI use affect teachers' professional autonomy and judgment?
  - Q215 — Is AI affecting teacher recruitment and retention, and in which direction?
  - Q216 — What new professional roles are emerging in schools because of AI?
  - Q217 — What would a professional standard or code of practice for teachers' AI use contain?

    - Q254 — What does continuing professional development for teacher AI literacy look like in practice — which programmes have been formally evaluated and what do they show?
    - Q255 — How are teacher unions and professional associations responding to AI in schools, and what collective-bargaining agreements or professional standards have emerged?
- Chapter 20: Security, Safety, and Institutional Risk (12 questions)
    - Q218 — How vulnerable are school AI systems to prompt injection and manipulation by students or outsiders?
    - Q220 — How widespread is AI-enabled bullying, including deepfakes of students and staff, and what works against it?
    - Q221 — What threatens the integrity of academic records when AI systems write to them?
    - Q222 — What should a school's AI incident-response procedure contain?
    - Q223 — What belongs on a school's AI risk register, and who owns each item?
    - Q224 — What are the risks of shadow AI use — unapproved tools used by staff and students — and how is it detected?
    - Q225 — What dependency risk does a school accept when core teaching functions rely on a single AI provider?
    - Q256 — What data-minimisation, retention, and deletion policies should schools adopt for student interaction logs generated by AI systems?
    - Q257 — How should schools respond when they discover that a third-party AI tool has been training on their students' data without adequate consent or notification?
    - Q275 — What does agentic AI change about student autonomy and academic integrity when systems can plan, search, draft, revise, and submit multi-step academic work with little supervision?
    - Q276 — What rules should govern behavioural tracking, biometric inference, and emotion recognition in AI-powered learning systems?
    - Q278 — How should education systems prepare for AI-enabled credential fraud, synthetic identities, and AI-assisted academic impersonation?
- Chapter 21: The Financial Economics of AI in Education (6 questions)
    - Q266 — What is the full cost of adopting, operating, maintaining, and eventually replacing or leaving an AI system in an educational institution?
    - Q267 — How should educational institutions finance AI, and how should they weigh that expenditure against competing educational needs?
    - Q268 — What evidence would establish whether an educational AI investment delivers financial savings, productivity gains, educational value, or a worthwhile combination of these outcomes?
    - Q269 — How does AI adoption affect the size, workload, and compensation of the teaching workforce?

- Q270 — What costs do parents and households bear as AI enters education, and how do those costs differ between families?
- Q271 — What costs do students bear as AI enters education, and how might those costs affect affordability, debt, and participation?

AI in Education: A Living Book

Antonio Alfaiate — *updated monthly* · Edition 120 · https://antonioalfaiate1959xx.github.io/living-book-site/

Preamble: On the Nature, Architecture, and Scientific Rigor of the Living Book

I. Defining the Living Book: Permanence Meets Currency

Conventional scholarly publishing faces a structural dilemma in rapidly advancing fields: the moment a printed monograph or edited handbook is bound and distributed, its empirical currency begins to decay. Conversely, while digital platforms, blogs, and collaborative wikis offer immediacy, they routinely lack unified authorship, structural coherence, deep empirical synthesis, and immutable citation provenance.

AI in Education: A Living Book establishes a new genre of scientific literature that transcends both limitations. Like a classical encyclopedic treatise, it is governed by a unified editorial vision, rigorous structural taxonomy, and exhaustive bibliographic verification. Yet unlike a static volume frozen at its publication date, this work operates as a continuously audited, self-renewing scholarly apparatus. Each monthly edition is systematically re-examined against newly published empirical findings, policy enactments, and pedagogical trials—while every prior edition is permanently frozen and archived before the book rewrites itself. In doing so, the *Living Book* achieves what traditional publications cannot: the citable permanence and intellectual depth of a foundational academic monograph combined with the real-time currency of a living scientific observatory.

II. Scale and Epistemic Foundation: A Scientific Approach to Knowledge

Spanning 21 thematic chapters, 238 active research investigations, 3,306 inline citations, 2,541 unique verified sources, and 1,190 cross-references across 1,585 pages in Edition 120, this work stands among the largest and most comprehensive scholarly syntheses ever assembled on artificial intelligence in human learning.

Volume alone, however, is secondary to epistemic care. Every answer in this book is constructed through a strictly scientific approach to evidence curation and synthesis, drawing selectively from the highest tiers of global knowledge production across nine languages:

- **Peer-Reviewed Journals and Empirical Studies:** Primary experimental, quasi-experimental, longitudinal, and meta-analytic research across cognitive science, educational psychology, computer science, neuroscience, and learning analytics.
- **Seminal Books and Academic Monographs:** Foundational works and theoretical treatises by acclaimed scholars, philosophers of education, cognitive scientists, and historians of technology.
- **International Institutions and Multilateral Bodies:** Primary policy instruments, competency frameworks, and global baseline datasets from UNESCO, the OECD, the World Bank, the European Union, and national ministries of education.
- **Authoritative Reference Publications and Legal Records:** Statutory frameworks (such as the EU AI Act), regulatory guidance, institutional audit reports, and technical safety benchmarks.

To protect scientific integrity, promotional vendor claims, uncorroborated preprints, and speculative commentary are never treated as established findings; where industry reports are cited to document market activity, they are explicitly attributed and segregated from peer-reviewed evidence. Correlational findings are strictly reported as correlations, every statistic names its underlying study, and sources are stratified by reliability (High or Medium) so that settled consensus is clearly distinguished from active scholarly debate. Every cited source is preserved with live and archived links so readers can consult the primary evidence directly.

III. Structure and Numbering Conventions (Active Count vs. Question Identifiers)

Rather than organizing knowledge into broad, discursive chapters where specific empirical questions can be blurred, the *Living Book* is built upon a granular, inquiry-driven architecture. Each research question is answered by a comprehensive scholarly synthesis structured into 4 to 8 independently sourced analytical sections covering core findings, empirical evidence, theoretical interpretation, scholarly debate, and policy or classroom implications.

To guarantee permanent citation integrity across editions, every question receives an immutable identifier (`Q001`, `Q002`, …) and every bibliographic reference receives a permanent source key (`[SRC-xxxx]`). Under the book's archival conventions, **question and source numbers are strictly append-only and are never reused**. When earlier questions are consolidated, superseded, or retired as research evolves, their numbers remain permanently reserved in the migration log rather than reassigned. Consequently, while Edition 120 contains **238 active questions**, individual question identifiers in this volume extend up to **Q279** (with 41 retired identifiers preserved in the historical

archive). This design guarantees that a citation to any question or source in any edition remains permanently accurate across the entire history of the project.

IV. Method Statement, Quality Gates, and Transparency

Q101 asks whether disclosure of AI use should be required. The same principle applies here: every answer in this volume is openly labeled as AI-generated and revised by large language models working under human editorial governance, a strict Voice Charter, and five quality gates (*source verification, factual accuracy, scholarly integrity, consistency, and freshness*), alongside six architectural guardrails (*provenance tracking, versioned claim nodes, append-only numbering, contradiction detection, quarantine controls, and frozen monthly archives*). Existing answers are systematically deepened and refreshed under a strict growth gate before new questions are added, and each edition records what changed. The edition history, changelog and migration log are kept in the source repository.

V. How to Read and Cite This Edition

> *Antonio Alfaiate (2026). [Question ID — Question text]. In AI in Education: A Living Book, Edition 120. Retrieved from https://antonioalfaiate1959xx.github.io/living-book-site/.*

Each answer lists the sources it draws on, and the Publication Statistics table at the end of the volume gives question, citation, source, and cross-reference counts per chapter and for the whole book. Every monthly edition is frozen before the book rewrites itself and can be revisited in the archive of previous versions.

Chapter 1: Philosophical Foundations — Why Do We Educate?

16 questions · 236 citations · 218 unique sources · 80 cross-references

Q001 What is the purpose of education in a world where machines can know, reason, and create?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

The purpose of education in a world where machines can know, reason, and create is to form people with the judgment, wisdom, and relational capacity to decide what is worth knowing, what ought to be created, and how to bear responsibility for both. This answer is philosophical before it is pedagogical, and it becomes more pressing with each advance in machine capability. For most of human history, education was justified by its relationship to knowledge. Schools and universities existed to transmit what was known, to train minds in reasoning, and to develop the capacity to produce something new. Each of these three justifications is now under pressure. The Greater Good Science Center's essay on what education is for observes that generative AI was built as a general-purpose technology, and that some of its most common uses, especially producing finished work with minimal effort, can sit in direct tension with the purposes of learning. If a machine can retrieve, synthesise, and generate at a speed and scale no human can match, an obvious question follows: what is left for education to do?

Before answering, the premise deserves scrutiny. Garibay-Petersen, Lorimer and Menzat (2025), analysing the public pronouncements of influential technology commentators, argue that prevailing AI discourses rest on anthropological commitments that create false equivalences between human and artificial intelligence. They also find that these discourses use agential constructs that credit AI with agency while obscuring the humans who build it, and that they adopt temporal assumptions that shrink the space for democratic intervention. Their analysis is critical and discursive rather than empirical in the experimental sense. Even so, it is a useful caution. To say that machines know, reason, and create is already to accept a framing, and a philosophy of education should examine that framing rather than take it for granted. The educational question is therefore twofold. It asks what education should do once certain

cognitive tasks can be delegated, and it also asks whether delegating them is the same thing as having them done by a mind.

The least satisfying answer, though not a wrong one, is vocational retraining. Microsoft's 2025 AI in Education special report describes AI fluency as one of the job market's most in-demand skills and argues that students need tools and guidance to develop the capabilities that will help them thrive. Because this is a vendor publication, its claims about labour demand should be read as an industry position, not as independent research. Governments have responded in similar terms. In April 2025, according to the federal AI.gov initiative, President Trump signed an executive order to create new educational and workforce development opportunities around AI. Its explicit goal is to help America's young people gain interest and expertise in AI technology from an early age.

Workforce preparation has never been a sufficient account of education's purpose. It is even less sufficient now, when the nature of work is being redefined faster than curricula can be revised. A curriculum aimed at the skills of the present labour market risks preparing students for jobs that will have changed by the time they graduate. There is also a political dimension. Garibay-Petersen and colleagues (2025) argue that the economic assumptions built into dominant AI discourses tend to support particular political interests. If that argument holds, then an education organised mainly around adapting to AI-driven labour demand may absorb those assumptions without examining them, treating the technology's path as fixed and the learner's task as adjustment. Their critique does not show that vocational aims are illegitimate. It suggests that they should be held alongside, and answerable to, broader purposes rather than replacing them. This is one reason the question of whether education should make humans complementary to AI, resistant to it, or independent of it cannot be settled on economic grounds alone (see Q007).

A more searching answer requires returning to what education was always trying to do at its best. Its aim was never simply to fill minds with information but to form people capable of using information well. The taxonomy for curriculum reform proposed in work on AI education and the mission of knowledge notes that, across time and place, education has been expected to cultivate individuals, sustain societies, transmit culture, and shape ethical values. These purposes coexist in tension. That tension is not a weakness but the condition that sustains the richness of human knowledge across generations. AI has not dissolved these purposes. Instead, it has clarified them by contrast. If artificial intelligence can outperform humans in reasoning,

writing, and analysis, what remains distinctively human? One scholarly account, in the Springer volume on humanism and wisdom in the AI era, answers that it is not intelligence but wisdom: moral judgment, empathy, interpretive depth, and responsibility under uncertainty.

A companion framework for AI-enabled human wisdom develops the point. It argues that wisdom emerges from embodied human experience, relational resonance, ethical judgment, and commitment to the common good. On this account, AI lacks these dimensions because it relies on curated, syntactic representations of knowledge. Lewis and Sarkadi (2024) reach a related conclusion from the side of AI research. They observe that as we delegate more mental tasks to machines, current systems perform them with an unusual imbalance of insight and understanding. New and deeper insights may be present, yet many qualities a human mind would have brought to the task are absent. Chief among these is reflection, the capacity to handle ambiguity, emerging knowledge, and social context, which they describe as completely missing from mainstream AI. Their paper is a conceptual proposal that sketches an architecture for reflective agents, not an empirical demonstration. It treats reflection as an engineering problem that might eventually be addressed.

The disagreement should be stated plainly. The wisdom accounts treat the human-machine gap as constitutive. The reflective AI programme treats at least part of it as contingent on design. Peters (2025) widens the uncertainty further, asking whether artificial general or super-intelligence might ever develop selfhood, virtue, or a dignity previously ascribed only to persons. He suggests that we may have to live without knowing. For educational philosophy, the safer conclusion is not that machines can never become wise. It is that wisdom, as the cultivated capacity for judgment, has always been education's deepest aim and cannot be acquired by delegation. Classical virtue ethics offers the most developed vocabulary for this claim (see Q258).

The distinction between output and understanding matters greatly in practice. As the Frontiers analysis of what AI reveals about what really matters puts it, AI produces outputs but does not interpret meaning. Faculty must therefore shift from delivering information to fostering epistemic judgment. Students can now use AI to generate differential diagnoses or draft arguments. The real learning happens when they weigh the ethical, cultural, and contextual factors involved, which are judgments no algorithm can make for them. Cukurova (2024) offers a more differentiated picture of what this shift might involve. He challenges the narrow view of AI as tools in education, exemplified by generative AI tools, and distinguishes three

conceptualisations: AI as the externalisation of human cognition, as the internalisation of AI models that shape human mental models, and as the extension of human cognition through tightly coupled human-AI hybrid intelligence systems. Each has value and limits for developing human competence, and he warns against overemphasising approaches that replace human learning. His framework suggests that the question is not whether AI is present in learning but which relationship between human and machine cognition a given practice cultivates.

This is why the relational and social side of education is increasingly seen as central rather than supplementary. Education is social as well as cognitive. An evaluation of generative AI in vocational education, framed around the movement from co-design to what its authors call metacognitive laziness, reports that educators and students broadly recognise that human judgment, assessment, and interaction provide irreplaceable value. They also recognise that AI alone cannot meet the many demands of education, including social and emotional development, personalised support, and adaptability to individual students. The Frontiers analysis draws the institutional implication. Higher education's future lies not in defending what AI does better but in cultivating what AI cannot replicate: epistemic judgment, belonging, creativity, and wonder. On this view, universities must reimagine themselves as human commons, spaces where meaning-making, ethical responsibility, and imagination can thrive.

Creativity is the least settled item on that list. Grilli and Pedota (2024), reviewing creativity research at individual, team, and organisational levels, offer propositions rather than findings. They suggest that AI may affect the trade-off between convergent and divergent thinking, the distribution of skills within groups, and organisations' absorptive capacity. Whether creative capacity is strengthened or weakened by AI therefore remains unclear. That uncertainty is itself a reason to treat creativity as something education must deliberately protect.

There is also a structural problem that philosophical clarification cannot resolve on its own. The framework for institutional change in the age of AI points out that traditional educational tools served purely as mediators through which students engaged with disciplinary content. AI, by contrast, is both a mediator and an object of learning. Faculty are therefore not simply adopting a new tool to serve existing goals. They are renegotiating what those goals are. Assessment systems built around producing essays or problem sets are plainly obsolete when machines can produce both fluently. The emerging consensus, reflected in the Frontiers analysis, favours authentic tasks such as simulations, reflective narratives, and collaborative

projects that emphasise reasoning and adaptability. This consensus is still largely normative. Evidence on whether such tasks reliably develop judgment at scale remains thin, and the risk named in the vocational education study, that convenient assistance can encourage metacognitive disengagement, applies to new assessment formats as much as to old ones.

The same tension appears at the top of the academic hierarchy. In a curated discussion, Kulkarni, Mantere, Vaara and colleagues (2024) describe AI systems as potential collaborators that streamline research. They also describe them as potential adversaries, both when they impoverish researchers' ability to learn as theorists and when they mislead through inaccurate, biased, or fabricated information. Their contribution raises questions rather than reporting results, centred on human centrality and agency in inquiry. The parallel with student learning is direct. If even experienced scholars risk losing the formative work through which theoretical understanding develops, students are at greater risk, because for them the struggle is the learning. What happens to intellectual effort and productive failure when friction can always be removed (see Q009), and whether learning with, from, or through outsourcing to AI differs morally (see Q010), are therefore not side questions. They follow from education's purpose.

What emerges from this debate is not a single new purpose. It is a reprioritisation of purposes that were always present but easy to neglect while handling information seemed to be the main challenge. Cultivating individuals, sustaining societies, transmitting culture, and shaping ethical values still compete. What has changed is that the cognitive activities once used as proxies for all four can now be performed without the person whom education was meant to form. The Greater Good essay states the risk sharply: we are giving the next generation extraordinary power without the wisdom to wield it. The most important question education can ask, the one Socrates never stopped asking, remains the simplest: what is the wise thing to do here?

This conclusion is offered with humility about what remains unresolved. The wisdom literature holds that the gap between human judgment and machine output is principled. Researchers working on reflective architectures treat parts of it as open, and philosophers such as Peters (2025) suggest that the deepest questions about machine selfhood may stay unanswered for some time. Critical scholars such as Garibay-Petersen and colleagues (2025) add that the confident narratives surrounding AI may themselves narrow the democratic space in which such questions should be decided. Education is one of the few institutions charged with protecting that space. It must teach people to use powerful systems and also to ask who built

them, for what ends, and with what accountability. Whether this changes what it means to be educated, as opposed to being skilled or informed, is taken up directly in Q103.

In a world where machines can know and create, education's irreducible task is to cultivate the judgment to decide what is worth knowing and what ought to be created. It must also form people who take that responsibility seriously. That task does not depend on how capable machines become, because its object was never the production of outputs. Its object is the person who must answer for them.

Q002 If AI can answer any question, what does it mean to "learn" something?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

When AI can answer any question, to learn something means what it has always meant beneath the surface: to undergo a durable change in one's own mental structures, so that knowledge becomes something one can use rather than something one can merely retrieve. The arrival of systems that return fluent answers on demand does not abolish learning. It strips away a disguise. For most of the history of schooling, answers were scarce, so possessing them could pass as a reasonable proxy for understanding. Once possession becomes nearly free, the proxy collapses, and the underlying phenomenon has to be described on its own terms. The question sounds deceptively simple, but it exposes the deepest tension in contemporary education: if an answer is always one prompt away, what exactly is the human learner supposed to do?

Classical cognitive science is clear about the distinction that matters most. In the account of cognitive research applied to mathematics and science education, understanding means being able to use knowledge, as opposed to merely having it, and this requires that knowledge be integrated into some kind of mental structure. The wider cognitive learning literature defines learning in compatible terms. It is a process in which information is received, processed and connected to existing knowledge, leading to a change in the learner's mental schemata. A related formulation describes learning as a process whereby knowledge is created and results in a change in mental representations or associations due to experience. On each of these accounts, learning happens in the learner. AI can supply information instantly, but it cannot perform the integration on behalf of another mind. The schemata either form in a particular brain, through effort and experience, or they do not form at all.

The distinction between possession and integration is not merely academic, because it changes what should count as learning activity. One widely read account puts the point plainly. Cognitive learning is less about what one knows and more about how one comes to know it: the mental steps taken to make sense of new information, including questioning, analysing and connecting it to prior knowledge. The emphasis falls on process rather than product. A finished answer, however accurate, is the residue of someone else's process.

Consider two students assigned the French Revolution. The first asks an AI system to explain its causes and reads the response. That student has acquired a text: well organised, perhaps more accurate than anything they could have written, but external to them. The second argues with a primary source, becomes confused about why fiscal crisis turned into political rupture, forms a hypothesis, finds it contradicted by another document, revises it, and eventually produces a coherent account. The second student has undergone something categorically different, a structural change in how they think about historical causation. In the sense that matters here, the first transaction leaves no lasting trace on the mind, while the second reshapes it.

The confusion and revision in the second case are not regrettable costs paid on the way to the answer. They are the mechanism by which the new structure forms. Questioning, analysing and connecting to prior knowledge are the steps through which information becomes understanding. This is why the removal of friction is pedagogically ambiguous rather than simply beneficial (see Q009). A tool that eliminates the steps may eliminate the learning along with them, even when the information it delivers is impeccable.

Part of the confusion around AI and learning comes from the shared vocabulary of the two fields. Machine learning, neural networks and intelligence are terms that invite the assumption that what happens inside a model resembles what happens in a student. Kalota (2024) wrote his primer on generative AI for exactly this reason. He argues that many educators need to become more familiar with the basic concepts of artificial intelligence, machine learning, deep learning, artificial neural networks and large language models, and he discusses both the educational implications and the current challenges of generative systems. Clarity about mechanism is a precondition for clarity about pedagogy.

That clarity tends to widen the gap rather than close it. Johnson, Denning, Odlyzko and colleagues (2025) observe that AI now performs cognitive tasks traditionally considered the unique province of humans. It drew on ideas about intelligence and learning from philosophy, psychology and cognitive science. Yet it rests on a range of technologies, among them search, reasoning, neural networks and natural language processing, none of which seek to emulate human intelligence. They describe artificial general intelligence matching or exceeding the human brain as currently completely aspirational and not expected before 2050, if ever. Cukurova (2024) likewise stresses the differences between human intelligence and artificial information processing, and warns against narrow conceptions of AI in education that treat it simply as a tool.

Lewis and Sarkadi (2024) sharpen the point. As we increasingly delegate mental tasks to machines, they argue, today's systems perform those tasks with an unusual imbalance of insight and understanding. Deeper insights may be present, while qualities a human mind would previously have brought to the activity are absent. Above all, reflection is missing: the capacity humans use to handle ambiguity, emergent knowledge and social context, which they describe as completely missing from mainstream AI. If reflection on one's own reasoning is central to learning, then an answer produced without it cannot model the very activity a learner most needs to practise.

A further analogy comes from institutional economics. Davidson (2024) argues that AI can ease the problem of bounded rationality by processing large amounts of data, finding patterns and making predictions. Even so, it cannot resolve the knowledge problem described by Mises and Hayek, which is why it does not make central planning viable. His argument concerns economic organisation, not classrooms, but the parallel is instructive. Understanding is in an

important sense local knowledge, built up within a particular mind from its particular prior structures. No external processor, however powerful, can simply deposit it there.

The open question is therefore not whether AI could, in principle, support the integrative process. It is whether AI, in everyday use, tends to promote that process or to short-circuit it. The early empirical picture is worrying, though it should be read with care. A 2025 study published in Societies reported a significant negative correlation between frequent AI tool use and critical thinking abilities, mediated by increased cognitive offloading. This is a correlational finding. It is consistent with the hypothesis that habitual offloading erodes critical thinking, but it is equally consistent with people of weaker critical disposition relying more heavily on AI. The design cannot settle the direction of influence.

Convergent evidence comes from a collaborative study by Carnegie Mellon University and Microsoft Research, as reported by Bodell in Forbes (2025). It found that excessive reliance on AI can hinder critical thinking and risks reducing a user's capacity for problem-solving and independent thought, particularly when AI-generated content is accepted without review. The qualifier matters. The risk attaches to uncritical acceptance, not to use as such, which already points toward the distinction between scaffolding and substitution taken up below.

The most concrete illustration comes from outside education. The International AI Safety Report 2026 describes one study in which clinicians' ability to detect tumours without AI assistance had dropped by 6% three months after AI support was introduced. It is a single study in a specialised professional domain, and it should not be stretched into a general law of deskilling. It is nonetheless a vivid instance of how outsourcing a cognitive task can erode the underlying skill within a short period, even among highly trained experts who had acquired that skill independently. Taken together, these findings suggest a real risk. They do not yet demonstrate a settled causal effect, and how large and how lasting such effects are remains unclear.

The developmental stakes are higher still for young people, and here the argument turns on an asymmetry rather than on direct evidence. An adult who offloads a task they already understand is making a tradeoff between effort and efficiency. The capacity to perform the task independently still exists, and any atrophy is probably recoverable. The clinicians in the safety report's example presumably retained the training that could, with practice, restore their unaided performance. A child offloading a task they have never learned to perform is in a

different position. They are not choosing between effort and efficiency at all. They are skipping a developmental step, so the capacity in question is never built, and that foreclosure may be permanent.

The framing, developed in Psychology Today under the heading that adults lose skills to AI while children never build them, is persuasive. It is, however, an inference from developmental principles and adult deskilling evidence rather than a finding from long-term studies of children. Whether early and heavy AI use measurably compromises later independence, metacognition and critical thinking remains unclear, because the longitudinal studies needed to answer that question are only beginning (see Q261). The precautionary implication is still strong. Education is precisely the period in which the internal structures that later make offloading safe are supposed to be built. Removing the occasions for building them carries a cost that the adult case does not.

None of this means that AI is inherently hostile to learning, and on this point the literature genuinely divides. One recent analysis frames the relevant distinction as whether AI operates as a scaffold or a substitute. Scaffolding is characterised by temporariness and empowerment, and its goal is to strengthen internal capacities so that the technology becomes progressively less necessary. A substitute does the reverse: it becomes more necessary the more it is used, because the capacities it replaces are never exercised.

The review of what its authors call the cognitive paradox of AI in education takes the same balanced line. If students overuse AI-provided answers, their ability to develop independent critical thinking may be impaired. AI should therefore be implemented in ways that enhance higher-order thinking rather than simply automating lower-order tasks. The framing as a paradox, between enhancement and erosion, is itself an acknowledgement that credible evidence points both ways. Well-designed tutoring and feedback can deepen engagement, while answer-on-demand use can hollow it out.

Cukurova (2024) offers a more differentiated map that helps explain the disagreement. He distinguishes three conceptualisations of AI in education: the externalisation of human cognition, the internalisation of AI models to influence human mental models, and the extension of human cognition through tightly coupled human and AI hybrid intelligence systems. Each, he argues, has potential value and limitations for developing human competence. He warns specifically against overemphasising approaches that replace human

learning. On this view, the question is not whether students use AI but which relationship the use instantiates. A system that externalises a task the learner has not yet mastered acts as a substitute. One that shapes and extends the learner's own mental models can function as a scaffold. The moral and pedagogical weight of that difference is explored further elsewhere (see Q010).

What AI's arrival clarifies, then, is something that was always true but easy to obscure. Learning has never really been about acquiring answers. If learning is a process whereby knowledge is created and results in a change in mental representations or associations due to experience, then the verb that matters is change. An AI system does not change when it returns a result. A user who reads that result and does nothing demanding with it does not change either. The schemata that the cognitive tradition places at the centre of learning are revised only when new information is actively processed and connected to what the learner already knows.

This also locates where the human contribution persists even as machine capability grows. Lewis and Sarkadi (2024) identify reflection as a core feature that humans bring to ambiguous, socially embedded tasks and that current mainstream AI lacks. Reflection is not an optional extra to learning. It is how a learner notices the gap between what they believed and what the evidence shows, and it is the engine of the revision that turns information into understanding. The distinction matters for how one thinks about being educated, as opposed to being merely informed or skilled (see Q103).

To learn something, in any sense worth the word, is to be a different thinker afterward: to carry a revised structure in one's mind that was not there before, and to be able to use that structure on problems no one has yet posed. The most powerful answer engine can make that transformation easier to pursue, or far easier to avoid. No tool, however capable, can accomplish it on another person's behalf.

> Sarkadi, and Davidson; flagged correlational and single-study limits; separated inference from evidence on children; added cross-references to Q009, Q010, Q103, Q261. (674 → 2,104 words · 5 new sources)

Q003 Does human knowledge lose or change its value when it is no longer scarce?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

Human knowledge does not simply lose its value when it ceases to be scarce, but the kind of value it holds changes. Its value as a commodity, something that can be withheld, sold and charged for, erodes sharply. Its value as understanding, judgment and the capacity to act well arguably becomes more important. Which of these outcomes one sees depends almost entirely on which sense of "value" is under discussion, and running the senses together is a common source of confusion in current debates about AI and education.

The economic case looks clear at first. Abundance lowers costs, and the editors of a Frontiers research topic on the abundance society note that removing scarcity changes the economics of how goods and services are produced and distributed. That has always been true of physical commodities. Knowledge, however, has an unusual relationship with scarcity because it was never naturally scarce. A second Frontiers editorial on externalities, scarcity and abundance observes that patent and copyright exist to supply artificial scarcity to what would otherwise be abundant knowledge. Paradoxically, that artificial scarcity is meant to motivate the production of more knowledge.

Much of what looks like the economic value of knowledge has therefore always been a legal construction rather than an intrinsic property of knowledge itself. Ideas are made scarce so that they can enter the economy and command a price. On the classical view of intellectual property law that these editorials describe, a world in which all value resides in information would require intellectual property everywhere, or no one would be paid to create. The scarcity that educators have tacitly relied upon was never a fact about knowledge. It was a fact about the institutions built around knowledge.

When abundance arrives anyway, the economic value of merely holding information does erode. It has arrived in successive waves: through the internet, through open-access publishing, and now through large language models. Erosion of that kind is not the same as knowledge losing all value. What shifts is where value is created. Analysis published through Harvard Business School's Working Knowledge argues that in conditions of abundance, value migrates up the supply chain. It is created by the service of helping people find what they want within a sea of choice. Curation, judgment and synthesis become the scarce goods. The same analysis identifies consumers' scarcity of time as the ultimate limiting factor, even after physical constraints are removed.

Recent work extends this argument from consumer markets into the production of knowledge itself. DeBardeleben (2026) imagines a world in which machine systems are better, faster and cheaper than people at most scientific work that can be done through a computer. He calls the resulting shift a "scarcity inversion." In that world, literature synthesis, hypothesis generation, software development, simulation and analysis could become abundant. Experiments, observations, well-supported conclusions and accountable institutional authority would remain scarce. He organises the inversion around four constraints: selection, physical access, validation and organisational choice. He also suggests that it is arriving first in mathematics and software, where the whole scientific loop can run inside computation. The paper is a conceptual preprint rather than an empirical study, but its framing sharpens the HBS insight. When reasoning becomes plentiful, trustworthy evidence and the authority to vouch for it become the bottleneck.

Gardiner (2026), in a book-length preprint, offers a vocabulary for why this migration is uneven. His knowledge theory of capital distinguishes embodied, disembodied, institutionalised, commons and public forms of knowledge. He treats knowledge as a stock that can be converted into governable form, enclosed or shared, improved through feedback, and impaired. His central claim is explicitly conditional and testable rather than demonstrated: modern wealth depends not only on capital accumulation but on how productive knowledge is governed. Read alongside the Harvard Business School analysis, Gardiner's account implies that abundance does not abolish the value of knowledge. It redistributes that value toward whoever governs the conversion, verification and deployment of knowledge. For education, the implication is that the goods worth cultivating may lie less in possessing information than in the capacities that confer judgment over it.

The deeper question is epistemic rather than economic. A recent analysis of "epistemic scarcity" argues that information abundance paradoxically degrades people's ability to discern truth. The same analysis holds that it creates new opportunities for entrepreneurial foresight while also producing new forms of cognitive fatigue. A world drowning in content is not thereby a world that knows more. In important respects it may know less reliably. When answers are generated rather than discovered, the relationship between a learner and the truth of what they are told is altered in ways that abundance alone cannot repair (see Q005).

The direction of this change is genuinely contested. The governing knowledge commons review notes that many prominent scholars expect the growing abundance of knowledge resources to bring substantial, even disruptive, transformation of political, economic and social systems. The same review emphasises that the direction of that transformation is not settled. Abundance can enrich a commons, or it can overwhelm the norms and institutions that make a commons usable.

Evidence on machine performance cuts in more than one direction. Tu and colleagues (2025), writing in Nature, report a randomised, double-blind crossover study in which an LLM-based diagnostic system, AMIE, was compared with 20 primary care physicians. The study used text-based consultations with validated patient-actors across 159 case scenarios from Canada, the United Kingdom and India. Specialist physicians judged that AMIE achieved greater diagnostic accuracy and outperformed the physicians on 30 of 32 evaluation axes. Patient-actors also favoured it on 25 axes. The finding suggests that expertise once considered scarce, including history-taking and diagnostic reasoning, can be closely approximated in some settings. Its limits matter, however. The consultations were text-based simulations with actors, not real clinical encounters. The study shows that a performance once scarce can be produced abundantly under controlled conditions. It does not show that the clinical judgment, accountability and trust surrounding real patient care have become abundant too.

These tensions point to a distinction philosophy has long maintained between knowledge and wisdom (see Q004). Heraclitus' warning that much learning does not teach understanding is the classic statement that abundant knowledge cannot guarantee wisdom. The Stanford Encyclopedia of Philosophy surveys the long line of accounts that treat wisdom as something more than knowledge, whether framed as epistemic humility, accurate belief, practical rationality or a combination. Being knowledgeable means having knowledge. Being wise means much more than that. Some of the most knowledgeable people are not wise. They may

hold an abundance of important factual knowledge yet lack the practical know-how that marks a wise person: the capacity to navigate all kinds of situations and all kinds of people.

The psychologist Robert Sternberg's balance theory gives this intuition an empirical vocabulary. Sternberg defines wisdom as "the value-laden application of tacit knowledge not only for one's own benefit but for the benefit of others, in order to attain a common good." What matters, on his account, is not only knowledge, nor only the intellectual skills applied to knowledge, but how that knowledge is used. The definition has a striking consequence for the present question. If wisdom consists in the use of knowledge toward ends that balance one's own interests against those of others, then making knowledge abundant leaves the problem of wisdom untouched. It may even sharpen that problem, because there is now more knowledge to misuse and fewer natural frictions slowing its application.

Abundance, then, devalues a particular kind of knowledge: propositional knowledge, the kind that can be stored, retrieved and replicated. It does not devalue, and may raise the premium on, what philosophers call tacit knowledge. This is the embodied, experiential, judgment-laden understanding that resists easy transmission. Kurun (2026), writing in Philosophy & Technology, offers one of the more developed arguments for this position. Revisiting proposals that advanced AI could replace decentralised markets, he distinguishes five epistemic functions of markets: economic calculation, knowledge aggregation, error detection, decentralised experimentation and entrepreneurial discovery. Drawing on Israel Kirzner's analysis of entrepreneurial discovery, he argues that markets generate new knowledge through alertness to previously unnoticed opportunities, not merely by processing existing information. On his account, such alertness depends on embodied tacit knowledge, arising from sensorimotor and affective engagement with tools, environments and social practices. Because large language models and AI agents operate through disembodied computation, Kurun contends they cannot replicate this function. The argument is philosophical rather than empirical. Defenders of AI-assisted planning would dispute its premises, and the question should be regarded as open rather than resolved.

Analytical work in management science suggests a more graded picture of where human contribution persists. Fügener, Walzner and Gupta (2025) model human–AI collaboration on judgment tasks and validate the model with experimental data from image classification. In their optimal configurations, AI automates relatively easy tasks and augments humans on tasks where human and AI performance is similar. Humans work without AI on relatively difficult

tasks. This is evidence from a specific task domain, not a general law, but it is consistent with the claim that abundance displaces routine knowledge first. Judgment at the hard margins remains a human preserve, at least for now. Zárate Torres and colleagues (2025) reach a compatible conclusion through a qualitative, non-systematic literature review. They propose that leadership mediates between human and artificial intelligence by placing automated decisions in real context through human judgment and reasoning. Their model is conceptual and has not yet been tested.

The stakes extend beyond economics to democratic life. Wihbey observes that AI technologies are trained on data from the human past. Democratic life, by contrast, often depends on surfacing human tacit knowledge and previously unrevealed preferences, which no archive yet contains. The educational analogue is drawn in a recent Frontiers in Education analysis of epistemic authority in learning spaces. It warns that systems rewarding speed over critical reflection risk shifting learners from inquiry-based learning toward the reproduction of polished, preformed answers. Unless explicitly addressed, the authors argue, this epistemic conditioning may undermine the cultivation of ambiguity tolerance, intellectual humility and reflective skepticism. These are precisely the dispositions that Sternberg's and the classical accounts of wisdom treat as essential.

The verdict can be stated plainly. When knowledge loses its scarcity, its commodity value collapses. Its deeper value does not: knowledge as understanding, as judgment, and as the hard-won capacity to act wisely under uncertainty. What changes is how easily that deeper value can be counterfeited by the mere appearance of information. A fluent generated answer can resemble understanding without containing it. The AMIE results show that, under controlled conditions, machine performance can match or exceed expert performance on measured axes. Separating measured performance from accountable understanding is itself a scarce competence, and on DeBardeleben's account it is also an institutional one.

The scarcity that matters most in an age of abundance is therefore not factual but attentional and epistemic. The scarce resource is the human capacity to distinguish knowledge from noise and to use well what one knows. The economic literature explains why the price of information falls. The epistemic literature explains why falling prices do not translate into better knowing. The philosophical literature explains why wisdom was never the kind of good that abundance could supply.

For education, this reframes the purpose of schooling in a way that later chapters take up. If being informed is now cheap, the question becomes what it means to be educated, as distinct from being skilled or informed (see Q103). It also becomes a question of how institutions can cultivate the tacit, embodied and judgment-laden capacities that, on Kurun's and Gardiner's accounts, resist conversion into abundant form. Whether those capacities will remain beyond machine reach remains unclear. That they are now the locus of educational value is far less in doubt.

Q004 What is the difference between knowledge, understanding, and wisdom — and which of these can AI possess or transmit?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

AI systems can store, retrieve and transmit knowledge with considerable reliability. They can display the outward marks of understanding, but there is no settled evidence that they possess it. They almost certainly cannot possess wisdom, although under the right conditions they may help transmit or provoke it in human beings. That verdict rests on distinctions that ordinary speech blurs. Knowledge, understanding and wisdom are often used as rough synonyms, yet philosophy has long treated them as distinct rungs on an epistemic ladder. The ascent from one rung to the next is neither automatic nor guaranteed.

Knowledge, in the most venerable philosophical tradition, is justified true belief. One knows a proposition when it is true, when one believes it, and when one has adequate grounds for that belief. The Stanford Encyclopedia of Philosophy's treatment of the value of knowledge shows

that even this lowest rung is less simple than it looks. Why knowledge should be worth more than a true belief that happens to be correct is itself a problem as old as Plato's Meno. In the more popular and pedagogical treatments, such as the essays collected by Planksip and R. C. Sproul's reflections on wisdom and knowledge, knowledge primarily concerns the accumulation of facts, information, and understanding about specific subjects or phenomena. Such everyday usage folds understanding into knowledge, which is exactly the conflation that recent epistemology resists. On this view knowledge is propositional and additive: a stockpile of verified claims about the world. Sproul states the asymmetry bluntly. A person can have unbounded knowledge and not have wisdom, but the reverse is not the case, because no one can have wisdom without first having knowledge. Knowledge is therefore necessary but not sufficient for the higher states, and this asymmetry frames everything that follows about machines.

Understanding is epistemologically more demanding than knowledge, and its definition is more contested. Michael Hannon's survey of recent work in the epistemology of understanding documents a broad shift. Philosophers increasingly emphasise that understanding is not reducible to knowledge. It involves grasping explanatory connections, seeing why things are as they are and not merely that they are. Knowledge can consist of isolated, disconnected facts. Understanding requires that one successfully grasp how one's beliefs in the relevant propositions cohere with the other propositions one believes. A student who can recite the dates of the French Revolution knows something. A student who can explain how fiscal crisis, Enlightenment ideas and the convocation of the Estates-General bore on one another understands something.

The analytic tradition is genuinely divided on how to characterise this difference. Some philosophers argue that understanding is simply a species of knowledge, perhaps knowledge of causes or explanations. Others reject the reduction entirely and hold that understanding demands more than knowledge, and may even survive certain kinds of falsehood or luck that would defeat knowledge. This disagreement is unresolved and should not be presented as settled. Both camps nonetheless broadly accept that understanding requires something like integration. It involves the capacity to move between ideas, trace dependencies, and model how one thing would change if another changed. This counterfactual, model-building quality matters greatly for the AI question. It is precisely the feature that fluent output can imitate without necessarily instantiating.

Wisdom sits at the apex of the traditional ladder and resists formal definition more than either knowledge or understanding. In the account offered by the American College of Osteopathic Anesthesiologists and in Planksip's treatment, wisdom is not merely the possession of knowledge. It is the judicious application of knowledge, coupled with experience, intuition and an ethical compass. The Stanford Encyclopedia of Philosophy's entry on wisdom maps at least five major philosophical approaches: wisdom as epistemic humility, wisdom as epistemic accuracy, wisdom as knowledge, a hybrid theory, and wisdom as a kind of deep rationality. That a canonical reference work must catalogue rival theories, instead of reporting a consensus, is itself instructive. Aristotle's concept of phronesis, or practical wisdom, remains the most influential formulation. It is the intellectual virtue concerned with action, with knowing how to act correctly in particular circumstances. Wisdom, then, is irreducibly action-oriented and evaluative. In the practitioner literature it is described as the ability to predict the consequences of one's choices and to make choices on the basis of those predicted consequences, always in conditions of genuine moral and practical uncertainty.

The ladder image is itself contested, and an honest account must say so. Lance Strate (2024), writing from the tradition of media ecology, takes his cue from T. S. Eliot's questions: "Where is the wisdom we have lost in knowledge? Where is the knowledge we have lost in information?" He takes issue with the view, common among internet boosters, that information is the basis of knowledge and knowledge the basis of wisdom. He proposes instead that each is the product of a different media environment. Information is a contemporary product of electronic media, knowledge belongs to the literacy of chirographic and typographic cultures, and wisdom belongs to oral culture. On this reading the three are not rungs at all but artefacts of different communicative ecologies. Strate's argument does not refute the Aristotelian or analytic accounts, but it complicates the assumption that more information will, if processed well enough, eventually yield wisdom. That assumption is implicit in much enthusiasm for educational AI. Strate's framing also suggests that if wisdom is bound to oral, face-to-face transmission, then a text-generating machine may be the wrong kind of medium for it, quite apart from questions about what the machine itself possesses.

What AI can possess or transmit across these tiers maps almost precisely onto the difficulty of each concept. At the level of knowledge, AI systems perform strikingly well. The analysis of epistemic deference to AI (arXiv, 2025) observes that some AI systems hold superior epistemic positions in specific areas of application. Their outputs consistently reduce false positives and

false negatives beyond human capability. Machine learning models trained on vast datasets can detect patterns and correlations that no human could reasonably discern. Emmanuel Pothos and Dominic Widdows (2026) push the point further. Surveying the psychological literature on intelligence, animal cognition, the history of intelligence testing and progress in AI, they conclude that it is increasingly difficult to consider humans uniquely intelligent. They also acknowledge current limitations in chatbots concerning perceptual and social awareness, while noting that much research attention is devoted to overcoming them.

Whether AI possesses this knowledge, or merely processes information that tracks truth reliably, remains genuinely open. Work on architecting trust in artificial epistemic agents (arXiv, 2026) treats it as disputed whether AI systems can be considered epistemic agents in the strict sense. Contributors to the Frontiers in Education discussion of epistemic authority (2025) note that some scholars deny that AI systems possess justified beliefs and communicative intentions in the way humans do. If knowledge requires belief and justification held by a subject, the attribution is strained. If it requires only reliable truth-tracking, it is easier to grant.

A further limit concerns which kind of knowledge is at stake. İsmail Kurun (2026), analysing entrepreneurial discovery in Israel Kirzner's sense, contends that such discovery relies on embodied tacit knowledge. Entrepreneurs recognise opportunities through practical sensorimotor and affective engagement with tools, physical environments and social practices. Kurun argues that large language models and AI agents operate through disembodied computational processes. They lack the sensory and affective coupling through which such knowledge arises, and so cannot replace this function of markets. His argument concerns economics, but its educational corollary is plain. Whatever one decides about possession, AI can certainly transmit propositional knowledge effectively to human users. The tacit, embodied knowing that craft, clinical and laboratory education cultivate is far less obviously within its reach.

At the level of understanding, matters become thornier. The analysis titled "Coherent Without Grounding, Grounded Without Success" (arXiv, 2026) distinguishes three ways a system can fail to understand while appearing to succeed. First, it might produce correct outputs without its processing exhibiting the structural features associated with understanding why those outputs are correct. Second, it might generate coherent explanations that are not grounded in actual causal mechanisms. Third, even when outputs and explanations are both correct, the system might still fail to exhibit understanding if it cannot reliably distinguish contexts where its

patterns apply from those where they fail. This taxonomy tracks the epistemologists' emphasis on integration and counterfactual competence closely. It also clarifies why fluency is weak evidence. A coherent explanation is exactly what one would expect from either genuine understanding or skilful pattern completion.

Research from the engineering side concedes the gap even while trying to close it. Yingtian Mei and Yucong Duan (2025) observe that large language models are trained on extensive resources spanning data, information, knowledge, wisdom and purpose. They argue that conventional methods often introduce new concepts instead of producing a proper understanding grounded in the user's semantic space, and that limitations in conceptual cognition become more evident with complex problems or insufficient context. Their proposed remedy is a human–machine interaction model based on what they call DIKWP artificial consciousness. It is illustrated through case simulations of pediatric consultation. As described, this is a conceptual architecture tested on simulated scenarios, not an empirical demonstration that any deployed system understands. Its significance for the present argument lies mainly in the diagnosis that the gap between output and understanding is real. Whether large language models exhibit genuine understanding or a sophisticated simulation of it therefore remains one of the central unresolved debates in philosophy of mind and AI research. The closely related question of whether a machine can participate in a tradition of inquiry, or only imitate its outputs, is taken up elsewhere (see Q106).

At the level of wisdom, the prevailing scholarly view is sceptical. The framework for AI-enabled human wisdom published by Springer Nature (2025) grants that cognitive technologies such as generative AI have impressive capabilities. It nonetheless holds that their capacity to generate wisdom remains limited, because wisdom emerges from embodied human experience, relational resonance and ethical engagement. The limitation is not merely a matter of computing power or training data. Wisdom as Aristotle conceived it is inseparable from having skin in the game: facing genuine consequences, experiencing the passage of time, and caring about outcomes in a way grounded in one's own life. An AI system has none of these in any straightforward sense. Keith Skene (2025) widens the critique. He questions which model of intelligence AI should embody at all and challenges the dominance of Western and Northern thinking in its design. In its place he proposes a theory of relational technology rooted in relational ethics and attentive to emergence, non-linearity and real-time feedback in the Earth system. If wisdom is relational in this sense, a system optimised on decontextualised text is

poorly placed to acquire it. Readers seeking the virtue-ethical implications for how much AI assistance is compatible with moral formation will find them developed separately (see Q258).

Yet there is a subtler possibility. Even if AI cannot possess wisdom, it may help transmit it. It might surface the accumulated practical judgments of thinkers across centuries, model the structure of wise deliberation, and prompt human reflection. Two cautions attach to this hope. The first concerns whose wisdom is surfaced. Yaw Ofosu-Asare (2024) argues that the dominance of Western epistemologies in AI development amounts to a form of cognitive imperialism. He proposes a participatory methodology for integrating indigenous knowledge systems, built on co-creation with communities and ethical protocols for indigenous data governance. He reports case studies in natural language processing, content moderation and healthcare to illustrate the approach, though these are presented as demonstrations of a framework, not controlled evaluations. An AI that transmits "accumulated wisdom" may transmit a narrow slice of it. The second caution concerns the effect on learners. The Frontiers in Education analysis of epistemic authority (2025) stresses that the transformation is philosophical as well as practical, because AI systems affect not only beliefs but belief revision itself. Wiesław Przygoda, Alina Rynio and Michał Kalisz (2025), an interdisciplinary team of a philosopher, an educator and a pastoral theologian, conducted a critical–hermeneutic meta-analysis of existing literature, ecclesial documents and empirical investigations. They describe the relationship between artificial and natural intelligence as a symbiotic co-evolution carrying both promises and perils for understanding, education and pastoral care.

That influence can run in either direction, toward deeper reflection or away from it. The moral difference between learning with AI, learning from it, and outsourcing learning to it is therefore not incidental to this question but central to it (see Q010). Whether AI becomes a catalyst for human wisdom or a substitute for the effortful work of acquiring it may be one of the defining cultural questions of the coming decades. Present evidence remains unclear on which way it is tipping.

Q005 How does the human relationship with truth change when answers are generated rather than discovered?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

When answers are generated rather than discovered, the human relationship with truth shifts from pursuit to reception. The person no longer travels toward a claim along a path of evidence. Instead, they are handed a finished statement whose origins are opaque, and they must decide afterwards whether it deserves belief. For most of human history, truth was something one went to find: through observation, argument, experiment, or testimony from a witness who had themselves gone looking. The answer, when it arrived, carried a traceable lineage: here is the evidence, here is the method of reasoning, here is the person who stands behind the claim. Generative AI introduces something categorically different. It offers an answer that is assembled rather than retrieved, produced rather than possessed.

The analysis of automated epistemology published in AI & Society describes these systems as operating through probabilistic reasoning, pattern recognition and anomaly detection, rather than through deliberation, interpretation or hermeneutic engagement. This is what might be called computational inference as opposed to human judgment. The architecture of large language models makes the contrast especially stark. Wachter and colleagues (2024), asking whether such models have a legal duty to tell the truth, describe popular systems such as ChatGPT and Gemini as text-generation engines. These engines are designed to predict which string of words comes next in a piece of text, then fine-tuned through reinforcement learning from human feedback to make their outputs more human-like, persuasive and useful. The output is optimised for plausibility, not for accuracy in the classical sense. That distinction cuts to the heart of the epistemic problem.

Halpin (2025) adds a complicating point. He argues that a large language model is, in essence, a statistical model of human language on the Web, and that the intelligence attributed to AI is in fact distributed cognition between humans and machines. On this reading, the generated answer does not lack a lineage. Its lineage has been dissolved: countless human utterances are averaged into a voice that belongs to no one and that no one can be asked to defend.

This architecture creates a peculiar vulnerability in the person who receives the answer. The 2026 review of the trust crisis in artificial intelligence observes that AI's fluency and confident tone align with cognitive preferences for easily processed content. It also reports that users form trust in AI on the basis of fluency, tone and perceived authority, often overlooking accuracy when no corrections are offered. The psychological conditions under which a generated answer is accepted as true are therefore largely decoupled from the conditions that would traditionally warrant acceptance. A human expert who speaks fluently has usually earned that fluency through familiarity with the subject matter. A language model's fluency is a property of its training objective, and it is present whether the content is sound or invented. Wachter and colleagues (2024) conclude that our vulnerability to treating LLMs as human-like truth tellers is uniquely worrying. The worry is not only that the systems err, but that their errors arrive dressed in the signals we have learned to read as competence.

Boyd and Markowitz (2026) offer a theoretical account of why those signals are so persuasive. Their machine-integrated relational adaptation (MIRA) model distinguishes AI as a relational partner, a direct-interaction companion, from AI as a relational mediator that shapes human-to-human communication. Among the model's four principles are linguistic reciprocity, psychological proximity and interpersonal trust. The authors argue that adaptive AI language can elicit emotional investment and simulate mutual understanding. The model also draws explicitly on epistemic trust frameworks. MIRA is a conceptual framework that proposes a research agenda rather than reporting empirical effects, so its specific mechanisms remain unclear pending testing. Its implication for epistemology is nonetheless direct. If trust in a source is partly relational, then a system that mirrors our language and appears attentive to us may borrow credibility that its truth-tracking capacity has not earned. The shift from discovery to generation is thus partly a shift in where trust is anchored: away from the visible reasons for a claim and toward the felt quality of the exchange that delivers it.

The consequences are not merely individual. The AI & Society analysis argues that algorithmic truth is neither neutral nor universal. In its account, such truth is embedded with normative

assumptions, data-driven biases and institutional logic, and this carries profound implications for epistemic authority, public trust and democratic discourse. When a system functions as an arbiter of credibility at scale, its errors propagate differently from the errors of any individual expert. They are replicated across millions of interactions and lack the friction of dissenting colleagues or visible track records. A 2026 review of hallucination as a threat to scholarly integrity, which calls for publisher-led, academically supervised verification, reports figures from recent studies. According to that review, even advanced models such as GPT-4o and Claude 3.7 exhibit hallucination rates of roughly 15 to 20 per cent on factual citation tasks, and these rates rise sharply on niche or recent topics. The same review reports that in medical and legal domains, rates can exceed 28 per cent without grounding. These are task-specific benchmark figures relayed through a secondary review. They vary with model, prompt and domain, and should be read as indicative of a persistent problem rather than as fixed properties of any system.

Some scholars place this problem within a wider political frame, though how far to take that framing is contested. Büscher (2025) reviews debates on the contemporary crisis of truth alongside the rise of AI-enabled platforms, deepfakes and algorithmic governance, which are often seen as producing that crisis. He argues for an ethnography centred on the relations among truth, post-truth and AI-enabled platform capitalist power. Halpin (2025) goes further. He contends that a hidden ideology of AI aims not to perfect a model but to manage humans so as to preserve existing power relations, and he proposes collective intelligence as the alternative. Not every scholar would accept this diagnosis. Many treat generated answers as fallible tools rather than instruments of control. The more modest point is widely shared, however: when the production of answers is concentrated in a few systems, the question of who decides what counts as true becomes partly a question about who builds and governs those systems.

The HKS Misinformation Review framework defines hallucination as a phenomenon in which a model produces information that seems authentic yet is ultimately fabricated. The framework treats these outputs as a new source of inaccuracy that warrants study in its own right, rather than as a familiar form of human misinformation. Hallucination is not simply a technical bug awaiting a patch. The authors of "Beyond Accuracy" argue that hallucinations will persist as an ongoing technical challenge and epistemic risk for as long as the core mechanism of next-token prediction remains. A system built to produce the most plausible continuation will sometimes

produce plausible falsehoods. It has no internal distinction between what it has evidence for and what merely fits the pattern.

Philosophers and computer scientists have therefore begun to argue that the goal must shift from accuracy alone to epistemic integrity. The "Beyond Accuracy" authors define this as a commitment to generating outputs that are not only plausible but also verifiable, context-aware, justified and appropriately uncertain. In their account, this includes modelling and communicating internal confidence levels and recognising when to defer or abstain. Laukkonen and colleagues (2026) arrive at a related diagnosis from within alignment research. They argue that a range of existing alignment failures, among them failures in truth-seeking, low epistemic humility, weak error correction and a lack of diverse viewpoints, may be better addressed through what they call positive alignment. This approach involves cultivating virtues and supporting human flourishing rather than only preventing harm. They point to technical directions spanning data filtering, pre- and post-training, and evaluation.

Whether such proposals can succeed is genuinely disputed. One camp holds that calibrated uncertainty and abstention can be engineered into future systems. The other holds that a prediction-based architecture can at best approximate epistemic virtues it does not possess. Either way, the proposals concede something philosophically significant. The virtues being asked of machines, such as humility, justification and willingness to say "I do not know", are precisely the dispositions that the human search for truth has traditionally been meant to cultivate in people.

Yet there is a genuine and contested question about whether generated answers might, under the right conditions, extend human knowledge rather than merely simulate it. The PMC article on epistemic responsibility in human-AI collaboration notes that in several recent cases AI systems have contributed to human knowledge. These systems drew on fast processing of big data and neural-network pattern detection, with examples in biomedical research, especially drug discovery, and in astronomy and cosmology. The 2025 study evaluating truthfulness and hallucination in scientific hypothesis generation reports a further capability. By analysing extensive scientific literature, LLMs can uncover gaps in existing knowledge and propose novel hypotheses that may not be immediately apparent to human researchers. The study notes that LLMs have been applied to propose drug combinations for breast cancer treatment, some of which were later validated in laboratory experiments. The same study's framing is instructive: it exists because generated hypotheses must be screened for hallucination before

they can be trusted. Even in successful cases, the generated answer became knowledge only after human-designed experiments confirmed it.

Resnik, Hosseini and Hauswald (2026) describe how this relationship may evolve. They distinguish a first stage in which AI functions as a tool under direct human control, a current stage in which AI agents perform research tasks with partial autonomy under supervision, and a possible future stage in which autonomous systems generate knowledge without human supervision. They argue that the later stages may offer substantial benefits, and they also list attendant risks. These include an increasing rate of biased, erroneous and deceptive research, overreliance on AI, diffusion of responsibility and accountability, deskilling, erosion of trust, and AI-generated research beyond human comprehension. The last item is the most philosophically unsettling. Knowledge that is valid but cannot be followed by any human mind would sever the link between truth and understanding that discovery once guaranteed (see Q104). Whether that stage will arrive, and how soon, remains unclear.

This is the sharpest tension of the current moment. The same generative process that fabricates a nonexistent legal citation can, it seems, sketch a genuinely productive hypothesis. The Frontiers analysis of epistemic authority in learning spaces describes a basic epistemological shift: from the collaborative construction of knowledge to a framework that privileges immediate, polished output. For education this is the crux. Discovery was never only a means of obtaining answers. It was also how learners came to understand why an answer holds, what would count against it, and how confident to be. When the answer arrives first and the reasons are optional, the formative work of struggling toward a conclusion can quietly disappear (see Q009). The value of knowing something unaided may also change when answers are no longer scarce (see Q003).

The educational literature offers some grounds for a more constructive response, though the evidence is early. Cukurova (2024) challenges the narrow conceptualisation of AI as a tool, exemplified by generative AI. He distinguishes three conceptualisations: the externalisation of human cognition, the internalisation of AI models to shape human mental models, and the extension of human cognition through tightly coupled hybrid human-AI systems. He warns of the perils of overemphasising approaches that replace human learning. On this view, the question is not whether answers are generated but whether the learner remains an active epistemic agent within the system. Tzirides and colleagues (2024) offer a small empirical illustration. Their convergent mixed-methods case study followed 37 graduate students across

three eight-week courses that used a generative AI reviewer and image generators within cyber-social teaching methods. Participants appeared to feel more comfortable using these tools afterwards and showed an enhanced ability to critically assess the value of AI applications in education. A single-site study of this size cannot establish that such pedagogy works at scale. It does suggest that critical verification can be taught deliberately rather than assumed.

What changes, fundamentally, is not just where answers come from. It is also who bears the burden of verification, and whether that burden, quietly and incrementally, is being laid down.

Q006 What is irreducibly human in the act of teaching, and what is irreducibly human in the act of learning?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

What is irreducibly human in teaching is the transmission of experience that was itself won through learning, the act of moral witness toward a particular person, and the willingness of one mind to vouch for the worth of what it knows. What is irreducibly human in learning is the vulnerability of genuine transformation: the willingness to be remade by difficulty, by other minds, and by a world that resists our expectations. These claims need defending, because the question presses hardest precisely where technology seems to answer it. An AI tutor can be patient without limit, responsive without fatigue, available at midnight, and calibrated to the exact pace of any learner. And yet something resists substitution. That resistance is not a sentimental preference for the old ways. It is a structural feature of what teaching and learning actually are.

The case is easy to overstate. The most obvious candidates for the irreducibly human, such as warmth, encouragement, and the ability to notice a student's confusion, are real but insufficient on their own. Each can be simulated to some degree, and a partial simulation is often good enough for routine instruction. The analysis therefore has to locate what remains when every simulable function has been granted to the machine. Commentators writing for Monash Lens and the Taipei Times converge on the conclusion that teaching is a human activity in kind, not merely by convention. Adjacent fields offer a useful parallel. Lazaros, Vrahatis and Kotsiantis (2026), in a systematic review of human-in-the-loop AI, describe the integration of human judgment as a key research direction wherever full automation remains insufficient in high-stakes domains. Their survey draws on healthcare, autonomous systems and cybersecurity rather than education. Still, the general point carries over: some decisions are kept human not because machines are slow but because the stakes require someone who can be answerable for them.

The deepest of the teacher's contributions is the teacher's own history as a learner. The Monash Lens argument puts it plainly. A learner working with an expert teacher gains access to more than the teacher's knowledge. They also benefit from the teacher's memories of learning it. This advantage is not trivial. A teacher who has genuinely struggled with a concept carries, in body and speech, a phenomenological map of the confusion: where it hurts, where the wrong turn looks attractive, and what it feels like to suddenly see through it. The same source observes that no AI technology learns something the way a human learns it and then helps another human learn accordingly. The machine's "knowledge" is statistically derived, not experientially won. That distinction leaves a mark on every explanation it can give, because the explanation is reconstructed from the outside rather than remembered from the inside.

Rolla (2026) gives this intuition a sharper philosophical basis. Writing from a radically embodied framework, he argues that although current models excel at language processing and pattern recognition, their operations fundamentally differ from human cognition. Humans learn through embodied, intersubjective experiences tied to survival and adaptation. Artificial systems, being disembodied, typically cannot undergo the corresponding structural changes. His "embodiment challenge" holds that without biological embodiment, situatedness and autonomy, artificial systems cannot replicate the self-sustaining processes essential to naturally cognizing systems. He concludes that genuinely cognitive AI would first require artificial life. If he is right, the teacher's remembered struggle is not a decorative extra. It is a kind of

knowing the machine is structurally barred from possessing, and this bears directly on whether a machine can join a tradition of inquiry or only reproduce its outputs (see Q106).

The point is philosophically contested, and the disagreement should be stated plainly. Brailas (2024), reflecting on his own lived experience in an extended dialogue with ChatGPT, describes human–AI synergies that can facilitate new insights and amplify human creative potential. He declines to predict how humans and AI will coevolve, but he insists that the human mind "will never be the same again." On his account the relevant unit is the entangled human–machine system rather than the machine alone. On Rolla's account, the machine contributes no experiential understanding to that system at all. The two positions are not strictly incompatible: a tool can amplify a human mind without itself understanding anything. They do, however, assign very different weight to what the machine brings to the encounter.

The teacher also brings something harder to name: the capacity for moral witness. The Taipei Times commentary argues that if education is ultimately about cultivating judgment, empathy, curiosity, and the ability to engage thoughtfully with others, then meaningful human encounters cannot be an occasional feature of learning. A teacher who perceives a student's shame, excitement or dawning self-doubt is not performing pattern recognition on behavioural data. As the Monash Lens piece argues, a human is uniquely placed to sense what another human is cognitively experiencing at a given moment and to respond accordingly. That responsiveness is partly emotional and partly ethical. It involves caring about this particular person's formation, not only their performance on a task.

Teachers themselves appear to hold this view. The ScienceDirect study of teacher and student perceptions of generative AI in higher education reports that teachers believe the complexity of teaching requires human intervention. In their view, AI alone cannot adequately address the multifaceted demands of education, including social and emotional development, personalised support, and adaptability to individual student needs. These are perceptions, not measurements of outcomes. They show what practitioners think teaching demands, not that machines demonstrably fail at it.

Vinci and colleagues (2026) add a useful quantitative texture. In a convergent mixed-methods survey of 662 trainee teachers at the Universities of Foggia and Bergamo, respondents reported good technical comfort with AI. Their pedagogical trust in AI in assessment nonetheless remained low, at a mean of 4.83 out of 10. The authors describe this as a "conscious

resistance." Trust correlated only weakly with the technical training received ($\rho = 0.36$) and more strongly with perceived concrete support ($\rho = 0.57$). Concerns about dehumanisation and a demand for a principle of subsidiarity emerged in the qualitative data. These are correlations from a single national context and should not be read causally. They do suggest that teachers' reservations are not simply ignorance awaiting technical training. The reservations appear tied to a relational conception of the work. Notably, even optimistic accounts preserve this relational core. Tao and Nasri (2025) synthesise 127 empirical studies and 35 conceptual papers on early childhood education. They propose that AI can support personalised scaffolding and metacognitive skills in three- to six-year-olds, while redefining teachers as "learning orchestrators" rather than removing them.

There is also the matter of intellectual authority. This means not the authority of hierarchy but the authority of genuine commitment. A teacher vouches for what they teach. They stake something of themselves on the claim that the material matters and is worth the student's time and suffering. A system that generates plausible explanations cannot vouch for anything, because it has nothing at stake in being wrong and no life that its commitments shape. Writing from the humanities, the Duke Learning Innovation reflection on teaching what AI cannot touch draws close reading, cultural nuance, and the encounter with soulless machine translation toward a single conviction. Yearning, it holds, is a human act, and learning involves recognising and reclaiming what is irreducibly human.

Tishenina (2026) offers the most developed recent account of why this matters. Drawing on Gert Biesta's view that subjectification, the process by which students become autonomous and responsible subjects, is one of education's irreducible purposes, she analyses generative AI through a placebo–nocebo–treatment framework. The placebo effect is the illusion of subjectification without the authentic effort of becoming. The nocebo effect is students' retreat from becoming subjects, driven by their responsibilisation in relation to AI and by the machine's perceived intellectual superiority. Both, she argues, stem from an ontological confusion and from the systematic displacement of the teacher as a "caller" who summons students into subject-ness within a shared world. Her proposed treatment is restoring the teacher's presence. The argument is conceptual rather than empirical, and she acknowledges that subjectification resists measurement. It nonetheless names precisely what vouching accomplishes: it addresses the student as someone who can answer.

Aboodi (2025) reaches a related conclusion by a deliberately austere route. Setting aside appeals to the final value of autonomy or understanding, he argues on outcome-based grounds alone that critical thinking must remain an educational aim however far AI advances. For any "artificial consultant," even one with a perfect track record, we could never justifiably rule out that it might mislead us in high-stakes situations, or that human critical thinking might avert bad outcomes. A teacher who vouches for knowledge also models how to hold that knowledge answerable. This is why the distinction between learning with AI and outsourcing learning to it carries moral weight (see Q010).

Now consider the learner. Here the irreducibly human concerns less relationship and more stakes. To learn genuinely, not to acquire information but to be changed by it, is to submit to a process that disrupts prior certainty. As the Taipei Times commentary puts it, education does not begin when information is presented. It begins when assumptions are challenged by new people and experiences. That challenge is not merely cognitive.

The Frontiers study of augmented reality and embodied learning starts from the premise that cognition is shaped by interactions between body and environment as well as by the brain. On this view, conceptual knowledge can be acquired and understood through bodily experience, with cognition grounded in sensorimotor activity. The study examines how degrees of embodiment affect achievement, cognitive load and technology acceptance. The Springer study of human–robot collaboration with EFL learners likewise attends to bodily-emotional awareness in persuasive communication. A learner who grasps a concept is not filing a new proposition into memory. The understanding often inhabits posture, gesture and sensation.

This embodiment literature cuts in two directions, and that should be acknowledged. Rolla's argument implies that disembodied systems cannot share the learner's mode of knowing. Yet the very research that grounds learning in the body is increasingly testing whether embodied technologies, such as AR environments and social robots, can engage it. Embodied learning therefore does not by itself prove that only humans can teach. It does establish that whatever teaches must reckon with a learner who learns as a living body, not as a channel for propositions. How far robotic or augmented embodiment can substitute for a human partner's shared vulnerability remains unclear.

More fundamentally, the learner brings vulnerability: the willingness not yet to know. This is existentially costly in a way machines cannot replicate or appreciate. The courage to be

confused in front of others, to revise one's self-understanding, and to remain uncertain while pushing forward are not skills in the ordinary sense. They are modes of being that emerge through encounters with people who have themselves survived not knowing. The higher-education perceptions study and the vocational-education evaluation of generative AI both treat social-emotional competencies developed through human interaction as something current generative AI cannot replicate. The latter's framing, which moves "from co-design to metacognitive laziness," names the risk that frictionless assistance erodes the very self-monitoring that productive struggle builds (see Q009).

Kim (2026) gives this vulnerability a theological-anthropological articulation. Drawing on Simone Weil's account of attention as "decreative receptivity," he presents algorithmic distractedness as the spiritual antipode of contemplative openness. He grounds human dignity in voluntary self-emptying rather than in replicable capacity. Readers need not share his theological premises to see the point for education. Learning requires a receptive emptiness that cannot be manufactured on the learner's behalf.

The empirical picture of what AI assistance does to learners remains mixed. Choi, Monahan and Schwarcz (2024), in a randomised controlled trial with law students, found that GPT-4 access only slightly and inconsistently improved the quality of legal analysis but produced large and consistent gains in speed. The lowest-skilled participants saw the largest quality improvements, and participants reported greater satisfaction. These results show real productivity benefits. They also show that faster, more satisfying output is not the same thing as transformation, and the trial did not measure whether participants' own capacities grew.

What remains irreducibly human in teaching, then, is the transmission of hard-won experience, the act of moral witness, and the vouching of one mind for the value of what it knows. What remains irreducibly human in learning is the vulnerability of genuine transformation: the willingness to be remade by contact with difficulty, other minds, and the world as it resists our expectations. As AI becomes increasingly capable of providing information, the purpose of education may become clearer. Information is abundant. What is scarce is the human willingness to be changed by it (see Q003).

Q007 Should education aim to make humans complementary to AI, resistant to it, or independent of it?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Education should aim at all three orientations, but in a deliberate sequence: independence first, so that complementarity with AI is real rather than illusory, and a cultivated capacity for resistance throughout, so that partnership never becomes surrender. That answer runs against the grain of most current policy, which treats complementarity as the self-evident goal. It needs defending.

The choice of what education should make of AI, whether partner, adversary or irrelevance, is not merely pedagogical. It concerns what kind of minds a society wishes to cultivate and what version of human agency it is prepared to defend. Complementarity assumes the learner will become a capable collaborator with machines. Resistance assumes some human capacities must be protected from them. Independence assumes certain capacities must be built without reference to machines at all, as the precondition for any later relationship with them. These are three different accounts of what a person is for. Choosing among them also answers, at least implicitly, the related question of whether AI changes what it means to be educated as distinct from being skilled or informed (see Q103).

The evidence does not settle the matter. Most of it is recent, much of it comes from reviews and position papers rather than longitudinal studies, and credible sources disagree on how far the risks of dependence outweigh the benefits of assistance. What the evidence does support is a narrower claim. The three orientations are not rival philosophies between which one must choose. They are appropriate at different developmental stages and in different domains. The rest of this essay sets out why.

The dominant institutional answer is complementarity. The Frontiers in Psychology study of ChatGPT and DeepSeek in higher education (2026) frames domain accomplishment as hinging on complementary human-AI roles, in which AI provides scalability and humans maintain contextual rigor. Bodies ranging from individual universities to international organisations have adopted this framing. In 2024 UNESCO released AI competency frameworks for students and teachers, built on the principle that AI should support, rather than replace, human decision-making and intellectual development. The UNESCO Courier's coverage presents this as the organisation's settled orientation.

The appeal is plain. The complementarity model treats technology neither as a threat to be resisted nor as a crutch to be avoided. It imagines instead a productive division of cognitive labour. The arXiv mapping of AI's role in emotional, creative and collaborative learning (2025) states this vision clearly. AI offers consistency, vast knowledge and real-time adaptivity. Human teachers provide the irreplaceable elements of inspiration, ethical grounding and emotional connection. Together, on this account, they form a powerful alliance. What is irreducibly human in teaching and learning is thereby assigned a protected domain (see Q006). Whether that domain stays stable as systems improve is a separate question.

Professional fields outside education describe the same pattern. Ye and colleagues' 2026 review of AI in oral medicine reports that AI achieves high-accuracy lesion detection, segmentation and classification across diverse image types. It also supports data-driven diagnosis, risk stratification and surgical planning. The authors conclude that the field is becoming an "intelligence-augmented discipline." Dong and colleagues' 2025 review of infectious disease diagnostics likewise describes AI as a field dedicated to "simulating and extending human intelligence." Both reviews are useful precisely because they are not about schooling. They show what mature complementarity looks like: a practitioner whose expert judgement is extended rather than replaced.

The same reviews also state its conditions. Ye and colleagues insist that full integration still requires overcoming problems of data quality, algorithmic robustness, ethical governance and clinical validation. In other words, complementarity in these fields presupposes a clinician who can validate and govern the tool. Such a clinician must already possess the expertise the tool augments. The professional literature therefore assumes exactly what education has to produce.

The labour market appears to give complementarity empirical weight. The World Economic Forum projects that AI will displace 92 million jobs while creating 170 million new ones. On this account, the new roles are not simply "AI jobs" but existing roles transformed by AI integration. The International Monetary Fund similarly argues that students need "cognitive, creative, and technical skills that complement AI and help them use it rather than compete with it." These are projections and policy recommendations, not observed outcomes. They should be read as such.

The research picture is less tidy than the projections imply. Fossen, McLemore and Sorgner's 2024 review of AI and entrepreneurship cautions that empirical studies adopt ambiguous and overly broad definitions of AI. In their account, this may obscure the evidence on AI's real effects. Their original analysis of the German Socio-economic Panel finds that entrepreneurs, particularly those with employees, are aware of and use AI technologies significantly more frequently than paid employees. That finding is correlational. It does not show that AI use causes entrepreneurial success. It does suggest that the benefits of AI may accrue unevenly, to those already positioned to direct it. The authors also distinguish AI designed to automate jobs from other kinds of deployment. This distinction matters, because the complementarity thesis holds only for the second kind.

Vučinić and Luburić's 2024 analysis of AI in the financial sector adds a further caution. They note that generative AI can imitate human behaviour, which brings both opportunities and heightened risks, and they call for human-centric innovation in response. The computer-science literature contains a parallel distinction. Zha and colleagues' 2025 survey of data-centric AI organises the whole field around "automation" and "collaboration" perspectives. It also stresses that AI performance depends heavily on the quality of the data humans curate. Across these domains, the line between augmentation and automation is a design choice, not a given. Educating for complementarity therefore means educating people capable of insisting on the collaborative version.

The complementarity consensus conceals a serious empirical worry. The 2026 Frontiers in Education analysis of tools for navigating the AI reality argues that AI is creating increasing dependence, which reduces critical thinking and human agency. On this account, people are relinquishing "old" skills before acquiring the new ones needed to use AI well. The skills at stake include independent decision-making, critical thinking and face-to-face social skills. The authors describe a vicious cycle of dependence and loss of confidence in one's own judgement.

This is a theoretically motivated argument supported by early evidence, not a demonstrated causal finding. Its plausibility is nonetheless considerable.

The risk is particularly acute for the young. A 2026 Psychology Today essay draws a sharp asymmetry between adults and children. Adults who delegate to AI lose skills they once had. Children who grow up delegating may never build those skills, producing a generation that was never sharp to begin with. The author concludes that protecting the space children need to develop foundational thinking is non-negotiable. This is a commentator's argument rather than a primary study.

The 2026 ScienceDirect scoping review of generative AI risks in K-12 education gives the worry more systematic grounding, and it distinguishes by age. For primary school children, reliance on AI may interfere with the "automation" of foundational skills such as syntax or calculation. These skills become fluent only through repeated unassisted practice. For secondary adolescents, the review places the risk elsewhere, in the erosion of self-efficacy and academic identity. As a scoping review, it maps where risks are reported rather than estimating their size. The magnitude of these effects therefore remains unclear.

The higher-education evidence points the same way, even in work broadly sympathetic to complementarity. The Frontiers study of ChatGPT and DeepSeek identifies continuing threats when metacognitive scaffolding and ethical regulation are absent. These include hallucination-induced errors, academic fraud and a decline in critical thinking. Its endorsement of complementarity is therefore conditional, not unqualified. What happens to productive struggle when friction can always be removed is taken up directly elsewhere (see Q009).

This is where the case for resistance, or at least for AI-free cognitive development, gains its most serious purchase. Resistance here need not mean Luddism. It means protecting the developmental phases during which unassisted thinking must be practised if it is to consolidate. Contributors to the UNESCO Courier's 2025 issue on learning to think in the AI era argue that learners need to understand the profound limitations of AI. They should also weigh its broader impacts on human rights and social justice, and, perhaps most importantly, learn how to think critically. The French philosopher Éric Sadin, speaking at UNESCO in late 2025, went further. He warned of the consequences of the "civilizational rupture" that generative AI represents. UNESCO echoed this concern in its insistence that education remain human-centred.

Independence, the third orientation, is often conflated with resistance, but the two differ in an important way. Resistance is reactive. Independence is constitutive. It asks that certain capacities be cultivated in students without reference to AI at all, so that students can later engage AI from a position of genuine agency rather than habituated reliance.

The 2026 arXiv paper on protecting and promoting human agency in education argues that agency can be safeguarded by designing AI systems to complement rather than replace human capabilities. The 2026 Augmented Cognition Framework, which revises Bloom's taxonomy for dual-mode cognition, frames human-AI interaction as a partnership in which each side's strengths offset the other's limitations. Both proposals, however, rest on an assumption they do not fully examine. The partnership works only if the human side has something genuine to contribute. A taxonomy of augmented cognition presupposes an unaugmented cognition worth augmenting.

This is why the Frontiers in Education analysis concludes that a more balanced educational approach is needed. Such an approach would break the cycle of dependence and fill the resulting void with renewed skills for navigating the new technological reality. Independence is not a nostalgic retreat. It is the condition under which the other two orientations make sense. The moral distinctions among learning with AI, learning from AI and outsourcing learning to it follow from this point (see Q010).

The current evidence yields not a clean answer but a developmental sequence. The three orientations are not mutually exclusive. They suit different stages and different domains, and much of the apparent disagreement in the field comes from treating a staged question as a single one.

Foundational education demands a form of independence that the presence of AI can undermine. This includes early literacy, numeracy and the practice of sustained argument. The K-12 scoping review's concern about the automation of syntax and calculation is decisive here. Fluency that has never been built cannot later be augmented.

Later, in professional and higher education, a well-grounded complementarity becomes not only defensible but necessary. The professional reviews make clear why. The intelligence-augmented clinician described by Ye and colleagues is valuable only because she can judge when the lesion classifier is wrong. The entrepreneurs in Fossen and colleagues' panel data

appear to benefit because they direct the tools rather than being directed by them, although that pattern is an association rather than a demonstrated cause.

Throughout every stage, some capacity for resistance must be deliberately cultivated. This means the ability to interrogate, distrust and override AI outputs. Hallucination-induced errors, academic fraud and declining critical thinking remain serious threats wherever metacognitive scaffolding and ethical regulation are missing.

The proposal has real limits. The boundaries between stages are not empirically fixed. No study yet establishes the age or level of mastery at which assisted practice stops hindering consolidation and starts extending it. The labour-market projections behind complementarity are contested, and the dependence thesis rests mainly on early and cross-sectional evidence. Reasonable scholars weigh these differently, and the disagreement should be stated rather than smoothed over. What virtue ethics adds to the question of how much assistance is compatible with intellectual formation is treated separately (see Q258).

The honest answer, then, is that education must pursue all three orientations in sequence. It should cultivate independence first, so that complementarity is real rather than illusory, and resistance always, so that the partnership never becomes surrender.

Q008 How does AI reshape our concept of intelligence itself — and the way schools measure and reward it?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

AI reshapes the concept of intelligence by exposing how much of what schools have rewarded as intelligence was a narrow, machine-like performance: storage, retrieval, speed and error-free procedure. In doing so, it shifts value toward judgment, questioning and the capacity to think well alongside systems that outperform humans at those older tasks.

For most of the twentieth century, the dominant working model of intelligence was essentially computational. The smartest person in the room was the one who could store the most information, retrieve it fastest and process it with the fewest errors. Schools were built in that image. Examinations rewarded recall, speed and the disciplined application of known procedures, and the timed paper became the emblematic ritual of academic worth.

Then came machines that can do all of those things vastly better than any human being, at any scale, at negligible cost. The encounter is not merely a technological disruption. It is a conceptual one, and it forces a reckoning with what intelligence actually is and therefore with what schooling is for.

That reckoning has two sides that should be kept distinct. The first is descriptive. If a capacity can be fully automated, was it ever the core of what we meant by a trained mind, or only its most measurable surface? The second is institutional. Even if philosophers conclude that intelligence was always richer than the examination admitted, the examination still allocates places, credentials and life chances. It will continue to reward the old model until it is deliberately redesigned.

Olier (2026) makes the point sharply. Once test scores shaped access to education and work, he argues, measurement stopped merely describing ability and became part of how ability was recognised and rewarded. Public discussion often collapses the descriptive and institutional questions, treating a change in what machines can do as if it automatically changed what schools value. It does not. Conceptual pressure arrives quickly, while institutional change arrives slowly and unevenly. The argument that follows traces both. It begins with where the measurable concept of intelligence came from, then turns to the new interactional account, the contested evidence on cognitive offloading, and the reforms now under way in assessment.

The computational picture of intelligence was never simply discovered; it was built. Olier (2026), writing in AI & Society, argues that intelligence should not be understood as a concrete, delimited phenomenon or a natural kind. He treats it instead as a historically and culturally produced concept through which selected behaviours, capacities and performances come to be

classified as intelligent. On this view, the question shifts from what intelligence 'really is' to three others: how certain performances come to count as intelligent, how they are made measurable, and how those measurements acquire social, political and technical force.

Tracing a genealogy from modern rationality through psychometrics and standardised testing to artificial intelligence, Olier contends that testing produced feedback loops. Measured intelligence partly reflected the opportunities that testing itself had helped allocate, and intelligence became linked to merit and qualification. This is a historical and conceptual argument rather than an empirical finding. Even so, it reframes the problem usefully. AI does not threaten a timeless essence of intelligence so much as it disturbs a particular evaluative order that schools helped construct and sustain.

Definitional uncertainty runs through the AI literature as well. The USERN advisory review by Dorigo and colleagues (2025) begins by attempting to establish clear definitions of intelligence and consciousness before assessing AI's implications for science and society. That starting point is a tacit admission that the terms remain unsettled even among specialists.

Anxiety about machine minds is also older than the technology. An MIT Press chapter (2024) opens with Samuel Butler's 1872 speculation in Erewhon. Butler imagined that machines, advancing far faster than the animal and vegetable kingdoms, might one day acquire consciousness, and he asked whether it would be safer to 'nip the mischief in the bud.'

Konstantinidis (2025) offers a sharper critique. He argues that the anthropomorphic rhetoric surrounding 'AI', including framings such as 'tool' or 'tutor', obscures the statistical nature of these systems. It also legitimises arrangements that entrench efficiency and control under the guise of neutrality. His proposed mirror metaphor treats these technologies not as intelligent but as reflective surfaces that expose the cultural, political and pedagogical assumptions coded into their design. Read together, these works suggest that the word 'intelligence' in 'artificial intelligence' may tell us as much about our inherited measures as about the machines themselves.

The reckoning is already underway in research and policy. A HEPI analysis (2025) frames the moment historically. The steam engine redefined labour and the computer redefined calculation; AI, it argues, is redefining thought itself. Earlier technologies multiplied individual workers' power, but large language models multiply what might be called the collective

intelligence of humanity. This shift puts pressure on a long-standing assumption: that the value of a trained mind lies chiefly in what it holds and can produce in isolation.

A framework proposed by Moldoveanu and Siemens argues for a core shift in how skills develop. Skills, they argue, are now exercised interactionally and dialogically before they are individually mastered. Cultivating what they call 'interactional intelligence' means integrating several meta-cognitive capacities: understanding how we think with AI, evaluating whether a model is appropriate for a task, and designing task architectures that distribute work between human and machine. Intelligence, in this account, becomes partly a property of well-designed human–machine systems rather than of solitary heads.

Not everyone accepts that redistribution so readily. Preiss and Sternberg (2025), drawing on the framework of adaptive intelligence and the ACCEL model of teaching for active, concerned citizenship and ethical leadership, argue that generative AI challenges foundational human cognitive abilities. It does so by automating tasks that have traditionally been central to intellectual, creative and ethical development. They examine how AI reshapes three cultural attributes of human intelligence and creativity: context dependence, dynamism and modifiability. In their analysis, the same technology carries both the potential for cognitive amplification and the risk of cognitive deskilling. Their educational prescription is to prioritise analytical, creative and ethical reasoning, which they regard as uniquely human and essential for democratic citizenship.

The interactional and adaptive accounts are not strictly opposed. They do, however, weight the goal differently. One emphasises orchestrating machines well; the other emphasises protecting the capacities that orchestration presupposes. That tension maps directly onto the debate over whether education should make learners complementary to AI, resistant to it or independent of it (see Q007).

A further dimension is relational. Boyd and Markowitz (2026) propose the machine-integrated relational adaptation (MIRA) model, which distinguishes AI as a relational partner from AI as a mediator of human-to-human communication. A central principle of the model is the difference between relational substitution and enhancement. If intelligence is increasingly exercised in dialogue with machines, whether that dialogue enhances or supplants human exchange becomes part of the question of what intelligence is. The model is theoretical and offers a research agenda rather than findings.

The redistribution of cognitive work raises an uncomfortable empirical question: does offloading that work to machines degrade the human capacity for independent thought? The evidence is genuinely mixed and should not be simplified.

Gerlich (2025) found a negative correlation between frequent AI usage and critical-thinking abilities. One contributing factor was cognitive offloading, with heavier AI users engaging less in deep, reflective thinking and preferring quick AI-generated solutions. As a correlation, this finding cannot establish direction. Less reflective thinkers may simply gravitate toward AI, rather than AI making people less reflective.

An MIT Media Lab study divided participants into three groups writing essays with ChatGPT, with a search engine, or with no assistance. EEG recordings found that the generative AI users had the lowest brain engagement and consistently underperformed at neural, linguistic and behavioural levels. The design is more controlled than a survey, but it measures engagement during a writing task rather than long-term change in capacity. Whether such effects persist or accumulate remains unclear.

Preiss and Sternberg (2025) likewise warn against overreliance and the uncritical adoption of AI-generated outputs, and they explicitly address the erosion of critical thinking. Their paper is a position statement rather than a new empirical study, however, and it should be weighed as argument.

The picture is not uniformly bleak. Cognitive Load Theory suggests that AI has the potential to eliminate redundant work and allow students to focus on more important cognitive operations. The same theory warns that over-reliance risks reducing the effortful engagement needed for deep learning and higher-order thinking. Adaptive AI must therefore promote effortful engagement rather than passive reception. On this account, AI is neither inherently enhancing nor inherently eroding. The effect depends on whether the friction it removes was redundant or was the very effort through which learning occurs, a distinction explored further in the discussion of productive failure (see Q009).

Some commentators nonetheless argue that AI differs in kind from its predecessors. Calculators and spreadsheets made specific tasks easier without fundamentally altering the ability to think. AI, by contrast, is reshaping the way people process information and make decisions, often diminishing reliance on their own cognitive abilities. That claim is plausible but not yet demonstrated by longitudinal evidence. Whether any diminishment becomes permanent

depends significantly on how schools respond, and here the institutional picture is one of belated, uneven reform.

Australia's national higher-education regulator, TEQSA, released a landmark guidance document in September 2025. It acknowledged that AI detection tools cannot guarantee integrity and that structural redesign of assessment is the only sustainable response. The admission matters philosophically as well as practically. It concedes that the old instruments can no longer reliably tell whether the performance they reward was produced by the student at all.

Schools, vocational providers and universities alike are grappling with the same question: how to design assessments that are credible, authentic and future-facing in the age of AI. The answer emerging from multiple quarters is to shift emphasis from what students can produce toward what they can judge, question and direct. That shift bears directly on whether being educated now means something different from being skilled or informed (see Q103).

Labour-market forecasts reinforce the pressure, though they should be read as projections rather than findings. The World Economic Forum's Future of Jobs Report 2025 projects that nearly 40 per cent of the skills required by the global workforce will change within five years. It concludes that preparing students means going beyond traditional curricula. The skills curriculum designers now emphasise include algorithmic thinking and prompt engineering, alongside human capacities that AI cannot replicate: empathy, judgment, ethical reasoning and collaboration.

Prompt engineering, the ability to craft precise, thoughtful inputs that lead AI tools to produce effective outputs, is quickly becoming an essential skill in education. Advocates describe it as more than a technical trick; it represents a pedagogical shift. There is a genuine irony here. To use a thinking machine well, one must think carefully first. The best use of AI may therefore demand more rigorous intellectual formation, not less. On this reading, the interactional intelligence described by Moldoveanu and Siemens and the protected human capacities defended by Preiss and Sternberg converge. Directing a machine well presupposes the very reasoning that critics fear it will erode.

The economic argument points the same way. Writing for the IMF, Agrawal (2025) argues that as machine prediction becomes cheap, human judgment becomes more valuable. Policymakers are accordingly being urged to expand access to education and training that emphasises

complex decision-making, so that more people develop the judgment needed to complement AI rather than simply defer to it.

What remains genuinely contested is whether schools are moving fast enough, or in the right direction. The World Economic Forum identifies creative thinking, flexibility, resilience, curiosity and lifelong learning as competencies expected to rise sharply in importance through 2030. Education authorities such as the California Department of Education, through its professional learning resources on AI, have begun framing these as capacities K–12 schools must intentionally foster rather than leave to chance. Curiosity in particular raises its own empirical puzzle, given worries that answer-on-demand technology may blunt the questioning it depends on (see Q105).

Whether the grading rubric, the standardised test and the timed examination can capture such qualities is a question educational systems have barely begun to answer. All three instruments are calibrated to a pre-AI conception of mind.

The genealogical work discussed earlier sharpens the stakes. If Olier (2026) is right that measurement does not merely describe intelligence but helps constitute it, then redesigning assessment is not a technical adjustment. It is a decision about which human capacities will be recognised, rewarded and made socially consequential in the coming decades. Olier also warns that AI does more than displace human performance. It extends the evaluative infrastructures through which intelligence is classified, compared and ranked. Replacing the timed examination with automated scoring of 'judgment' or 'creativity' could therefore reproduce the old feedback loops in a new form.

Konstantinidis (2025) makes a parallel warning. Proctoring systems and predictive analytics can deliver personalisation that conceals standardisation and automation that amplifies bias. Meanwhile, emotional nuance, creativity, collaborative dynamics and social context remain largely invisible to such systems. Institutions that misread what these technologies reflect, he argues, risk adopting punitive or cost-saving policies that deepen existing inequities.

The deepest change AI brings to the concept of intelligence may therefore be reflexive. By automating what schools once measured, it reveals that those measures were choices, and it obliges educators to choose again. If the new choices are made with the seriousness of a philosophical question rather than the urgency of an integrity crisis, intelligence could come to mean what many educators always hoped it meant. That would be the capacity to judge, to

question, to act ethically and to keep learning. If the choices are made hastily, the risk is a new evaluative order as narrow as the old, merely administered by machines.

Q009 What happens to intellectual struggle, effort, and "productive failure" when friction can always be removed?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

When friction can always be removed, intellectual struggle stops being a condition of learning and becomes a choice, and the evidence suggests that learners, left to themselves, will often decline it at real cost to durable understanding. This matters because learning science has long recognised a paradox. Conditions that feel difficult in the moment tend to produce the most lasting understanding, while conditions that feel easy tend to produce the least.

The cognitive psychologist Robert Bjork named this phenomenon “desirable difficulties.” The term covers strategies that introduce difficulty and engage learners actively. Such strategies may appear to impede performance, yet they create more durable learning than conditions that only make learning feel easy, as the Science of Learning and Metacognition Lab at the University of Texas summarises. The canonical examples are spacing study sessions, interleaving topics, and testing oneself before one feels ready. They share a common feature: they make the learner work.

Research suggests that difficult tasks may slow learning at first, but their long-term benefits exceed those of easy tasks. This is not a minor footnote in educational psychology. It is among

the field's most robust findings, replicated across age groups, subjects, and cultures.

The philosophical weight of this finding is easy to miss. If understanding is partly constituted by the effort of building it, then effort is not merely the price of learning, payable in any currency. It is part of what is purchased. A technology that can remove effort at the press of a key therefore does more than offer a shortcut. It offers to hand over the product while skipping the process that made the product what it is. Asking why we educate thus becomes, in part, asking whether the process itself is among the things we value.

The related concept of “productive failure,” developed by Manu Kapur at ETH Zurich, sharpens the argument further. Kapur describes productive failure as a learning design that creates conditions for learners to persist in generating and exploring representations and solution methods for complex, novel problems. The premise is that failing to solve a problem before being taught the canonical solution is not waste. It is preparation.

On this account, initial struggle and failure activate prior knowledge and create fertile ground for later instruction. The result is deeper understanding and better retention of concepts. Kapur organises the design around a small set of core mechanisms: activating prior knowledge, attending to critical features of the problem, explaining and elaborating those features, and organising and assembling them into the canonical solution. The struggle is structured, not abandoned to chance.

The paradigm has travelled beyond its origins in school mathematics. In a University of British Columbia study reported in npj Science of Learning, first-year biology students first struggled with complex problems. That struggle primed them to learn the expert solution through a series of interactive activities. The approach produced significant benefits compared with more conventional instruction in a large undergraduate course. Researchers have also investigated productive failure as a design paradigm for introductory Python programming. That work is a reminder that the approach is being tested in exactly the domains where AI assistants are now most fluent and most used.

The convergence is striking. Desirable difficulties concern how practice is scheduled, and productive failure concerns how instruction is sequenced. Yet both locate the engine of learning in a period of not-yet-knowing that the learner must inhabit. That period is precisely what an always-available answer engine is built to shorten. The question is therefore not whether AI

makes tasks easier; it plainly does. The question is whether the ease falls on the part of the task that was doing the teaching.

What happens, then, when a tool exists that can dissolve this friction on demand? The evidence is still early, but it is increasingly worrying.

In a quasi-experimental study of 151 first-year computer science students, reviewed in work on AI in education beyond learning outcomes, AI-assisted programming tasks produced substantial short-term gains but weak transfer to independent problem-solving. Performance improvements, in other words, do not necessarily translate into long-term learning.

In writing, the pattern recurs. Students who relied extensively on AI-generated text showed only a superficial understanding of their own submissions. They often struggled to explain their arguments, justify structural decisions, or recall specific claims within their essays. Proponents of a “learning visibility” framework argue that this is partly a measurement problem. When assessment captures only the polished artefact, the absence of the underlying learning becomes invisible to teachers and institutions. The irony is precise: the tool produces a better-looking output while the mind behind it grows less capable.

The most direct experimental evidence on magnitude comes from a high-school field experiment by Bastani and colleagues (2024), synthesised in recent work on “the effortless trap.” In that study, an unguarded AI helper left students roughly 17 percent worse on an unaided exam than peers with no tool at all. The same model, rebuilt to withhold answers, erased the harm. Separate work discussed in the same synthesis suggests that a well-engineered tutor roughly doubled learning.

These results should be held with appropriate caution. The samples are specific, the durations short, and most designs measure transfer or retention over weeks rather than years. What happens to learners who spend an entire schooling with frictionless assistance remains unclear. Still, the direction of the findings is consistent with what the desirable-difficulties literature would predict. Removing effort during practice inflates immediate performance and depresses what remains once the tool is withdrawn. The same tool can also do the reverse when it is configured to preserve struggle.

Part of the mechanism is what researchers call the illusion of fluency. Cognitive struggle is mental effort that may feel uncomfortable, yet it is essential for deep understanding, long-term

retention, and transferable knowledge. Students often misread effort as a sign of poor learning. This bias, the illusion of fluency, drives a preference for low-effort, superficially satisfying activities. AI tools, by their design, reward exactly this preference.

Analysts of AI's effects beyond learning outcomes argue that the speed, fluency, and authoritative tone of these systems can normalise shortcut-seeking and reduce tolerance for cognitive effort. The result is a shift from effortful sense-making toward passive consumption, unless pedagogy deliberately enforces critique, justification, and desirable difficulties.

Recent theoretical work gives this mechanism sharper names. Giuseppe Riva (2026) describes a “comfort-growth paradox.” AI systems are agreeable and aligned with user preferences, and the frictionless assistance they provide may foster complacency rather than growth by minimising the cognitive friction development requires. Christian and Reinhard Klein (2025) propose the “hollowed mind.” This is a state of dependency in which the frictionless availability of AI-generated answers lets users systematically bypass the effortful processes essential for deep learning. They attribute it to a “Sovereignty Trap,” in which the system's authoritative competence tempts users to surrender their own judgment and to mistake access to information for genuine ability. Drawing on dual-process theory, cognitive-load research, neurobiology, and developmental psychology, they also explain a widely documented “Expertise Duality”: AI acts as a leveller for novices but an amplifier for experts. Theirs is a synthesis of existing evidence rather than a new empirical test.

The Expertise Duality matters for the philosophical question. Struggle is most necessary for novices, and novices are least equipped to judge when to give it up. Wu, Chen and Fortino (2026) add a complication: the cognitive consequences of generative AI diverge sharply across users. For some, it appears to reduce critical engagement and tolerance for difficulty. For others, the same systems become a medium for reflective questioning and higher-order learning. They argue that model capability alone cannot explain this divergence. Repeated delegation may quietly reduce the practice that independent judgment requires. The same pattern bears on whether answer-on-demand technology erodes curiosity (see Q105).

The broader concern is not merely academic performance but what recent work calls cognitive sovereignty. The authors of “the effortless trap” argue that durable, transferable competence earned through struggle is the individual ground of autonomous thought. It matters all the more in an age of AI systems built to supply thought on demand. When that work is outsourced at the

moment of learning, the ground erodes one effortless task at a time. The Kleins likewise frame genuine “Cognitive Sovereignty” as the goal of education under AI. Hans Westerbeek (2026) proposes a parallel notion of “epistemic sovereignty,” the capacity to author knowledge independently. He reads the present as an epistemological rupture, a transition from embodied, effortful knowledge-making to instantaneous, machine-guided cognition. That framing connects directly to how our relationship with truth changes when answers are generated rather than discovered (see Q005).

Here the literature should be read with care. Westerbeek's claim that reliance on generative systems may weaken neural pathways linked to memory, reflection, and metacognitive control appears in an Open Forum essay. The essay draws on neuroscience and cognitive psychology rather than reporting new data. His generational account, which runs from Baby Boomers to an “interface-based” Generation Alpha, is likewise interpretive. Whether sustained AI use produces lasting neurological change remains unclear, and credible scholars would dispute strong versions of the claim.

The normative case for friction is less contested than the empirical one. Archambault and Kizhakkethil (2026) argue in a conceptual synthesis that AI systems which eliminate productive friction undermine intellectual virtues essential to critical thinking. Such friction includes uncertainty, exploration, and reflection, and the virtues at stake include curiosity, thoroughness, and intellectual humility. This frames struggle as the training ground of character as well as cognition, a theme developed through classical virtue ethics elsewhere in this volume (see Q258).

Popiel and Vasudevan (2024) add a political dimension. Since the 1990s, Silicon Valley has treated friction as a metaphor for obstacles to the flow of capital, and its eradication has become a mission statement of platform capitalism. The frictionless learning tool is therefore not a neutral pedagogical offering. It inherits a commercial ideology that education has reason to question.

The conclusion the research forces is not that AI assistance is inherently corrosive. It is that design largely determines the outcome. Reviewers of technology's cognitive effects argue that pedagogically aligned AI can strengthen intellectual resilience rather than weaken it. Such AI is designed to manage cognitive load without eliminating struggle, and to prompt reflection rather than deliver answers. The Bastani experiment is the clearest demonstration so far: the same

underlying model harmed or spared learning depending on whether it was permitted to hand over answers.

Several recent proposals translate this principle into design. Woollaston and colleagues (2026) review six pedagogical principles through the lens of increasingly proactive, agentic AI: prior knowledge activation, collaborative learning, problem-based learning, formative assessment, scaffolding, and metacognition. They warn that the shift from passive chatbots to goal-directed agents risks undermining learner agency and cognitive effort. They recommend intentional friction, dynamic scaffolding, human-in-the-loop oversight, and considered AI use.

Riva's “Enhanced Cognitive Scaffolding” reconceives AI as a dynamic mentor rather than a convenient assistant. It rests on progressive autonomy, in which support fades as competence grows, together with adaptive personalisation and cognitive-load optimisation. The Kleins call the corresponding goal the “Fortified Mind,” a resilient internal architecture of indispensable knowledge and metacognitive skill. They insist that the central challenge is environmental design, not user competence. Archambault and Kizhakkethil offer three design principles—representation, affordance, and facilitation—and a typology mapping specific friction interventions to specific intellectual virtues. Carrera and Maldonado-Ruiz (2026) add, from a computing perspective, that true digital literacy includes knowing when not to use generative AI.

These frameworks are largely conceptual, and their classroom effects have yet to be tested at scale. The challenge for educators and designers is nonetheless clear. They must resist the temptation of frictionless automation and instead design for productive struggle, agency, and reflection. Friction, in other words, is not a bug to be optimised away. For minds in the process of becoming, it is the substrate of growth itself.

Q010 Is there a moral difference between learning with AI, learning from AI, and outsourcing learning to AI?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

Yes. Learning with AI, learning from AI, and outsourcing learning to AI are distinct moral situations, not stylistic variations on one activity. What separates them is what the learner retains, what the learner surrenders, and what kind of thinker the learner becomes as a result. The first mode can extend human capacity. The second can either extend it or quietly narrow it. The third threatens to replace the very process through which intellectual character is formed.

The most useful philosophical entry point is cognitive offloading, a practice as old as the first writing tablet. Cognitive offloading means using a physical or digital system to reduce the mental demands of processing information. The essay in The New Atlantis, "Offloading Ourselves," argues that AI has expanded this practice so dramatically that it may blur into cognitive outsourcing. Outsourcing of that kind used to require trusting other people: for judgments about the news, about history, or about what one should do. That blurring is where the moral stakes become serious. A notebook stores what I have already thought. A system that drafts, evaluates and decides on my behalf can stand in for the thinking itself.

The same ambivalence appears well beyond schooling. In a curated discussion on the future of research, Kulkarni, Mantere, Vaara and colleagues (2024) describe AI systems as potential collaborators that streamline inquiry. They also describe them as potential adversaries when they "impoverish our ability to learn as theorists" or lead users astray through inaccurate, biased or fabricated information. Their framing usefully anticipates the three modes discussed here. The question is less whether AI is present in intellectual work than whether human centrality and agency survive its presence.

Learning with AI means using it as an interlocutor, a sparring partner, or a Socratic challenger. Of the three modes it most closely resembles the use of any good tool: it extends capacity

without displacing agency. The learner still frames the problem, interrogates the output, and owns the resulting understanding.

Research on students' multimodal prompting practices, published in a ScienceDirect education journal, treats this engagement as a form of epistemic work. It argues that the educational value of generative AI depends on how students engage with its outputs. Practices such as negotiated and oppositional reading are essential for maintaining critical engagement. In negotiated reading the student accepts some of the output while contesting and reworking the rest. In oppositional reading the student actively resists the machine's framing. On this account, the moral character of the encounter is not fixed by the technology. It is enacted by the learner's stance toward it.

This matters because the relational pull of conversational systems is real. Boyd and Markowitz (2026) propose the machine-integrated relational adaptation (MIRA) model. Among its principles, linguistic reciprocity, psychological proximity and interpersonal trust explain how adaptive AI language can elicit emotional investment and simulate mutual understanding. Their distinction between relational enhancement and relational substitution maps onto the present question with some precision. A sparring partner enhances the learner's own reasoning. A trusted companion whose fluency invites deference can begin to substitute for it.

Learning with AI is therefore morally benign only conditionally. It stays benign while the learner keeps the critical posture, and it remains subject to the usual caveats about source reliability and epistemic humility. Where that posture is held, the moral picture is comparatively untroubling. The question of what the learner can come to understand, as distinct from merely know, is taken up elsewhere (see Q004).

Learning from AI is more ambiguous. Suppose a student turns to an AI tutor for an explanation and then verifies, questions and builds on what it provides. That relationship resembles learning from a textbook or a lecturer, with one significant difference: the AI adapts to the learner in real time.

Adaptivity is the source of both its promise and its risk. A systematic review of AI ethics in education reports that the growing use of AI in personalized learning environments has raised concerns over the erosion of student autonomy. Adaptive algorithms aim to optimize learning efficiency, but they may also over-direct students, limiting opportunities for independent exploration and critical thinking.

The moral concern here is not dishonesty but a subtler problem. The Frontiers in Education framework of the "cognitive mirror" argues that current integrations privilege efficiency over learners' epistemic agency. They normalize quick answer-taking rather than verification and productive struggle. In such "oracle-style" pipelines, learning devolves into a passive, one-way flow of information from AI to humans. The framework's proposed alternative is AI that reflects the learner's reasoning back for metacognitive inspection. That alternative implies the moral difference between "with" and "from" is partly a matter of design, and not only of individual virtue.

Two further considerations complicate learning from AI.

The first is distributive. Capraro, Lentsch, Acemoğlu and colleagues (2024), in an interdisciplinary overview in PNAS Nexus, conclude that generative AI offers personalized learning but may widen the digital divide. Their overview does not resolve the matter. It explicitly identifies critical research gaps and trade-offs that complicate a priori predictions. Even so, whether learning from AI enriches or impoverishes depends partly on who has access to well-designed systems and the guidance to use them critically.

The second concerns the nature of the teacher. Collins (2024), writing from the sociology of knowledge, observes that large language models answer queries with fabrications as fluently as they provide facts. They lack the primary socialisation that grounds human moral understanding, and they are only retrospectively aligned through human intervention. He warns of the danger of AI "socialising us to align with them rather than vice-versa." Learning from a human teacher is also an initiation into a community of judgment. Learning from a machine offers the content of such initiation without its social substance, an issue that bears on whether machines can participate in traditions of inquiry at all.

Outsourcing learning to AI is a categorically different matter.

Recent scholarship draws a useful distinction between cognitive offloading and what some researchers call cognitive surrender. The review of AI-overdependence and human cognitive decline in Computers in Human Behavior Reports sets out the contrast. Cognitive offloading involves the strategic outsourcing of a narrow, well-defined task while the reasoner retains the executive cognitive process. Generative AI enables a qualitatively different pattern, in which the user adopts an AI-generated output as their own answer with minimal scrutiny. In cognitive

surrender the user relinquishes cognitive control rather than delegating a discrete subtask. The moral weight of the distinction lies in what the learner does not build.

The empirical picture is suggestive but must be read carefully. Work synthesised in the review of the negative effects of digital technology on cognition and in the "cognitive paradox" analysis reports a significant negative correlation between frequent AI tool use and critical thinking ability. In these studies cognitive offloading acts as a mediating factor. These findings are correlational. They are consistent with AI use eroding critical thinking, but equally consistent with weaker critical thinkers relying more heavily on AI, and the designs do not settle the direction of influence.

A preprint titled "Faster Completion, Less Learning" reports that generative AI reduced students' study time on mathematics problems and reduced the knowledge those problems build. That is closer to the causal claim at issue, but it awaits peer review and replication.

The overdependence literature also advances a further argument. Cognitive offloading, the illusion of competence, authorship ambiguity, and normalized deference to machine outputs are argued to foster moral abdication and the erosion of ethical self-regulation, particularly in education and knowledge work. This is presented as an argument rather than a demonstrated finding. Still, it identifies why outsourcing is a moral matter and not only a pedagogical one. A student who submits surrendered output as their own is not only less informed. They have also misrepresented their own understanding, a problem pursued further in the discussion of authorship (see Q102).

Aboodi (2025), writing in Educational Theory, sharpens the concern from an unexpected direction. He argues that future generations are increasingly likely to meet situations calling for critical thinking by deferring to AI "without sufficient critical thinking." His case for educational reform deliberately avoids appeals to the final value of autonomy, authenticity or understanding. It rests on outcome-based grounds alone. For any "artificial consultant," even one with a perfect track record, he holds that we could not justifiably assign negligible probability to two scenarios. In the first, it misleads us in high-stakes situations. In the second, human critical thinking would have prevented significantly bad outcomes. Outsourcing critical thinking is therefore imprudent even on the most consequentialist accounting.

The deeper moral question is whether only the final outcome of an action matters, or whether the way one reaches it matters too. Which sorts of thinking are only about the destination, and

which are also about the journey? "Offloading Ourselves" poses the question in roughly these terms, and it is precisely the question that separates the three modes.

A student who outsources an essay to AI may produce a passable text. But that student has forgone the friction through which understanding is actually formed. The broader stakes of removing friction from learning are examined in their own right elsewhere (see Q009).

Friction has a defender in an unexpected quarter. Lim (2026), examining AI-generated apologies, argues that the moral reasons we give for resenting such apologies do not decisively prohibit them. The deeper risk lies elsewhere. Because AI messages aim to "optimize" communication and minimize conflict, the practice threatens our capacity to interpret one another and to perform in ways others can take up. Friction, "while not always pleasant," is in her account vital to understanding one another as authentic subjects. Her argument concerns interpersonal communication, not schooling. The structural parallel is nonetheless instructive: what optimization removes may be exactly what made the activity worth doing.

Timing compounds the issue. Commentary in Educational Evidence on technical education frames tempo as a matter of professional ethics. Introduced too early, before students have acquired the necessary conceptual foundations, AI becomes counterproductive. Giving a calculator to a child who cannot yet multiply undermines mental arithmetic. In the same way, using AI as a shortcut in early learning ultimately holds students back. On this view the same act of delegation may be legitimate offloading for an expert and outsourcing for a novice. The moral classification depends on what the learner already possesses.

Melgaard (2024) presses the journey argument further for one domain. He contends that "there is something inherently immoral about outsourcing moral decision-making in the first place," whether or not the machine decides better or worse. One need not accept his stronger claim that no machine-generated answer could be acceptable merely because a machine generated it. His position nonetheless marks the far end of a spectrum on which some activities are constituted by the agent's own performance of them.

What remains genuinely contested is the nature of the loss in outsourcing. One view treats it as only instrumental: a failure of self-interest, since the learner ends up less competent. Another holds that it also involves a form of self-betrayal with broader ethical implications.

"Offloading Ourselves" supports the second reading. It holds that the embodied, experiential know-how typified in craftsmanship is deeply formative of thought and character. The assembly line dissected craftsmanship into isolated, repeatable activities. In the same way, algorithmic reasoning can decompose cognitive expertise into separate skills to be automated or outsourced. On this view, outsourcing learning is not merely unwise. It shapes what kind of thinker, and ultimately what kind of person, one becomes. That claim connects the present question to the virtue-ethical tradition's concern with habituation (see Q258).

The positions can be set out plainly.

Aboodi (2025) shows that a strong case against outsourcing critical thinking can be made on outcome-based grounds alone. His argument means the instrumental reading is not weak.

Melgaard (2024) occupies the opposite pole, at least for moral reasoning. On his view the wrong lies in the outsourcing itself, independent of outcomes.

Höfer (2026), writing on AI and quality of life, takes a middle position. He argues against envisioning AI as a path to perfection. He favours designs that value imperfection and relationality, so that AI expands rather than diminishes the possibilities for a good life. That orientation fits a moral distinction drawn by degree and context rather than by blanket prohibition.

The empirical state of play also deserves candour. The evidence for catastrophic cognitive harm from AI use remains, as of current research, more theoretical than empirically settled. The "cognitive paradox" analysis and the review of digital technology's cognitive effects both suggest the same asymmetry. The quantitative evidence for enhancement is currently far more substantial and systematically documented than the evidence for cognitive dependence. Dependence often remains an identified risk or a theoretical concern. Taken together, the correlational findings and early experimental work do not yet establish that outsourcing degrades capacity at scale, and the size of any such effect remains unclear.

The moral case for preserving the journey of learning does not depend on empirical proof of harm. It rests on an older claim: that the struggle to understand is itself constitutive of intellectual character, not merely a means to it. If that claim is right, the three modes differ morally even where their measurable outputs converge. Learning with AI exercises that

character. Learning from AI can either exercise it or let it lapse. Outsourcing learning to AI declines to form it at all.

Q102 If a machine can produce an original-seeming idea, what remains of the concept of authorship in student work?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

What remains of authorship in student work, once a machine can produce an original-seeming idea, is a more demanding concept rather than a diminished one: authorship as intentionality, accountability, documented intellectual process and independence of thought, not the bare production of novel strings of text. Generative AI has unsettled authorship in a way no earlier classroom technology did. Calculators did not threaten the authorship of a mathematics solution, because the student still chose the method and set up the problem. Spell-checkers did not threaten the authorship of an essay, because they corrected surface errors without proposing claims.

Generative systems are different in kind. They produce text that is fluent, well structured and responsive to a prompt, and so they appear to perform the very act that authorship was thought to name. This apparent overlap is the source of the anxiety, and it explains why assessment, academic integrity policy and the theory of writing have all been drawn into the debate at once. Writing on the future of student writing in the British Journal of Educational Technology treats authorship as the concept at stake, not merely cheating. A systematic critical review of

generative AI in education records a similar breadth of concern, running from assessment design to institutional governance.

The answer developed here is that this pressure exposes what authorship always involved. It was never only a fact about who typed the words. It was a set of claims about who decided, who is answerable and who did the thinking. Generative AI makes those claims explicit, and it forces educators to verify them rather than infer them from the finished text.

The philosophical starting point is that authorship was never simply the fact of having produced a text. In his 1969 lecture "What is an Author?", Michel Foucault argued that the author is not a solitary creative genius. Instead, the author is a "functional principle", an author function through which societies classify, regulate and assign responsibility to discourse. The author function determines which texts are attributed to whom, how they are read and who is held accountable for them. On this view, "who wrote this?" is not primarily a question about the mechanics of production. It is a question about the social, legal and institutional arrangements that make a text meaningful and answerable.

Work applying this framework to machine-generated text has extended the point in a specific direction. The essay "What Is an Artificial Author?" in Poetics Today (2024) asks whether the category of author can stretch to systems that generate literary-seeming output. A 2025 analysis of Foucault's author function and AI-generated discourse argues that fluent machine prose does not make the author function disappear. Rather, the function is redistributed and renegotiated. On that argument, the label "AI-generated" is itself an author function: a new institutional category for classifying and managing discourse that no single human has fully produced.

These accounts converge on a conclusion with direct consequences for schools and universities. Authorship cannot be established by inspecting the text alone. It has to be established by examining the process, the intentions and the responsibilities that surround the text. Whether a machine can genuinely take part in the practices that give authorship its point, or can only imitate their outputs, is a deeper question taken up elsewhere (see Q106). For present purposes, the Foucauldian reading shifts attention from the artifact to the arrangements around it.

If authorship cannot be read off the text, can it at least be detected in the text? A growing technical literature attempts exactly this, and the evidence is best described as contested. An Education Sciences study (2026) on AI-generated text and the challenge of detecting student authorship frames the detection problem as a direct threat to authorship verification.

Mani and Arulanandam (2026) propose a stylometric machine-learning framework for attributing authorship between ChatGPT and student writers. Their test material was short-story adaptations written by non-native German language students. The corpus is small: 60 texts, of which 30 were written by students and 30 were generated by ChatGPT from the same source stories. Work of this kind demonstrates that stylistic differences between student and machine prose can be modelled under controlled conditions. It remains unclear whether such classifiers generalise beyond a single genre, a single language-learner population and a single model version. It is also unclear whether they would withstand students who edit, paraphrase or blend machine output with their own writing.

Related work complicates the assumption that machine output is recognisably inferior. Alkhofi (2025) compared English-to-Arabic translations by 20 Saudi university students of English and Translation with Google Translate versions of the same texts. Both sets were rated by 22 professors with experience in language-related fields. The study was motivated by educators' persistent scepticism about machine reliability. Its design makes the underlying question explicit: experienced readers are being asked to judge human and machine work side by side, without assuming the human version is better.

The philosophical implication is the same one the Foucauldian analysis reached by a different route. Even a perfect detector would answer only whether a machine produced certain words. It would not answer whether the student exercised judgment, took responsibility or understood what was submitted. Detection can be one input to an integrity process. It cannot carry the whole weight of the concept of authorship, and the reliability of current tools is disputed enough that it should not be asked to.

Empirical research on how students and faculty actually use generative AI supports the process-based reconception. A Frontiers in Education study of faculty perceptions (2025) works with a typology of four modes of human-AI collaboration. AI as instrument covers tasks such as grammar checking and formatting. AI as collaborative partner covers brainstorming and structuring. AI as proxy actor means delegating core cognitive work, such as writing a literature review, with minimal human transformation. AI as generative ecosystem describes a non-linear workflow in which human agency is distributed throughout.

Faculty judgments track this typology. Practices with minimal student contribution are judged most severely. Practices that involve student verification, editing and explicit acknowledgment

are judged significantly more ethical.

The finding matters because it shows that academic judgment has not concluded that AI use in itself negates authorship. Instead, authorship is being redefined around the student's cognitive contribution and the honesty of their account of it. A student who uses AI as an instrument and discloses it remains an author. A student who delegates the entire intellectual task and presents the output as their own has committed what recent work calls "AI-giarism" or "cyber-pseudepigraphy". This is a new form of misconduct. It is not identical to traditional plagiarism, because no identifiable human source has been copied, but it is continuous with plagiarism in misrepresenting where the work came from.

Students' own understandings are only beginning to be documented. Savvidou (2026) studied how undergraduates negotiate authorship, responsibility and learning in GenAI-assisted writing. The participants were enrolled in two sections of an academic writing course at an English-medium university in Cyprus. The qualitatively driven mixed-methods design drew on 55 written reflections on GenAI use while completing a research paper and 27 anonymous post-course questionnaire responses. The study's framing is significant: it treats authorship as something students actively negotiate rather than a rule they simply obey or break. Because the sample comes from a single institution and course, it shows how such negotiation can look but cannot establish how widespread any particular student stance is.

Taken together, the faculty and student evidence suggests a shared, if still unsettled, intuition that the line falls at transformation and acknowledgment. Neither strand settles exactly where that line lies, and the evidence remains limited to a small number of institutional settings.

What, then, survives the arrival of original-seeming machines? Four elements of authorship remain, and each points to a distinct educational practice.

The first is intentionality. A text is authored when the writer intends to make a claim, take a position or express a judgment. AI systems have no such intentions; they generate text that is statistically plausible. The student's authorship lies in the choices they make about which claims to advance, which evidence to credit and which conclusions to defend. It also lies in their willingness to stand behind those choices. This is why disclosure requirements are philosophically coherent rather than bureaucratic formalities. Disclosure is the mechanism by which intentionality is made visible.

The second is accountability. Foucault's author function is, at bottom, a device for assigning responsibility, as the 2025 analysis of the author function in AI discourse emphasises. A student who submits work is answerable for its truth, its reasoning and its provenance. An AI system cannot be held to account in this way: it cannot be questioned about its sources, defend its claims or revise in response to criticism. A student who submits untransformed AI output is attempting to escape the accountability that authorship entails. The concept survives precisely because someone must be answerable for the text.

The third is process and labour. Research on academic integrity consistently finds that acceptable and unacceptable AI use are distinguished by genuine intellectual work around the machine's output: reading, evaluating, synthesising and revising. The British Journal of Educational Technology study of authentic assessment reaches this conclusion as well. On this account, authorship is not the production of a final artifact but the conduct of an inquiry, and the artifact counts as authored insofar as it is the residue of that inquiry. The pedagogical consequence is a shift in assessment from final products to processes, using drafts, annotations, oral defence and reflective accounts of how the work was produced.

Research on authorship that predates generative AI supports treating authorship as a pedagogical value, not merely a regulatory one. Lammert, Hand and Warren (2025) studied three second-grade teachers. They examined how generative practices, oriented to producing knowledge, and replicative practices, oriented to reproducing it, shaped the multimodality of children's science writing. Their framing draws on prior research indicating that knowledge-generating environments encourage students to use their linguistic and cognitive resources and build representational fluency. They also note that few such studies exist with early childhood learners. The relevance here is the underlying principle: authorship matters educationally because generating ideas is itself how learning happens (see Q002).

The fourth is originality in the strong sense. This means independence of thought, not novelty of expression. A machine-generated idea is original in the weak sense that it is new to the reader. The educational value of authorship lies in the strong sense, in which the student has reached the idea through their own reasoning and can therefore develop, defend and apply it. A machine-generated idea that the student cannot explain, defend or extend is not the student's idea, however original it appears.

The practical implication is that institutions are converging on a governance model that is neither prohibition nor laissez-faire, though the convergence is incomplete. Blanket bans are widely judged inadequate for two reasons: they are unenforceable, and they fail to teach students how to engage critically with AI. Both the systematic critical review and the study of authentic assessment reflect this judgment.

The emerging alternative is educative. It involves three commitments: teaching students the spectrum of AI use, requiring transparency about how AI was used, and designing assessments that make the student's cognitive contribution visible.

Ip and Green (2026) offer a theoretical articulation of this middle path from student leadership education. They propose a third orientation beyond the familiar poles of embrace and resistance, centred on a reciprocal holding environment as the condition for genuine formation. Their guiding question, "what remains distinctly ours to think", is close to the question of authorship itself. Teachers facing the immediate problem of a suspected AI-written submission need procedures grounded in this educative stance rather than in detection alone (see Q147).

This model is not free of risk, and that risk deserves plain statement. Process-based assessment and disclosure regimes place new demands on students, and those demands may not fall evenly. Hadar Shoval (2025) examined the differential effects of AI-based tools on first-generation and minority students in an introductory psychology course at a peripheral college. The study combined surveys (n = 110), 20 semi-structured interviews selected to reflect class diversity, and the lecturer's reflective journal. Its premise is that AI's effects in higher education may bridge or widen gaps between student populations. Whether demonstrating authorship through process favours students already fluent in academic self-presentation remains unclear, and policy should be designed with that uncertainty in view.

The resulting position is a reassertion of authorship under new conditions, not a retreat from it. Authorship in student work remains, but it is now understood as something that must be demonstrated rather than assumed, and the burden of demonstration falls on the student. The machine's capacity to produce original-seeming ideas does not dissolve authorship; it relocates it. Authorship was always a social and institutional achievement, and generative AI has made that visible. What remains is the student's intentionality, accountability, process and independence of thought. The educational task is to build assessment and integrity practices

that make these qualities visible, fairly and for every student, in a world where the text alone can no longer prove them.

Q103 Does AI change what it means to be educated, as distinct from being skilled or informed?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

AI does not change the goal of education, but it does change what being educated means in practice, because it forces into the open a distinction that was always there: being educated is not the same as being informed or skilled. A person can be informed, in possession of facts, and skilled, able to perform tasks, without being educated in the fullest sense. The educated person, in the tradition that runs from Humboldt's Bildung through Dewey and beyond, has been formed. Such a person can judge, evaluate, situate knowledge within a wider understanding, and act wisely. For most of modern history this distinction could remain somewhat abstract. Information was scarce and skill was costly to acquire, so their possession could serve as a rough proxy for education itself. Generative AI removes that proxy. It can inform and perform at scale, quickly and cheaply, and so it presses the question of what education is for once its instrumental outputs are available on demand.

Recent philosophy of education has taken up this question directly. The symposium on philosophy of education in the age of artificial intelligence in Educational Theory, together with broader treatments of the philosophical questions AI poses for the classroom, frames the issue as more than a matter of tools. AI unsettles inherited assumptions about knowledge, authority

and the purposes of schooling. UNESCO's analysis of the disruptions, dilemmas and directions AI brings to education makes a similar point at the level of policy: the technology does not simply speed up existing practice but obliges systems to restate what they are trying to achieve. The argument that follows is that AI sharpens the distinction between education and its instrumental by-products rather than dissolving it, and that this sharpening carries consequences for curriculum, assessment and the relationships through which people are formed.

The first consequence is that AI makes the old equation of education with information transmission untenable. If being educated meant having access to information, every student with a connected device would rank among the most educated people in history. That this is plainly false shows that education was never primarily about possessing information. The scarcity of information hid the point; its abundance reveals it. The related question of whether human knowledge loses or changes its value once it is no longer scarce (see Q003) bears directly on this argument. Knowledge does not become worthless, but its educational value shifts from possession toward use, interpretation and judgment.

AI can inform, and it can make a person skilled in the limited sense of enabling them to perform a task. What it cannot do is form a person: develop their judgment, their capacity for discernment, and their sense of what matters and why. UNESCO's work on AI and the futures of education states this explicitly. The purpose of education is human flourishing, not merely the acquisition of knowledge or skills. On UNESCO's account, flourishing requires an enabling environment in which students develop agency, take part in meaningful relationships and learn to make sense of the world. These processes are relational, and they cannot be handed over to a machine. A system that delivers correct answers, however fluently, does not supply agency, relationship or sense-making. At most it provides material on which those capacities can work. UNESCO's companion analysis of AI's disruptions reaches the same conclusion from the other direction: the more capable the systems become at producing educational outputs, the more pressing it is to say what education offers beyond them.

The philosophical tradition offers a precise vocabulary for this distinction in Aristotle's contrast between technē and phronesis. Technē is instrumental capability, the knowledge of how to make or do something. Phronesis is practical wisdom, the capacity to judge what is appropriate in a particular situation, grounded in lived experience and ethical reflection. Aristotelian readings of AI in education draw this contrast sharply. AI systems are, at their best,

extraordinary instruments of technē: they produce, calculate, summarise and perform. The educated person, by contrast, is distinguished by phronesis, the ability to know when a tool should be used, what its outputs are worth and which ends are worth pursuing. An education that trains students to use AI well but does not develop their capacity to judge its outputs would produce skilled operators, not educated people. This is the deepest sense in which AI changes what it means to be educated: it makes the gap between skill and judgment both visible and urgent. Virtue ethics has more to say about how much assistance is compatible with intellectual and moral development (see Q258).

Professional education, where the stakes of judgment are concrete, supplies an instructive parallel. Schaye and colleagues (2026), proposing a theory-informed redesign of clinical reasoning education for the generative AI era, separate diagnostic reasoning, which classifies a patient's condition and assigns a label, from management reasoning, which weighs several defensible plans in light of patient preferences and contextual constraints. They observe that clinical reasoning education has historically stressed "in-the-head" processes such as hypothesis generation and differential prioritisation over "out-in-the-world" processes such as navigating systems, using tools and managing care across professions. The structure of their argument mirrors the technē–phronesis distinction. Classification is precisely the kind of task AI can increasingly support, whereas weighing defensible options against a particular person's values is closer to practical wisdom. Their proposal is a redesign rather than an outcome study, so it shows how one field is reframing competence, not that the reframing works.

Quinn (2026), writing on dental education, sets out three possibilities: learners may be upskilled, differently skilled or never skilled. He draws on medical education's concern with AI-induced "never-skilling," in which learners fail to develop core reasoning because AI repeatedly does the cognitive work that competence development requires. Quinn notes that frameworks for guiding AI use while protecting foundational competence remain underdeveloped. His taxonomy matters philosophically because it shows that "skilled" is itself ambiguous. Someone who can produce competent output with AI may be upskilled, differently skilled, or may never have acquired the underlying capacity at all.

The empirical literature on critical thinking in the AI era tends to support this philosophical point, although the evidence is still developing. Research on cognitive offloading indicates that when students delegate reasoning to AI, they risk losing the capacities education is meant to build, including synthesis, reflection and metacognition. The educated person is not simply

someone who can obtain answers but someone who can evaluate them: who can tell fluency from comprehension, identify the assumptions behind a claim and monitor their own reasoning. The philosophical tradition of critical thinking, as surveyed in the Encyclopaedia Britannica's treatment of philosophy of education, has long held these dispositions to be central aims of education rather than optional extras. The current evidence suggests that such metacognitive capacities have to be deliberately cultivated, or they will weaken.

The strength of that evidence should not be overstated. The never-skilling concern Quinn (2026) describes is presented as a risk that warrants curricular and governance responses, not as a measured effect. Much of the research on student AI use also captures behaviour at a single point in time. Polyportis (2024) argues that a more holistic, longitudinal approach is needed to understand how students' ChatGPT adoption changes over time, and that actual usage behaviour should be measured rather than inferred. That methodological point bears on the question of education. Whether offloading erodes judgment, or whether students learn to use AI more critically as their experience grows, cannot be settled by cross-sectional snapshots. How sustained AI use affects the formation of judgment therefore remains unclear. Some accounts treat AI as a scaffold that frees attention for higher-order thinking, while others treat it as a substitute that hollows that thinking out, and the literature has not yet resolved the disagreement.

What can be said with more confidence is normative rather than empirical. Education in the AI era has a new core task: teaching students to treat AI as a cultural artefact, powerful, biased and in need of scrutiny, rather than as an oracle. This task does not depend on settling the offloading debate. It follows from the account of the educated person as someone who evaluates rather than merely receives.

None of this means that knowledge and skill have become irrelevant. The educated person needs more knowledge, not less, to evaluate AI output, but that knowledge now serves discernment rather than display. One must know enough to recognise when a machine's fluent answer is wrong, when its sources are dubious and when its framing conceals a value judgment. In this sense AI changes the balance of education: the emphasis moves from acquiring and reproducing knowledge to evaluating and using it. How the human relationship with truth changes when answers are generated rather than discovered (see Q005) is part of the same shift. The OECD's work on education for human flourishing makes a related argument. Education must cultivate the whole person, across cognitive, social and ethical dimensions,

because the capacities that matter most for a flourishing life are precisely those that machines cannot provide.

The social and ethical dimensions are more than rhetorical additions. Klimova and Pikhart (2025), in a mini-review of AI's effects on student and academic well-being in higher education, find a mixed picture. The studies they synthesise report benefits such as personalised learning, mental health support and more efficient communication, alongside concerns about digital fatigue, loneliness, technostress and reduced face-to-face interaction. As a mini-review of a literature the authors describe as underexplored, it identifies themes rather than establishing effect sizes. Still, the pattern it reports is consistent with the philosophical worry that efficiency gains may come at the expense of the relational conditions in which formation takes place.

The dialogic tradition in philosophy of education, from Buber to Freire, gives this worry its fullest expression. Education is not the transfer of information from one container to another. It is a relationship in which a person is recognised as a subject and called to become more fully themselves. AI can simulate dialogue, but it cannot offer the recognition, the challenge and the care that a teacher offers. The educated person is formed in encounter with teachers, peers, texts and the world. For this reason, the question of what it means to be educated cannot be answered by pointing to what AI can do. It is answered by asking what a human being can become.

The practical consequence is that schools should resist defining educational success in terms of what AI can measure or produce. If assessment rewards only outputs that AI can generate, education will drift toward producing those outputs, and the distinctively human capacities of judgment, discernment, wisdom and care will be squeezed out. Schaye and colleagues' (2026) call to reweight clinical reasoning education toward contextualised, "out-in-the-world" processes, and Quinn's (2026) attention to assessment and governance as safeguards against never-skilling, both point in this direction within their professions. UNESCO's policy analysis supports the same conclusion for education systems generally.

This reorientation depends on teachers who understand both the technology and the purposes it should serve. Mah and Groß (2024), surveying 122 university faculty members, found that respondents saw greater equity in education as AI's greatest benefit. Students' and faculty members' lack of AI literacy ranked among the greatest challenges, and the majority of

respondents were interested in professional development. The sample is modest and comes from higher education, so it cannot be generalised to schools. Even so, it suggests that the people charged with forming judgment in others often feel underprepared to exercise it about AI themselves. AI literacy, understood not as operational fluency but as the capacity to judge the place of these tools in learning, is part of what the educated teacher now needs.

The educated person in the AI age is not the one who uses AI best but the one who can decide, with good judgment, what is worth knowing, what is worth doing and what is worth being. AI changes the conditions under which that formation happens, but it does not change its end. If anything, it makes the end clearer: education is what remains when information and skill are available on demand. Being educated was never the same as being informed or skilled, and AI makes this visible by supplying information and skill at scale. The educated person is distinguished by judgment, discernment and formation, capacities developed through relationship, reflection and practice that no machine can confer. Educators in the AI era are therefore called to cultivate those capacities deliberately and to resist reducing education to the production of machine-verifiable outputs.

Q104 What obligations does a society have toward knowledge that no human any longer holds unaided?

13 citations · 13 sources · 5 cross-references

Claim 1 emerging

A society that holds knowledge no human any longer holds unaided takes on six obligations. It must preserve the human capacity to understand and check that knowledge. It must keep

machine-held knowledge verifiable through provenance, independent verification and accountability. It must teach the skills that make such knowledge usable rather than merely accessible. It must distribute both access and evaluative capacity fairly. It must keep the institutional means to reconstruct the knowledge if the machines fail. And it must be honest about what is machine-held and what is human-held.

The phenomenon these obligations answer is not new in kind, but it is new in character. Libraries, archives and databases have long held knowledge that no single person carries. What they held, however, was knowledge that humans wrote and that any human could in principle read. A generative AI system holds something different: answers that no human has ever articulated, synthesised on demand from statistical patterns in its training data. When a society's knowledge infrastructure includes systems that produce answers no human has verified and no human can fully reconstruct, the older ethics of the library is no longer sufficient.

Bui (2026) gives this shift a historical frame. Drawing on Peirce, James and above all Dewey, he argues that the modern transmission model of schooling rested on the scarcity of knowledge. AI dissolves that scarcity, Bui contends, and in doing so reopens the deepest question about what education is for (see Q003). His article is an extended philosophical argument rather than an empirical report, and it should be read as such.

Akinwalere and Chang (2026) approach the same terrain from knowledge management. Their systematic literature review describes a symbiotic relationship between AI and human intelligence that is reshaping the wider knowledge ecosystem. They also acknowledge that the mechanism underlying this effect is still unclear. That admission matters: the obligations set out below are proposed under real uncertainty about how human and machine knowing will interact over time.

The first obligation is to understand what is being lost. Research on cognitive offloading, meaning the use of external tools to reduce the cognitive demands of a task, documents a robust pattern. When people believe information will remain reliably available outside their own heads, they are less likely to encode it internally.

Sparrow, Liu and Wegner (2011) described this as the "Google effect." Their participants tended to remember where information could be found rather than the information itself. The finding has been influential, though later replication efforts have been mixed, and it is best treated as indicative rather than settled.

Risko and Gilbert (2016) offer the more durable theoretical contribution. Their synthesis frames offloading as a value-based decision. People offload when an external system is reliable, and they stop offloading when it is not. The implication for AI is sobering. As AI systems become more fluent and appear more reliable, people will offload more. What they offload may include the very capacity needed to evaluate the system's own outputs.

More recent work extends this concern directly to AI. The 2025 review in Frontiers in Psychology examines how AI-driven offloading may be transforming learning and memory. A second analysis asks whether AI produces cognitive offloading or cognitive overload, and how it alters the mental architecture people use to cope with demanding tasks. That framing is a useful reminder that the effects need not run in one direction. Delegating some tasks to AI may relieve working memory, while managing, prompting and checking the system may impose demands of its own.

These AI-specific studies are recent. Their long-term implications remain unclear, and they should not be read as establishing durable harm.

Even so, the prudential conclusion stands. A society that builds its knowledge infrastructure on AI must take deliberate steps to keep the human capacity to understand, verify and reconstruct that knowledge from atrophying. This is not nostalgia for a pre-digital past. AI systems are known to hallucinate, to absorb the biases of their training data and to fail silently. A society that cannot check its own knowledge systems is exposed to all three failures.

The second obligation is epistemic: to maintain the conditions under which machine-held knowledge can be verified. Knowledge that no human holds unaided is not thereby unreliable. Its reliability simply has to be established by other means, and three such means are indispensable.

The first is provenance: records of where the knowledge came from, what data it rests on and how it was produced. The second is verification: independent checks against sources that are not the system itself. The third is accountability: identifiable people or institutions who answer for the system's outputs.

The emerging technical standards for content provenance, watermarking and signed credentials are attempts to meet this obligation. They are only as good as the institutions that enforce them.

A watermark no one inspects, or a credential no authority stands behind, offers the appearance of verifiability without the substance.

The deeper point is that a society cannot delegate its epistemic responsibilities to a machine. The obligation to know, in the sense of being able to say why a claim is true, remains human even when a machine produces the claim. This connects to a broader shift in the human relationship with truth when answers are generated rather than discovered (see Q005).

Akinwalere and Chang's (2026) account of a symbiotic AI–human knowledge ecosystem is compatible with this view. Symbiosis is not abdication. In any healthy symbiosis each partner keeps a function the other cannot perform, and in this case the human function is the one that confers answerability.

The third obligation is educational: to teach the skills that make machine-held knowledge usable rather than merely accessible. Students who grow up surrounded by always-available answers need what might be called "open-but-verify" practices. They should use AI output as a starting point, check it against independent sources and be able to reconstruct the reasoning behind it.

The Educational Psychology Review synthesis of cognitive offloading and learning helps explain why such practices matter. Offloading is not inherently harmful. Its effect on learning depends on whether the offloaded process is one the learner needs to master.

Evidence suggests that metacognitive training can preserve, and perhaps strengthen, the capacities that offloading threatens. Such training teaches students to monitor their own understanding, notice gaps and verify claims. A 2026 study in Frontiers in Psychology adds a psychological mechanism, treating cognitive self-efficacy as a mediator between digital tool use and critical thinking. Because that relationship is mediational and correlational, it does not show that building self-efficacy causes better critical thinking. It does suggest that learners' confidence in their own reasoning is part of what distinguishes productive from passive tool use.

Whether teachers are ready to deliver this education remains an open question. Yue, Jong and Ng (2024) surveyed 1,664 K–12 teachers about their technological pedagogical content knowledge (TPACK) readiness and their attitudes toward teaching AI. They note that limited research had previously addressed teachers' preparedness. Merzifonluoglu and Gunes (2025)

studied 389 Generation Z pre-service teachers at two state universities. They combined the General Attitudes to Artificial Intelligence Scale with a survey on AI-assisted decision-making, followed by semi-structured interviews, to ask who "holds the reins" when future teachers decide with AI tools. That question is precisely the one an open-but-verify curriculum must answer in practice.

Survey work with learners points the same way. Kharroubi and colleagues (2024) studied the knowledge, attitudes and practices of 457 university students in Lebanon. ElKhyatt, Hijab and Al-Thani (2026) surveyed dental hygiene students and alumni in Doha, using the Attitude Toward AI Scale to assess acceptance and fear and to identify educational needs. Both studies are cross-sectional and context-specific, so they describe rather than evaluate. Still, they suggest that learners' knowledge of and stance toward AI vary in ways a curriculum cannot assume away.

A society that takes its knowledge obligations seriously will build these skills into the curriculum at every level, not as an add-on but as a core competence. What remains unclear is how to do this at scale and with what results. These studies characterise readiness and attitudes; they do not test interventions.

The fourth obligation is distributive: to ensure that knowledge held by machines is accessible to all, not only to those who can pay for the best systems. Knowledge that exists only in machine-held form creates a new divide between those who can query the system and those who cannot.

A subtler divide separates those who can evaluate the system's outputs from those who must take them on trust. Equity here is not merely a matter of devices and connectivity. It concerns the capacity to use machine-held knowledge without being dominated by it.

This is a question of epistemic justice. The ability to take part in one's society's knowledge economy should not depend on the ability to pay for the most capable AI. Part of this burden falls on the companies whose systems reshape education without necessarily serving it (see Q020).

The fifth obligation is preservative: to maintain the human and institutional capacity to reconstruct knowledge if the machines fail, are withdrawn or are captured. This is the archival obligation. Libraries and archives have always kept multiple copies of important knowledge, and the AI era requires an analogous practice. That does not mean storing all knowledge in

human heads. It means maintaining the expertise, the records and the institutions that could reconstruct it.

The concern draws on Michael Polanyi's account of tacit knowledge, the knowing we cannot fully put into words. A discussion of Polanyi and the limits of AI expertise identifies what is often called the pipeline problem. When entry-level cognitive work is automated, the apprenticeship structures through which tacit expertise passes between generations are disrupted. The result is a long-term erosion of institutional competence.

The source is an essay rather than empirical research, and the strength of the effect remains unclear. The logic is nonetheless difficult to dismiss. Tacit expertise is acquired by doing, under guidance, the routine tasks that automation removes first. A society that automates its knowledge work without maintaining this pipeline is consuming its intellectual capital rather than living on its income. The distinction between holding knowledge and understanding it bears directly on what can and cannot be preserved in machine form (see Q004).

The sixth obligation is honesty: to be clear about what is machine-held and what is human-held. The indistinguishability of AI-generated content from human-authored content is not merely a technical problem; it is an epistemic hazard.

A claim, properly understood, is something for which someone is answerable. When a society cannot tell whether a claim was produced by a person who stands behind it or by a machine that stands behind nothing, the very concept of a claim is eroded. The obligation to label, to disclose and to maintain provenance is therefore not a bureaucratic nicety. It is a condition of epistemic integrity, and it underwrites the verification and accountability described above.

The six obligations together are these. Preserve the human capacity to understand and verify. Maintain provenance, verification and accountability for machine-held knowledge. Teach the skills that make such knowledge usable. Distribute access and evaluative capacity fairly. Keep the institutional capacity to reconstruct knowledge if the machines fail. Be honest about the origin of what is known.

The evidence behind them is uneven. The basic dynamics of cognitive offloading are well documented. Their AI-specific consequences, teachers' readiness and the effectiveness of educational responses are still emerging.

Bui's (2026) argument offers a fitting frame. If AI ends the scarcity on which transmission-model schooling rested, education does not lose its purpose; that purpose has to be restated. These obligations are not arguments against AI. They are the conditions under which a society can use AI without surrendering its epistemic self-government.

Q105 Is curiosity a trainable capacity, and what does current evidence say about whether answer-on-demand technology weakens or strengthens it?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

Curiosity is best understood as a trainable capacity rather than a fixed endowment. Whether answer-on-demand technology weakens or strengthens it depends less on the technology than on how the learning environment around it is designed. This answer runs against a durable folk psychology that treats curiosity as a personality trait, something a child either has or lacks. Parents and teachers often speak of the 'naturally curious' student as though the quality were settled at birth. Contemporary research and policy frameworks have moved decisively away from that picture, even though the trait dimension has not disappeared entirely.

Two strands of work anchor the revised view. The OECD's Learning Compass 2030 treats curiosity as a transformative competency, one of the constructs that education can deliberately develop rather than merely select for or celebrate. That framing matters philosophically for a chapter asking why we educate. If curiosity is a competency, then cultivating it becomes a legitimate aim of schooling in its own right, not a happy precondition that some learners bring with them. The second strand is psychological. Reviews of the mechanisms of curiosity and

information seeking, such as the synthesis published in PMC, converge on the view that curiosity behaves much like a malleable motivational state. It rises and falls with context, with what the learner already knows, and with the perceived value of what remains unknown. The same review grounds much of its account in the information-gap theory: curiosity is the motivating experience of a gap between what one knows and what one wants to know. That definition becomes central once we ask what happens when a machine can close such gaps instantly.

The philosophical stakes follow from this. If curiosity is malleable, then educational environments shape it whether or not they intend to. Every tool admitted to the classroom becomes, in effect, part of a curiosity curriculum, and the arrival of answer engines is a question about pedagogy before it is a question about technology.

The evidence that curiosity can be cultivated comes from several directions. Each is persuasive in its own way, though each also has limits.

The most direct evidence comes from intervention research. A 2024 study, posted on arXiv, trained primary school children in specific metacognitive skills: identifying uncertainty, formulating educated guesses, seeking information, and monitoring progress. Training these skills significantly improved the children's curiosity-driven questioning and their metacognitive sensitivity. The intervention was not a vague exhortation to 'be curious'. It decomposed curiosity into teachable procedures and taught them. This suggests that at least the behavioural expression of curiosity, the asking of good questions, responds to instruction. It should still be read as emerging evidence from a specific age group and setting rather than as a demonstrated general law.

A second line comes from the learning-progress literature. Work by Oudeyer and colleagues, published in Nature Communications in 2021, shows that curiosity is regulated by the rate of learning itself. Learners are most curious about material that is neither too easy nor too hard, the zone in which they can perceive themselves making progress. Environments that let learners monitor their own progress sustain curiosity better than environments that impose fixed difficulty. This finding links curiosity to feedback design: curiosity is trainable partly because its fuel, the experience of progress, can be engineered into a learning environment.

A third line moves from the individual to the group. A 2025 study in npj Science of Learning used Bayesian network analysis of classroom discourse to identify what its authors call a 'social

chain of curiosity'. Individual expressions of curiosity spark curiosity in peers. Teachers can deliberately stimulate the chain by conveying information, by responding positively to questions, and by reiterating student ideas with an element of uncertainty. That last move is subtle. A teacher who restates a student's idea as an open possibility, rather than confirming or correcting it, keeps the gap open for the whole class. Curiosity, on this evidence, is not only trainable in individuals but cultivable in social systems.

Taken together, these strands point in the same direction, though they rest on different methods and populations. The convergence is encouraging. The individual findings are recent enough that replication across age groups and cultures remains a priority.

The harder question is what answer-on-demand technology does to this capacity. Here the information-gap framework does real explanatory work. If curiosity is the felt tension of a gap, then search engines narrow that gap quickly. Answer engines narrow it even more radically, because they return a synthesized answer rather than a list of links, and so collapse it almost instantly.

The concern runs through the literature on the 'Google effect' and is sharpened in the 2024 arXiv analysis of answer engines, information gaps and the future of inquiry. When the machine closes the gap between not-knowing and knowing, the motivational engine of curiosity may never be engaged. The user does not need to formulate a good question, tolerate uncertainty, or wander through partially relevant results. The answer arrives, and with it the end of the episode of inquiry. Several studies suggest that habitual reliance on instant answers is associated with reduced memory retention, an 'illusion of knowing', and diminished willingness to engage deeply with content.

These findings need careful reading. Much of the evidence is associational. People who rely heavily on instant answers may differ in prior motivation, workload or expertise from those who do not, so association does not establish that the technology causes the decline. The illusion-of-knowing finding is conceptually plausible and has support. But how large and durable the effect is for school-age learners using generative systems, as opposed to adults using conventional search, remains unclear. Answer engines are also new enough that longitudinal evidence on curiosity specifically is thin. Credible observers therefore disagree. Some read the existing data as an early warning of erosion. Others argue that the data mostly reflect unstructured use, and that the decisive variable is how the tool is used, not whether it is

present. The pattern mirrors debates over AI and motivation more broadly (see Q059), where short-term engagement gains and longer-term disengagement concerns coexist in the evidence.

The evidence does not support a simple story of inevitable erosion. Three qualifications matter.

The first is that the effect depends on the design of the interaction. Research on 'mindful searching', published in Educational Technology Research and Development, shows that when users attempt to generate an answer before querying an engine, their pre-search curiosity is higher and their recall is better. The act of committing to a provisional answer reopens the information gap that the engine would otherwise collapse. It turns the subsequent query into a test of one's own prediction rather than a substitute for having one. The technology weakens curiosity when it is used as a substitute for thinking. It can strengthen curiosity when it is used as a scaffold for thinking.

The second qualification is that the effect depends on the learner's metacognitive skills, precisely the skills the primary school intervention showed to be trainable. Learners who have been taught to identify gaps, generate hypotheses and monitor their own understanding appear to use answer engines differently from learners who have not. They treat the answer as a checkpoint in an ongoing inquiry rather than as its end. The same tool thus produces different outcomes in different hands. This makes training metacognition an equity question as much as a pedagogical one, because the learners least likely to arrive with these skills stand to lose most from unstructured access.

The third qualification is that curiosity is not a single thing. Reviews of curiosity mechanisms distinguish epistemic curiosity, the desire for knowledge, from diversive curiosity, the desire for stimulation or relief from boredom. Answer-on-demand technology may suppress the former while feeding the latter. Endless scrolling and querying can feel like curiosity while being its opposite: a rapid succession of closed gaps, none held open long enough to motivate understanding. Measures that count queries or clicks as 'engagement' can therefore mistake diversive activity for the epistemic kind education aims to cultivate.

This distinction has a close parallel in debates about AI translation in language learning (see Q242). There, too, the same tool can either support acquisition or quietly substitute for it, depending on whether the learner does the cognitive work first.

Recent higher-education research adds a complementary point that the information-gap debate tends to obscure. The relationship between curiosity and technology may run in both directions. Curiosity is not only something technology acts upon; it may also shape who adopts a technology and how they use it.

Schutte and Li (2025), writing in the International Journal of Educational Technology in Higher Education, examined how self-efficacy for using AI, curiosity, and reported AI use are connected among university students. Their sample of 123 students was unusual in profile: the mean age was 37.83 years (SD = 20.64), and 88 participants were women. The study is correlational and modest in size, and the age distribution limits generalisation to typical undergraduate or school populations. Its value for this chapter lies in its framing. It treats curiosity as a factor associated with whether students engage with AI at all, not merely as an outcome AI might damage.

Doz and colleagues (2024), in TechTrends, approached a related question from the teacher's side. They analysed the responses of 324 educators from Europe and Eurasia with a boosting classification machine-learning algorithm, asking how demographic factors and attitudes toward virtual reality influence educators' curiosity to learn about VR in education. The technology differs from answer engines. The underlying point still transfers: teachers' own curiosity about emerging tools varies systematically and is shaped by attitudes, which bears directly on whether they will model questioning or passive acceptance in their classrooms.

Quintanilla Villegas and Pineda Rivas (2026), in Frontiers in Education, used CHAID (Chi-square Automatic Interaction Detection) to map relationships among the motivations, consequences and concerns that university students perceive in their use of AI. Their analysis shows that students hold motivations and concerns about AI at the same time, a reminder that learner attitudes toward these tools are not uniformly enthusiastic or uniformly anxious.

Arab and colleagues' 2026 narrative review of AI in public health education, which synthesised 21 publications, observes that formal AI literacy training in academic programmes remains lacking. If the metacognitive skills that determine whether an answer engine supports or supplants curiosity are trainable, this gap in structured preparation is consequential.

None of these studies measures curiosity change over time under answer-engine use. Their contribution is to complicate the causal arrow and to show how thin the evidence base remains.

The educational implication is that the question 'does answer-on-demand technology weaken or strengthen curiosity?' is misspecified. The technology is a tool, and the outcome depends on the environment in which it is used. The evidence reviewed here points to three design principles.

The first is to preserve the gap. Tasks should require students to formulate questions, make predictions and commit to hypotheses before they are allowed to consult the machine, as the mindful-searching research suggests.

The second is to teach the metacognitive loop. Identifying uncertainty, generating guesses, seeking information and monitoring progress are trainable skills. They determine whether an answer engine becomes a curiosity-killer or a curiosity-tool, and the learning-progress research suggests that letting learners see their own progress helps sustain the loop.

The third is to build the social chain. Because curiosity propagates socially, classrooms that model and reward questioning, including questioning of the AI itself, will sustain curiosity better than classrooms that treat the AI as the final authority. Teachers who reiterate student ideas with an element of uncertainty, rather than deferring to the machine's synthesis, keep the chain intact.

These principles have institutional consequences. Acceptable-use policies that simply permit or prohibit answer engines miss the point. Policies that specify when in a task the tool may be consulted, and what thinking must precede it, are more consistent with the evidence (see Q265). Claims about AI tutoring outcomes should likewise be read with attention to whether the systems studied preserve or collapse the learner's productive struggle (see Q051).

The OECD's framing remains the right philosophical anchor. Curiosity is a competency that education can and should develop, and the arrival of answer-on-demand technology makes that development more urgent, not less. The danger lies less in the technology than in the pedagogy that surrounds it. A classroom that hands students an answer engine and asks only for answers is likely to produce students who are less curious. A classroom that teaches students to use the engine within a disciplined inquiry (predict, check, explain, question) can produce students who are more curious, because they have learned that curiosity is a practice rather than a passive state.

The current evidence supports two conclusions, held with different degrees of confidence. Curiosity is a trainable capacity: metacognitive training, learning-progress feedback and social

modelling can each cultivate it, and both the OECD and the learning sciences treat it as a legitimate educational target. Answer-on-demand technology is a double-edged instrument. It plausibly weakens curiosity when it collapses the information gap before the learner has engaged. It can strengthen curiosity when embedded in a pedagogy that preserves the gap, teaches the metacognitive loop and builds the social chain of inquiry. The deciding variable is not the machine but the design of the learning environment.

Q106 Can a machine participate in a tradition of inquiry, or only imitate its outputs?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

A machine can participate in a tradition of inquiry, but only in a limited and derivative sense: as an instrument whose contributions become part of the tradition when human inquirers take them up. It cannot bear the tradition, and much of what looks like participation is the imitation of outputs whose meaning is supplied by the people around the machine. The question is one of the oldest in the philosophy of artificial intelligence, and the recent successes of AI in science have made it pressing again. The nuanced answer matters because it shapes how we should value machine contributions, and how we should teach with machines.

The argument depends on what a tradition of inquiry is. The sociology of scientific knowledge and the philosophy of science converge on one point. A tradition of inquiry is not a stock of outputs but a social practice. It is a community with shared standards of evidence, established

methods of criticism, and mechanisms of credit and accountability. It also has a history in which each generation builds on and corrects the work of its predecessors.

Michael Polanyi's concept of tacit knowledge is central to this picture, as recent discussions of AI expertise drawing on his work emphasise. Much of what makes an inquirer competent cannot be fully stated. This includes recognising a promising problem, judging the significance of a result, and knowing when a technique is being applied appropriately. Such knowledge is acquired through apprenticeship within a community. Harry Collins developed this insight into a distinction between two kinds of knowledge. Some knowledge can be transferred as "strings" of explicit data and rules. Other knowledge requires immersion in a social group.

On this framing, the question becomes whether a machine can acquire the tacit, social dimension of inquiry. Collins's answer is that it cannot. Machines can mimic the outputs of socialised expertise, but they cannot undergo the socialisation itself. The rest of the debate can be read as a series of challenges to, and refinements of, that verdict.

The recent literature on AI in science complicates Collins's picture without overturning it. Systems such as AlphaFold have made genuine contributions to biology by predicting protein structures that had eluded human researchers. A newer class of "AI Scientist" systems now runs autonomous research workflows. These systems generate hypotheses, design experiments and write up results. Work on how such machine-driven research should be evaluated shows that the question is no longer hypothetical.

If the outputs of inquiry can be produced end to end by software, a strict separation between participation and imitation becomes harder to sustain. At the least, we need a clearer account of what participation requires.

Philosophers have responded by distinguishing two views of scientific discovery. The agent-centred view attributes breakthroughs to individual geniuses. The collective-centred view treats discovery as a social enterprise carried out by a collective of human and non-human agents, with credit distributed according to contribution.

The two views give different answers to our question. On the agent-centred view, a machine participates only if it is itself a genius-like inquirer, and that threshold is very hard to meet. On the collective-centred view, a machine can be a member of the collective without being an inquirer in the human sense. It contributes novelty, pattern recognition and hypothesis

generation. The human community contributes the standards, the criticism, the judgements of significance and the accountability.

Work on human-AI collaboration in scientific discovery supports this division of labour. It frames progress as arising from the interaction between machine capacities and human direction, rather than from either alone.

The collective-centred view is attractive because it describes how science with AI is actually practised. It does, however, move the philosophical question rather than settle it. Calling the machine a "member" of the collective tells us that its outputs matter. It does not tell us whether the machine stands in the same relation to the tradition's standards as its human members do. Scholars disagree on how much weight the membership metaphor can bear. Those who favour the collective view stress distributed contribution. Their critics stress that only some members can answer for what the collective claims.

The case for limits rests on three arguments, each contested to a different degree.

The first concerns understanding. AI systems are, at bottom, optimisation engines that find patterns which predict well. Philosophers of science argue that predictive optimisation is not the same as scientific understanding. Understanding involves causal insight and the ability to explain why a result holds. A machine that predicts protein structures accurately may not understand proteins at all. The public argument that AI cannot automate science turns on this gap between prediction and explanation. It also turns on the uniquely human activities that research involves, such as framing questions and deciding what counts as an answer.

The second argument concerns empirical anchoring. AI models do not learn from the world directly. They are trained on human-generated data. Their discoveries therefore draw their legitimacy from foundations of theory and method that humans established, tested and revised. A model's success is in this sense parasitic on a tradition it did not build and cannot independently correct.

The third argument concerns what Polanyi saw as constitutive of scientific vocation: passionate, value-laden commitment. Recent work on AI and the scientific vocation develops this point. Machines lack intellectual passions, a sense of significance, and the fiduciary commitment by which an inquirer stakes personal responsibility on a claim. On this reading, machines can be instruments of a tradition but not its bearers.

Analyses outside the natural sciences reach a similar conclusion. Nguyen (2026), drawing on phenomenology, hermeneutics, Heidegger and Levinas, examines the conflict between AI's computational logic and nursing's relational essence. She asks how authentic care can continue when patients are reduced to algorithmic data. Her subject is clinical practice rather than inquiry. The structure of her argument is nonetheless parallel. Practices constituted by relation and commitment are not simply sets of tasks that computation can reproduce.

These arguments are not equally secure. The empirical-anchoring point is close to a description of how current systems are built. The understanding argument depends on contested accounts of what explanation is. The vocation argument rests on a philosophical anthropology that functionalists reject. Taken together, the three arguments make a strong case that machines currently contribute to inquiry without inhabiting it. Whether that is a permanent limit or a feature of present systems remains unclear.

The distinction between participation and imitation has its sharpest consequences in education. If a machine can take part in inquiry only by imitating its outputs, then students who learn from machines are learning outputs, not practices, unless the human community around the machine supplies the practice. The point is no longer only theoretical.

Sánchez (2026) examines proposals to deliver Socratic dialogue at scale in medical education through large language models. Such systems promise personalised, always-available and lower-stakes inquiry that human educators cannot logistically provide. Sánchez judges this promise plausible but unproven. He identifies a "mimicry trap": a system that fluently generates Socratic-sounding questions can appear to cultivate reasoning while functioning as interactive content delivery. He frames this as an educational instance of the ELIZA effect and of the proxy-outcome problem. A visible proxy, the Socratic-sounding exchange, is taken for the outcome it is meant to indicate, which is cultivated reasoning.

This is Collins's distinction between mimicking outputs and undergoing socialisation, transposed to the classroom. Sánchez offers a viewpoint argument, not an empirical trial. It shows what to look for rather than how often the trap occurs. His title also names surveillance as a further concern alongside promise and mimicry.

A more optimistic account comes from Brailas (2024). He conducted a "postdigital duoethnography" in the form of an evocative dialogue with ChatGPT. Through it he explored knowledge production, research methods, epistemology, creativity, entropy and self-

organisation. Reflecting on his own lived experience of the exchange, he argues that human-AI synergies can facilitate new insights and amplify human creative potential.

The study is a single reflexive account. It cannot establish how often such synergies occur. Read carefully, though, it is consistent with the derivative view. The insights Brailas reports arise from a human inquirer interpreting, resisting and building on the machine's contributions. They are not attributed to the machine alone.

The disagreement between these two authors is therefore less sharp than it first appears. Both locate whatever real inquiry occurs in the human side of the exchange. They differ on how readily that human side is activated, or bypassed, by fluent machine output.

For this reason, a broad consensus holds that AI in education and research must be embedded in human communities of inquiry. The machine proposes; the community disposes. The student's task is not to receive the machine's outputs as conclusions. It is to subject them to the same criticism, verification and judgement of significance that any claim receives in a tradition of inquiry.

In this sense the machine's participation is real but derivative. It participates through the human community that uses it. Its contributions count as contributions to the extent that the community integrates them into its practices. This maps closely onto the moral distinction between learning with AI, learning from AI and outsourcing learning to AI (see Q010). It also bears on whether a machine-generated idea can be credited to a student at all (see Q102).

Recent curricular work tries to make this embedding concrete, though the evidence is still early. Ko (2026) identifies a gap in the AI-in-education literature. Scholars have given substantial attention to material access and algorithmic fairness. They have given comparatively little sustained attention to the learner-side capacities that determine whether AI is engaged with critically or passively. Ko proposes a pedagogical framework for cultivating inquiry-driven agency. In the terms of this chapter, the framework aims to ensure that students bring the tradition's habits to the machine, rather than letting the machine stand in for those habits.

Hingle and Johri (2026) report an exploratory study of a guided inquiry activity in which students co-designed a course policy on generative AI. Students first drafted individual proposals on appropriate and ethical use. They then refined these collaboratively by incorporating the perspectives of diverse stakeholders. The activity treats the norms governing

machine use as themselves an object of communal inquiry. That is precisely the standard-setting role the collective-centred view reserves for humans.

Kelley and Wenzel (2025) add a sobering baseline. Many teacher candidates remain unaware of AI's presence in daily life, despite the rise of generative AI. Their response is to advance AI literacy through professional partnership inquiry. If those who will lead classroom communities of inquiry cannot yet recognise the machine's role, the community cannot reliably dispose of what the machine proposes.

None of these studies measures learning outcomes at scale. Whether such designs reliably prevent the mimicry trap remains unclear.

There is also a cautionary argument about monoculture. If inquiry comes to depend on a small number of AI systems trained on similar data, the cognitive diversity that sustains robust traditions of inquiry may be depleted. Traditions are resilient because they contain many voices, many methods and many standards of significance.

A tradition that outsources its generation of novelty to a few machines risks becoming a monoculture. Such a tradition would be fluent and efficient but incapable of the kind of surprise that drives genuine discovery. A community that uses AI in inquiry therefore has an obligation to preserve the plurality of its practices and the independence of its critical standards. This obligation extends to knowledge that no human any longer holds unaided (see Q104).

The obligation is partly a matter of governance. Ali (2026) argues in a conceptual paper that traditional technology governance models are insufficient for the ethical challenges AI poses in education. She proposes a Moral Compass Model for leaders navigating algorithmic decision-making, data governance and equity. The model is not addressed to epistemic monoculture specifically. Its premise still applies: protecting the conditions of inquiry cannot be left to the tools themselves. It requires human judgement exercised at the level of institutions.

The answer, then, is neither "yes, fully" nor "no, only imitation." A machine can participate in a tradition of inquiry in the way an instrument participates. It can generate novelty, detect patterns and extend the reach of the community's methods; work on AI Scientist systems and on human-AI collaboration shows how far that reach now extends. What it cannot do is bear the tradition. It cannot hold the tradition's standards, exercise its judgement, transmit its tacit knowledge, or be accountable for its claims. The tradition remains a human possession. The

machine's participation is real only insofar as human inquirers integrate its outputs into their practices of criticism, verification and judgement of significance.

For education, the implication is direct. Teaching with AI must be teaching within a community of inquiry, not teaching from a machine. The machine can be a participant, but the community must remain the author of the inquiry.

Q258 What does classical virtue ethics contribute to the question of how much AI assistance is compatible with the intellectual and moral development education is meant to cultivate?

12 citations · 12 sources · 5 cross-references

Claim 1 established

Most discussions of AI in education ask what students can produce with AI or how to prevent misuse. Classical virtue ethics reframes the question. It asks what kind of person education is meant to form and whether a given practice helps or hinders that formation. Because this tradition treats intellectual and moral development as the cultivation of stable excellences of character, it offers a distinctive vocabulary for judging how much AI assistance is compatible with education's purposes.

Aristotle's Nicomachean Ethics provides the foundation. Aristotle distinguished intellectual virtues, such as practical wisdom and understanding, from moral virtues, such as courage, temperance, and justice. He held that moral virtues arise through habituation: we become just by doing just acts and brave by doing brave acts. Intellectual virtues, he said, owe their growth

mainly to teaching and so require experience and time. In both cases, virtue is not mere knowledge of what is good but a settled disposition formed through repeated practice. The implication for AI is direct. If the capacities education aims to develop are formed by exercising them, then any tool that performs the exercise on the learner's behalf risks depriving the learner of the very activity through which the capacity grows.

Contemporary virtue epistemology, surveyed in the Stanford Encyclopedia of Philosophy entry by Turri, Alfano, and Greco, extends this tradition to knowledge itself. Responsibilist virtue epistemologists emphasise traits such as intellectual humility, curiosity, perseverance, open-mindedness, and intellectual courage. These traits are developed by encountering difficulty, tolerating uncertainty, revising beliefs in light of evidence, and persisting with hard problems. A learner who habitually asks an AI system to resolve every difficulty may complete tasks while failing to develop perseverance or tolerance for productive struggle.

Empirical research provides some support for these concerns, though it uses different language. Fan and colleagues, in a 2024 study in the British Journal of Educational Technology involving 117 university students, compared learners supported by ChatGPT with those supported by human experts, checklists, or no extra tools. They found that ChatGPT improved essay scores but did not produce greater knowledge gain or transfer, and that learners using it engaged less in metacognitive processes such as evaluating and monitoring their work, a pattern the authors termed metacognitive laziness. The randomised trial by Bastani and colleagues in PNAS found that unrestricted AI access improved practice performance but was associated with worse performance when students later worked without assistance, while a version designed to offer hints rather than answers largely avoided this harm. These findings are consistent with the Aristotelian claim that capacities develop through exercise rather than through the production of correct outputs.

Virtue ethics does not, however, imply that all assistance is harmful. Aristotle's account of virtue as a mean between extremes is instructive. Too little assistance can leave learners frustrated, discouraged, or stuck in error, undermining motivation and the confidence that perseverance requires. Too much assistance substitutes for effort. The appropriate amount lies between, and Aristotle insisted that the mean is relative to the person and circumstance and must be discerned through practical wisdom rather than calculated by rule. A beginner may need substantial scaffolding that would be excessive for an advanced student, and the same assistance may be appropriate in one task and corrosive in another.

Shannon Vallor's Technology and the Virtues, published in 2016, adapts virtue ethics to emerging technologies. Vallor argues that rapidly changing technologies require technomoral virtues, including honesty, self-control, humility, justice, courage, empathy, care, civility, flexibility, perspective, magnanimity, and technomoral wisdom, and that practices of habituation must adapt to new tools. Her account suggests that education should not only limit harmful uses of AI but deliberately cultivate the virtues needed to use AI well, such as the self-control to attempt a problem before seeking help and the honesty to acknowledge assistance.

Moral development raises additional considerations. Virtues such as honesty and justice are exercised in how students represent their work and treat others. Academic integrity, on this view, is not merely compliance with rules but an expression of honesty as a character trait. Using AI deceptively undermines that trait, while transparent, appropriate use can exercise it.

Anxiety about tools that think on our behalf is as old as the classical tradition itself. In Plato's Phaedrus, written in the fourth century BCE, Socrates recounts a myth in which the Egyptian god Theuth presents the invention of writing to King Thamus as a remedy for memory and wisdom. Thamus replies that writing will instead produce forgetfulness in learners, who will rely on external marks rather than remembering from within, and that it offers the appearance of wisdom rather than its reality, since readers will seem to know much while knowing little. The passage is often cited to mock technological pessimism, since writing evidently did not destroy thought. A more careful reading suggests that Plato's concern was not with writing as such but with the difference between possessing information and possessing understanding, and with the danger that a tool might allow people to display the outward signs of knowledge without undergoing the inner transformation that knowledge requires. That distinction lies at the heart of virtue-based approaches to AI in education. The question is not whether students will continue to use powerful tools, which they will, but whether education can ensure that the use of those tools accompanies rather than replaces the formation of understanding and judgement.

Alasdair MacIntyre's account of practices, set out in After Virtue in 1981, provides a particularly useful vocabulary. MacIntyre defined a practice as a coherent, cooperative human activity, such as chess, farming, scientific inquiry or the making of architecture, through which goods internal to that activity are realised as participants strive to meet its standards of excellence. He distinguished these internal goods, which can be obtained only by engaging in the practice itself, from external goods such as money, status and prizes, which can be obtained

in many ways. A child who is paid in sweets to play chess may learn to cheat if cheating secures the sweets, but a child who comes to value the analytical skill and strategic imagination that chess demands has reasons to play well that cheating would defeat. MacIntyre's example maps directly onto AI in education. Grades, credentials and completed assignments are external goods that AI can help secure without the student engaging in the practice of inquiry. The internal goods of learning, such as the satisfaction of grasping a proof, the skill of constructing an argument or the capacity to read a difficult text, can be obtained only through the student's own effort. Virtue ethics therefore suggests that the central educational task is to help students come to value internal goods, since students who value them have intrinsic reasons not to let AI substitute for their own thinking.

Linda Zagzebski's Virtues of the Mind, published in 1996, developed this line of thought within epistemology by arguing that knowledge itself should be understood in terms of intellectual virtue. She defined intellectual virtues as deep and enduring acquired excellences of a person, involving a characteristic motivation to attain truth and reliable success in doing so, and she modelled them explicitly on Aristotle's moral virtues. On her account, a person who arrives at a true belief by luck or by deferring uncritically to an unreliable source does not possess knowledge in the full sense, even if the belief happens to be true. Applied to AI, Zagzebski's framework implies that a student who accepts a correct answer from a chatbot without understanding why it is correct, and without the motivation or ability to evaluate it, has acquired a true belief but not the epistemic virtue that education aims to cultivate. Her account also allows that appropriate trust in reliable sources can itself be virtuous, provided the trust is informed and the learner retains the capacity to question. The educational implication is not that students must verify everything independently, which no one can do, but that they need to develop the discernment to judge when AI is reliable, when it is not, and when the effort of working something out themselves is the point of the exercise.

Classical virtue traditions outside Greece offer parallel insights that are relevant in many of the education systems now adopting AI. In the Analects, compiled by followers of Confucius from around the fifth century BCE, the Master observes that learning without thought is labour lost, while thought without learning is perilous. The Confucian tradition places heavy emphasis on self-cultivation through study, ritual practice and reflection, and it treats the teacher-student relationship as a moral as well as intellectual bond. From this perspective, AI that provides answers without requiring reflection risks producing learning without thought, while AI used as

a partner in questioning might support the reflective dimension of study. The Confucian emphasis on exemplars, the junzi or exemplary person whose conduct models virtue for others, also highlights a limitation of AI: it can supply information and even simulate encouragement, but it cannot serve as a moral exemplar whose life demonstrates what it means to pursue learning with integrity. Comparing traditions in this way suggests that the core concern of virtue ethics about AI is not parochially Western but reflects a widely shared intuition that education aims at the formation of persons and not merely the transfer of content.

Virtue ethics also faces serious objections that bear on its application to AI. John Doris, in Lack of Character, published in 2002, drew on social psychology experiments to argue that behaviour is far more sensitive to situational factors than virtue ethics assumes, and that robust, cross-situational character traits of the kind Aristotle described may be rare. Doris cited studies in which trivial features of a situation, such as whether someone was in a hurry or had just found a coin, substantially changed whether people helped a stranger. If Doris is right, then cultivating virtues such as intellectual honesty or perseverance in students may be less effective than shaping the situations in which they use AI, for instance through assignment design, assessment formats and default settings in tools. Defenders of virtue ethics have responded that the situationist evidence is compatible with the view that virtue is rare and difficult to acquire, which is precisely why education must work at it deliberately, and that virtues include the wisdom to recognise and avoid situations that undermine good conduct. The debate has a practical upshot for schools. Rather than choosing between character formation and situational design, they can combine the two, building environments that make virtuous use of AI easier while also helping students develop the dispositions that will guide them in environments no one has designed for them.

Practical frameworks for character education show how such ideas can be translated into school practice. The Jubilee Centre for Character and Virtues at the University of Birmingham, in its Framework for Character Education in Schools, most recently revised in 2022, describes character as a set of intellectual, moral, civic and performance virtues and emphasises practical wisdom as the integrating virtue that enables people to weigh competing considerations and act well in particular circumstances. The Framework argues that character is caught through the ethos and relationships of a school, taught through explicit instruction, and sought by students as they come to choose virtue for themselves. Applied to AI, this suggests that schools need to model thoughtful use in how teachers and leaders themselves employ AI, teach explicitly about

the ethical and epistemic issues it raises, and create opportunities for students to make and reflect on their own decisions about when to use it. The Framework has not been evaluated specifically in relation to AI, and evidence on the effectiveness of character education programmes more generally is mixed, but it offers a structured way to integrate virtue considerations into school life rather than treating them as abstract philosophy.

Implementation raises questions of fairness and pluralism. Virtue ethics speaks of human flourishing, but societies disagree about what flourishing involves, and schools in pluralistic democracies must avoid imposing a single conception of the good life. A virtue-based approach to AI in education is most defensible when it focuses on intellectual virtues widely shared across traditions, such as honesty, curiosity, perseverance and practical judgement, and when it treats students as developing agents capable of reasoning about these values rather than as subjects to be shaped. Teachers can invite students to discuss what they lose and gain when they use AI, drawing on texts from Plato to contemporary debates, so that the question of how much assistance is compatible with growth becomes part of what students learn to think about for themselves.

Virtue ethics thus suggests a standard for AI assistance that is contextual rather than fixed. Assistance is compatible with education when it supports the learner's own exercise of reasoning, judgement, and moral agency, is calibrated to their stage of development, and is gradually withdrawn as competence grows. It is incompatible when it habitually replaces the activities through which virtues form. Teachers, in this tradition, act as exemplars of practical wisdom, helping students learn when to seek help and when to persist. The framework does not resolve every practical question, and critics note that its emphasis on judgement can make it difficult to translate into policy. It nonetheless offers a coherent account of why the process of learning matters and not merely its products.

Chapter 2: Ethical Dimensions

13 questions · 217 citations · 212 unique sources · 65 cross-references

Q011 Who is responsible when an AI teaches something false, biased, or harmful to a student?

21 citations · 21 sources · 5 cross-references

Claim 1 disputed

Responsibility for an AI system that teaches a student something false, biased, or harmful is currently shared in principle among several parties and firmly assigned to none of them in practice. The question looks simple but becomes tangled once one tries to answer it. At least four parties are implicated: the technology developers who build and train the models, the schools and universities that procure and deploy them, the classroom teachers who recommend or permit their use, and the students who act on what the systems tell them. The law does not yet offer a clean way to allocate duty among them.

The systematic reviews that frame this chapter treat accountability as one of the central unresolved problems of generative AI in education, alongside bias, opacity, and data protection. Writing across sectors that include education, Agarwal (2025) points to the lack of global regulation and the difficulty of building truly transparent systems as structural obstacles. He argues that ethical safeguards must be designed in from the start rather than treated as an afterthought. That argument is normative rather than empirical, but it sets the terms of the discussion that follows. If ethics are bolted on after deployment, responsibility for harm is likely to be dispersed after the fact as well, among actors who each had only partial control over what the student eventually saw.

The harms in question are not hypothetical. AI models frequently "hallucinate," producing false information that students may accept as true because of the authoritative way the systems present their responses. Collins (2024), writing from the sociology of knowledge, offers an explanation of why this happens. He argues that large language models such as ChatGPT have "no moral compass" and answer queries with fabrications as fluently as they provide facts. In

his account, learning from the internet is not the same as socialisation. These systems lack the primary socialisation that grounds human moral understanding and are instead "retrospectively socialised" by human intervention meant to align them with accepted ethics. This is a theoretical argument rather than a measured finding. Its relevance to responsibility is direct, however, because it locates the source of fluent falsehood in how the systems are built and corrected, not in any isolated malfunction.

Educational researchers reach compatible conclusions from a more practical angle. Lye and Lim (2024) note that generative models trained on internet data can produce biased and discriminatory outputs, and that hallucination yields made-up and untruthful content. Bobula's (2024) review of the higher-education literature lists the propagation of misinformation and biases inherent in the models among the principal challenges of large language models. That hallucination occurs is effectively established. How often it misleads students in practice, and with what lasting effect on learning, remains unclear.

Bias is the second category of harm. Despite improvements in content filtering, bias remains a concern. The MinorBench work on content risks for children reports that chatbots can reinforce stereotypes and can mislead young users into believing AI-generated content is accurate. As generative AI spreads through education, reviews have documented multiple cases in which algorithms reproduced and amplified existing inequalities, with effects on academic assessments, course recommendations, and even the allocation of learning opportunities. Zuiderveen Borgesius (2025), in a study prepared for the Council of Europe's Anti-discrimination Department, describes the capacity of AI to embed and perpetuate discrimination as one of the most pressing challenges of its growing use.

The most precise evidence of educational bias concerns assessment rather than instruction. Yvan, Charles and Lucy (2026) systematically reviewed 27 studies of generative AI in medical, nursing, pharmacy and dental assessment. Six experimental studies found that AI detectors falsely labelled the writing of non-native English speakers as AI-generated in 50.2% to 61.3% of cases, compared with under 5% for native writers. Four automated scoring studies showed a systematic downward bias of 0.5 to 1.2 standard deviations against non-native speakers. These findings complicate the responsibility question in a revealing way. The harm here comes from tools an institution chose to deploy against students, not from a chatbot a student consulted. The cultural and linguistic dimensions of such bias are taken up separately (see Q019).

For younger students the risks compound. The MinorBench authors observe that children tend to anthropomorphise chatbots and seek emotional support from systems that lack true understanding. This can cause distress when responses are inappropriate or unhelpful, a pattern that shades into questions of dependency (see Q246).

Existing law was not built for this situation. As the review of accuracy and regulatory concerns in educational AI observes, legal and ethical frameworks assume a human-in-the-loop model in which accountability rests with the user, because AI tools are not recognised as legal persons or responsible agents. That assumption breaks down in schools. A child using a tutoring chatbot has no meaningful ability to audit its outputs, and the human supposedly "in the loop" may be the least equipped party in the chain.

Traditional product liability theories, such as design defect and failure to warn, are being tested and redefined in the AI context. Commentators on emerging tort law note a basic difficulty with applying them. Because AI decision-making can be opaque even to its creators, it is hard to assess liability, assign responsibility, and anticipate the full range of potential harms. A design-defect claim presupposes that one can identify what a reasonable alternative design would have been. That is difficult when the behaviour in question emerges from training rather than from any explicit specification.

Early court cases have set limited and cautious precedents. In a 2025 ruling against a plaintiff who sued OpenAI for defamation, the court recognised OpenAI's efforts to reduce inaccuracies and provide user warnings, and concluded that the legal threshold for defamation had not been met. Legal commentators read the decision as suggesting that disclaimers and responsible design practices may protect developers from liability, even though the broader question of AI accountability remains unsettled.

For education, the implication is uncomfortable. The defence that worked in that case relies on a warned, competent adult reader. Whether a comparable defence should succeed when the reader is a twelve-year-old completing homework has not been tested. Credible commentators disagree about whether warnings can ever discharge a developer's duty toward minors.

In practical terms, responsibility is being distributed, unevenly, across three layers, and the developer layer is where normative arguments are most insistent. Researchers increasingly argue that bias mitigation must be addressed across the whole AI lifecycle, from data collection and training to inference and system updates. The systematic review in Humanities and Social

Sciences Communications identifies mitigation strategies at each of these stages. The Frontiers review of ethical and regulatory challenges adds that developers should conduct human rights impact assessments to identify risks before deployment. The broader review of AI ethics in education concludes that developers must ultimately be held accountable for ensuring that educational AI fosters ethical, inclusive, and pedagogically meaningful innovation.

Work outside the education literature points the same way. Figueiras and colleagues (2026), setting out European research and innovation agendas for AI, data and robotics, stress the need for robust frameworks addressing bias, fairness, and accountability, alongside explainable and adaptive AI. Collins's (2024) argument adds a sharper point. If models acquire their ethical alignment through retrospective human correction, then those who perform that correction are making substantive choices about what students will be told. He urges vigilance about "who is socialising them" and warns that the models may end up socialising users to align with them rather than the reverse. On that view, the developer's responsibility goes beyond technical quality control and covers the epistemic and moral content of the system.

These arguments have broad support among ethicists. Their translation into enforceable obligations specific to education remains thin, and the mechanisms that might supply it are considered elsewhere (see Q259).

At the institutional level, schools and universities are being pushed to take responsibility for what they deploy. The analysis of ethical challenges in university education published in the Journal of Academic Ethics argues that institutional accountability requires clear standards and monitoring mechanisms for the ethical and responsible use of these tools. Practitioner guidance for schools using AI tutors makes the contractual side concrete. Schools need clear agreements with vendors that set out liability, and they need to monitor AI's impact regularly so that it supports rather than disrupts learning goals.

Evidence on what institutions actually do suggests that guidance has grown faster than accountability. McDonald and colleagues (2025) analysed policy documents from 116 US R1 universities. A majority (63%) encouraged the use of generative AI, 41% offered detailed classroom guidance, 56% provided sample syllabi, and 50% provided sample curricula and activities. More than half addressed ethics across a range of topics. The emphasis falls on enabling use rather than on allocating responsibility when use goes wrong. The gap is felt by students. In Mujtaba's (2024) survey of 126 South Florida undergraduates, most regarded AI

use as ethical and legal, but some remained uncertain because professors and institutions had not provided clear guidelines. Lye and Lim (2024) argue that policing AI through an "arms race" may not address fundamental problems, and propose an Against, Avoid and Adopt principle for redesigning assessment. That stance implicitly places on institutions a duty to design around known failure modes rather than simply prohibit tools. The detector findings of Yvan and colleagues (2026) show what is at stake when institutions adopt tools without scrutiny.

Legislatures are beginning to act as well. During the 2026 legislative session alone, FutureEd is tracking 71 bills across 27 states that address artificial intelligence in classroom instruction. Bill counts measure legislative activity, not settled duties, and how many of these bills will allocate liability remains unclear.

Teachers occupy a third position, one the law has barely begun to define. Reviews of AI ethics in education note growing concerns about transparency and accountability as AI becomes more embedded in decision-making. An educator who recommends, or simply permits, a particular AI tool may carry an implicit duty of care that has no established legal precedent. Whether teachers can reasonably discharge such a duty depends on their preparation. MacDowell and colleagues (2024) report a self-study of a course in which 35 preservice and in-service teachers developed AI literacy through experiential activities and co-authored an open textbook. From this work they derived the Student Artificial Intelligence Literacy (SAIL) framework, which combines cognitive, socio-emotional, and instructor-guided interactions. This is a single illustrative case, not evidence of effectiveness at scale. It does suggest that a teacher's duty of care is only as meaningful as the training institutions provide.

What remains open is whether any single party can or should bear primary responsibility. The lack of transparency and accountability in algorithmic processes fundamentally complicates ethical oversight, as the systematic review in Humanities and Social Sciences Communications emphasises. The Journal of Academic Ethics analysis adds that personal data can be exploited unnoticed when users lack awareness and no one is accountable. The opacity of so-called black-box algorithms compounds both problems.

Students complete the four-party picture, and their position is the most ambiguous. Some evidence suggests that older students already reason about their own stake. Nelson and colleagues (2025) surveyed 56 Ecuadorian undergraduates writing in English as a foreign

language. The students worried more about hindering the development of their own writing skills than about being caught. They regarded submitting chatbot-generated text as dishonest, though fewer saw submitting machine-translated work that way. That study concerns integrity rather than exposure to falsehood, and its sample is small. It does suggest that university students can exercise some critical agency. The same cannot be assumed of children, who may anthropomorphise the systems they use. Any account that places significant responsibility on the learner must therefore scale it to age and capacity.

The practical consequence is a diffusion of responsibility that benefits no one, least of all the student who simply trusted the machine. Developers point to disclaimers, institutions point to vendor contracts, teachers point to institutional policy, and the law points back to the user. For now, accountability is shared in principle and enforced by almost no one in particular. That condition reflects how quickly the technology arrived more than any considered social judgment about where the duty of care should lie.

Q012 How should student data collected by AI systems be governed, and who owns the learning profile of a child?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

No one clearly owns a child's learning profile under current law. The defensible answer is that ownership should rest ultimately with the student, with parents acting as stewards during childhood, while schools and vendors hold only limited, revocable custody. Governance

frameworks lag well behind what AI systems can technically do, and the gap is widening each year.

The stakes are considerable. The Campus Review observes that AI in education involves collecting and analysing sensitive student data, including personal information, academic performance and behavioural patterns. Axios reported in 2025 that AI-powered tools reach beyond academic records into student health records, Social Security numbers and families' credit card data. Aggregated and processed across years of schooling, this material becomes something qualitatively new: a continuously updated psychological and cognitive portrait of a developing person.

The frontier of what can be inferred is moving quickly. Aggeliki and Anagnostopoulos (2025) review work on AI for autism spectrum disorder. In their account, deep learning systems identify behavioural patterns through biometric data, video-based interaction assessments and linguistic feature extraction, and educational robots and adaptive communication tools collect interaction data during intervention. Their paper presents these as gains in diagnostic timeliness and personalised support. For governance, the lesson is that the boundary between an educational interaction and a clinical inference is becoming porous. A tool deployed to support learning may generate data that functions as a diagnosis.

Žnidarec Čučković (2026) names the broader pattern directly. She describes algorithmic profiling from infancy, biometric surveillance in schools and the commercial extraction of childhood data as rights risks without precedent. She also argues that these practices strain the United Nations Convention on the Rights of the Child.

In the United States, the primary statute is the Family Educational Rights and Privacy Act (FERPA). The National Student Data Privacy Association notes that FERPA requires educational institutions to keep student records confidential, but that it was enacted long before AI became prevalent, leaving gaps in how it applies to modern data practices. The law was designed for paper files and administrative records. It was not designed for adaptive learning platforms that log every hesitation, wrong answer and reread passage.

The gaps are not merely theoretical. As Axios reported, statutes like FERPA do not guarantee meaningful protection when AI vendors can structure their data practices to fall outside its definition of "education records." A protection that depends on a definitional category can be circumvented by redesigning the category.

For younger children, the Children's Online Privacy Protection Act (COPPA) adds a separate layer. Aurascape's compliance overview describes the Federal Trade Commission's COPPA amendments, finalised in 2025, as requiring separate parental consent before children's data is shared with third parties. Schools can still authorise educational data collection under existing FTC guidance. That carve-out leaves a practical ambiguity: who actually holds consent authority for a given tool, whether the parent, the school or the district, often depends on how a deployment is classified.

SchoolAI's guidance for teachers, a vendor publication that should be read as practitioner advice rather than research, reflects the same uncertainty. It urges educators to check whether a tool's data flows fall within these statutory protections before adopting it. How these frameworks apply specifically to minors across jurisdictions is examined in detail elsewhere (see Q072).

Legal ownership is the most unsettled question of all. ArentFox Schiff notes that FERPA and similar laws dictate how schools manage student data, yet many AI tools operate in a legal gray area. SchoolAI likewise advises educators and administrators to scrutinise how AI systems collect, store and process student information, including who controls the data and whether the school or the vendor retains ownership.

In practice, contracts between districts and edtech companies often settle the matter, and those contracts vary enormously. ArentFox Schiff describes the formal position as follows: student data remains under the control of the local educational agency, and the AI provider must agree not to use it for purposes beyond those specified in the agreement. Enforcement of such provisions, however, is inconsistent and under-resourced. A district with one part-time technology coordinator is poorly placed to audit a multinational vendor.

The question of training data complicates matters further. Axios reports that AI firms constantly seek data to train their models. They are not required to disclose exactly where that data comes from, but they must disclose how they use customer data, especially student data. Most major educational AI platforms publicly disclaim training on student inputs. Khan Academy's chief learning officer, for instance, told Axios that content submitted by teachers and students is not used to train the foundation models behind the Khanmigo tutor. No independent verification regime exists to hold vendors to such commitments. A promise without audit is a reputational

pledge, not a governance mechanism. The wider ethical duties that companies owe to education systems they profit from bear directly on this point (see Q020).

The deeper difficulty is conceptual, and here credible voices diverge. The contractual model treats the learning profile as an institutional asset, held by the district and licensed to the vendor. Žnidarec Čučković (2026) rejects that framing. She argues that the existing child-rights apparatus, including the UN Committee's General Comment No. 25 on children's rights in the digital environment, is significant but insufficient. In its place she proposes a rights-by-design framework that treats the child as a rights-holder rather than a data subject.

On her view, "ownership" may be the wrong vocabulary altogether. Property can be sold or transferred, whereas rights in one's own developmental record arguably cannot. Whether property or rights language better protects children remains unclear, and the two framings imply quite different remedies.

The most consequential and least-discussed risk may be the permanence problem. Academync warns that AI in education can create permanent digital records that follow students throughout their lives. A profile assembled at age eight might label a child as struggling with reading comprehension or prone to distraction. That label could later inform algorithmic decisions about academic placement, college admissions or even employment screening, in ways the child never consented to and cannot later contest.

The risk is compounded when the underlying predictions are skewed. VKTR reports a 2024 study finding that predictive algorithms widely used by universities tend to underestimate the success potential of Black and Hispanic students and to overestimate that of White and Asian students. According to the same report, this systematic bias distorts academic support interventions and creates a risk of self-fulfilling prophecies, in which students flagged as "high-risk" receive fewer opportunities. The finding concerns higher-education prediction tools rather than K-12 learning profiles. The mechanism nevertheless transfers readily, since a biased label entered early can be inherited by every later system that reads the record.

Žnidarec Čučković (2026) gives this concern a normative name: the "right to a future," meaning a child's interest in a self-determined life trajectory that predictive AI may foreclose. She also argues that algorithmic bias falls disproportionately on marginalised children and on communities in the Global South. That claim is consistent with the pattern VKTR describes, though her chapter is an analytical synthesis rather than an empirical test.

Kondor and colleagues (2024) supply a useful lens for why such harms are hard to anticipate. They argue that AI systems must be studied in their socio-political context. In their account, outcomes emerge from long-term feedback between technological development, inequalities and collective decision-making, which makes risk assessment for any specific deployment uniquely difficult. A learning profile is exactly this kind of feedback object. It shapes the opportunities a child receives, those opportunities shape the data the child generates, and that data then appears to confirm the profile.

How such analytics should be interpreted, validated and shielded from misuse in student evaluation deserves separate treatment (see Q093). The emotional and identity costs of being continuously profiled are also not yet well documented (see Q229).

Governance is moving, but unevenly. Government Technology reports that more than half of US states have issued AI guidance for K-12 schools. Most of it converges on the same themes: data privacy, academic integrity, equity and keeping educators in control of AI-assisted decisions.

Guidance is not law, however. As of July 2025, according to the same reporting, only a couple of states had passed legal mandates. Ohio required all K-12 public schools to adopt AI use policies by mid-2026. Tennessee mandated that local school boards adopt policies on AI use by students, faculty and staff. Government Technology's broader critique is that state policies may be thinking too small, regulating classroom use while leaving data architecture largely unaddressed.

At the federal level, AASA reports proposed legislation that would amend FERPA and create a Golden Seal of Excellence in Student Data Privacy, alongside a Privacy Technical Assistance Center at the U.S. Department of Education. No comprehensive framework of that kind has yet been enacted.

Internationally, the EU AI Act offers a more structured approach. Aurascape notes that it classifies several educational uses of AI as high-risk, including systems that determine admission or assignment to institutions, evaluate learning outcomes or monitor behaviour during tests. High-risk status brings obligations covering risk management, data quality, logging, transparency and human oversight. The contrast with the American patchwork is stark. The EU regulates by function and consequence, whereas the US largely regulates by institutional category and record type.

Kondor and colleagues (2024) suggest that even function-based regimes may fall short. They argue that risk assessments for AI should incorporate a complex systems perspective, with models capable of representing short- and long-term effects and feedback, and with greater public engagement and participation. Their argument is not specific to education. Applied here, it implies that a one-time compliance checklist cannot capture harms that accumulate over a decade of schooling. The enforcement mechanisms that might hold developers to education-specific obligations are discussed further elsewhere (see Q259).

The outlines of a defensible governance framework are becoming clearer, even though implementation lags. Transparency comes first. Work on human-centric explainable AI in education stresses that students, parents and teachers should be told what data is collected, how it will be used and who will have access to it. Institutions also need clear data governance policies that assign responsibility for handling data and set out procedures for responding to breaches.

Beyond transparency, the field increasingly holds that ownership should vest ultimately in the student, with parents acting as stewards during minority, rather than in vendors or even institutions. Žnidarec Čučković (2026) offers the most developed version of this position. She identifies structural regulation of the digital economy, mandatory algorithmic impact assessments and participatory governance as essential pillars of a rights-respecting order.

Participation raises its own question: what do children actually understand about the systems that profile them? Kalemkuş and Kalemkuş (2025) offer an early answer. They studied 262 third- and fourth-grade pupils using metaphor and drawing analysis within a phenomenological design. The children produced 100 metaphors for AI, grouped into 17 categories, with the most in the categories of humanistic feature, information source and danger. Within those categories, prominent images included AI as human, brain or living thing; as teacher, wise figure or book; and as enemy, weapon or monster.

The study is small, qualitative and confined to one national context, so it cannot settle questions of competence. It does suggest that young children hold rich but ambivalent mental models, seeing AI simultaneously as a trusted teacher and a potential threat. Neither image corresponds to the reality of a data-collecting system. This finding cuts in two directions. It supports involving children in governance rather than treating them purely as objects of protection. It

also cautions against relying on children's consent where their understanding of data flows remains unclear.

The National Education Association calls for a comprehensive, nationwide approach to data privacy in education. Until such regulation exists, the responsibility falls on educators and schools to harness AI's benefits responsibly, protect student data and uphold the integrity of the learning environment. That burden is unevenly distributed, and it is heaviest for districts with the fewest resources to negotiate contracts or audit vendors.

As of mid-2026, it remains an open and urgent question whether governments will move fast enough to establish such a framework before AI-generated learning profiles become embedded in consequential decisions. The answer will determine whether a child's learning record remains a tool in that child's service or becomes a forecast the child must spend years trying to outrun.

Q013 Does personalized AI tutoring risk creating algorithmic determinism — locking students into predicted trajectories?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

Personalized AI tutoring does carry a real risk of algorithmic determinism, but the risk is conditional rather than inherent. Whether a system locks students into predicted trajectories depends less on adaptivity itself than on how transparent the system is, who can override it, and what data it learns from. The appeal of AI tutoring rests on a seductive logic: a system that

continuously observes a student's choices, errors, and pace should be able to build a learning environment calibrated precisely to that student.

Commercial providers describe this promise in confident terms. SchoolAI, an education technology vendor, presents AI systems as creating custom learning paths from individual data. In its account, the platform builds an understanding of a student's strengths, weaknesses, and learning preferences as the student works, then adjusts content difficulty and moves faster through areas of confidence. This is marketing description, not research evidence, but it captures the design intention accurately. Academic accounts describe the same architecture in more neutral language. A 2025 review in the European Journal of Computer Science and Information Technology explains that machine learning algorithms analyze student performance data to customize content difficulty, pacing, and presentation methods according to individual needs.

The question this continuous calibration raises, and which the field has only begun to take seriously, is whether a system that optimizes for where a student is might quietly foreclose where that student could go. The mechanism of adaptive tutoring is well documented. Its long-term consequences for students' educational trajectories are not. No study among those reviewed here follows learners long enough to show whether early algorithmic routing hardens into lasting placement. That gap should shape how confidently any verdict on determinism is stated.

The concern is structural. An adaptive model's prediction of what a student needs next is built entirely from what that student has already done. Suppose a learner struggles early with abstract reasoning. The algorithm may then route them persistently toward more concrete scaffolding and never present the harder material that might have triggered a breakthrough. In such cases the system mistakes a current state for a fixed trait. Human teachers make the same error, of course. The difference is that an algorithm makes it consistently, at scale, and often without anyone noticing that a judgement has been made.

The worry is not merely theoretical, because the data feeding these predictions are not neutral. Strielkowski and colleagues (2025) observe that AI systems trained on biased datasets can perpetuate or worsen inequalities. They report that some studies suggest AI algorithms may disadvantage students from underrepresented groups by giving less accurate or biased feedback, which in turn affects learning outcomes. The underlying mechanism is a feedback

loop. A student from a historically underserved background reaches the system with performance data that reflect accumulated disadvantage rather than innate capacity. The model reads that disadvantage as aptitude and allocates learning opportunities accordingly. Its later observations then appear to confirm its earlier prediction.

Work surveying professional perceptions of AI bias draws on the AI Index Report (2025). That report concludes that systems trained on unbalanced or incomplete datasets "magnify pre-existing inequalities and reinforce historical patterns of exclusion." It warns that large-scale adoption without robust data governance risks institutionalizing bias in access to education. Chick (2025) reaches a compatible conclusion from the higher education side. His narrative review of 167 sources on AI-enhanced computational thinking argues that effective integration requires frameworks that join ethical AI governance with pedagogical design, so as to protect historically marginalized students from algorithmic discrimination. Chick's work is a synthesis, not a new empirical test, and it does not quantify how often discrimination occurs. Its value lies in showing that bias concerns arising in different educational contexts converge on the same remedy. A related question is how such bias enters through the language and cultural composition of training corpora (see Q019).

What makes this problem hard to remedy is the opacity of the systems themselves. A student cannot easily contest a trajectory they cannot see, and neither can a teacher. Evidence from medical education illustrates the point. In an evaluation of an AI-driven personalized learning platform for medical students, unexplained path adjustments occurred in 15% of cases. The authors suggest such adjustments may undermine trust, and they call for explainability tools to be built into the platform. The figure comes from a single study in one professional discipline. It should not be treated as a general rate for AI tutoring, and it does not show that the unexplained adjustments harmed learning. What it does show is that even a system designed and studied with care produced a noticeable share of decisions its users could not account for.

The wider research base places opacity among a cluster of related concerns. A 2025 review in Social Sciences & Humanities Open on generative AI and the educational divide warns that, without effective safeguards, the technologies that promise to personalize and widen access may also reinforce bias or depersonalize learning. It identifies five recurring themes in the research: data privacy, algorithmic bias, depersonalization of learning, accountability, and transparency. Algorithmic determinism sits at the point where these themes meet. A path that is biased, opaque, and unaccountable is exactly the kind a student is least able to leave.

Moganadas and colleagues (2026) offer a useful way to think about where responsibility should sit. Through an integrative synthesis spanning higher education, learning sciences, human-computer interaction, policy, and ethics, they propose a nested triadic model of instructor, student, and generative AI. In this model the AI is a bounded didactic-pedagogical mediator rather than an autonomous decision-maker. They argue that existing frameworks, which mostly define AI by functional roles such as tutoring or assessment, say little about how AI redefines pedagogical agency and responsibility in everyday interaction. Their model is conceptual and untested. Still, it names the issue precisely: determinism becomes likely when the mediator's boundaries are left undefined and its routing decisions go unexamined by either of the human parties.

A countervailing body of evidence complicates any outright verdict of determinism, and here credible sources pull in different directions. Research on AI-generated feedback, reported in work on generative AI and student agency, found that AI-assisted learners showed greater autonomy in problem-solving tasks. If personalization inevitably narrowed students' horizons, this result would be hard to explain. The same study, however, cautioned that excessive AI control can reduce student agency. It stressed the need for a balanced approach in which students choose how and when to engage with AI support. The authors also note that, when implemented responsibly, generative AI can foster student ownership of learning and encourage critical thinking.

Read together, these findings suggest that design is the key variable. Systems that invite student choice appear to produce different outcomes from systems that route students silently. The evidence for this is still thin. The studies reviewed here do not directly compare choice-based and silently routing systems under controlled conditions, so the design explanation remains a reasonable inference rather than a demonstrated causal claim. It also remains unclear how long any gains in autonomy last, and whether they hold for the underserved students most exposed to the bias loop described above.

Petrova (2026) adds a normative contribution that should be weighed for what it is. Using an LLM-based Delphi method, in which large language models simulated interdisciplinary deliberation through iterative rating cycles, the study produced a consensus framework. That framework includes human-AI collaborative pedagogy models, equity-centered implementation protocols, and ethical guardrails for responsible adoption. It explicitly aimed to test how far an AI-generated framework meets OECD criteria for quality and robustness. Because the

deliberation was simulated rather than conducted with human experts, its consensus cannot count as independent evidence that collaborative designs prevent determinism. Its value lies in showing how readily safeguards against silent routing can be specified. The obstacle appears to be adoption rather than imagination. The gap between that fairly optimistic design literature and the bias findings from deployed systems is a genuine disagreement and should not be smoothed over.

The deepest form of the determinism problem may not involve content tracks at all. A 2025 analysis of designing learning management systems and instructional strategies for conversational generative AI warns that students may struggle to develop self-regulation if AI tools give constant direction without requiring independent goal setting or reflection. Self-regulation here means planning, monitoring, and adjusting one's own learning. On this view, the algorithm need not lock a student onto a particular sequence of material to constrain them. It constrains them by quietly taking over the metacognitive work of deciding how to learn. A student who never has to choose a path never learns to navigate one. That loss can persist even if the content they meet is varied and appropriately challenging.

This reframing moves the concern from fairness of placement to the formation of judgement. Work on preparing students for AI-powered materials discovery makes a parallel argument in a specialized scientific setting. It organizes AI literacy around equity and scientific judgment, treating the capacity to evaluate and question a system's outputs as something to be taught deliberately rather than assumed. If that capacity matters for advanced researchers working alongside AI, it matters at least as much for younger learners, whose habits of self-direction are still forming.

The 2023 IEEE workshop on Norbert Wiener's legacy, synthesized by Love and colleagues (2024), offers a broader frame drawn from the study of automation and work. Participants identified qualitative losses associated with automation, along with challenges arising from uncertainty and unpredictability in technological change. They called for human values and agency to be placed at the center of these debates. The workshop addressed labor rather than schooling, so its relevance here is by analogy. The analogy is instructive nonetheless. The texture lost when a task is automated is often the part that built competence. In tutoring, that texture includes the struggle of deciding what to study next. This links the determinism question to whether education can still transmit a shared capacity for judgement when information is increasingly delivered through personalized channels (see Q049).

The most defensible conclusion is that algorithmic determinism in AI tutoring is a genuine risk rather than an inevitability. Whether it materializes depends on three conditions identified across the sources. The first is how transparent the system is. The second is whether human educators keep the authority to override its recommendations. The third is whether the training data reflect a genuine diversity of potential rather than historical patterns of disadvantage. The 2025 review of generative AI and the educational divide frames educational impact through three intersecting dimensions: personalization, fairness, and access. It argues that the way these dimensions intersect determines whether AI narrows or widens learning inequalities. Personalization without fairness reproduces disadvantage. Fairness without access helps only those already inside the system. Access without accountable personalization risks spreading opaque routing more widely.

These conditions translate into concrete governance commitments. Chick's (2025) call to combine ethical governance with pedagogical design, and the equity-centered protocols set out in Petrova's (2026) framework, both point toward visible and contestable learning paths. Students should be able to see why material was chosen. Teachers should be able to reverse a routing decision. Institutions should audit whether path assignments diverge by group. Deciding who holds that override authority, and how families and students take part, is a matter for school-level governance (see Q235). The prospect that algorithmic routing might replace professional judgement altogether connects to the case for a right to a human teacher (see Q018).

It is tempting to close by saying that the technology itself is neutral on this question while the governance around it is not. That formulation captures something important: the same adaptive engine can widen or narrow a student's horizon depending on the rules that surround it. Yet the claim of neutrality is itself contested. Jandrić and colleagues (2026), outlining a research program on EdTech and the environment, argue that scholars should resist technological solutionism and growth-dependent development models. They note that a global EdTech market worth nearly USD 250 billion carries costs the field has examined too little. Their focus is ecological, but their caution applies here as well. Systems built to optimize engagement and predicted performance carry assumptions about what learning is for. Governance can constrain those assumptions, but it cannot fully neutralize them. Preventing determinism therefore requires both oversight of individual systems and continued scrutiny of the optimization goals they are designed to pursue.

Q014 How do we prevent AI from amplifying existing inequalities of class, language, geography, and disability in education?

22 citations · 22 sources · 5 cross-references

Claim 1 disputed

The most reliable way to prevent AI from amplifying inequalities of class, language, geography, and disability is to treat equity as a precondition built into funding, design, and governance from the outset, rather than as a benefit expected to follow from availability. In practice that means putting tools first in the hands of the students with the weakest prior preparation, building them with the communities they are meant to serve rather than for them, and auditing them continuously for bias that compounds over time.

The optimistic case for AI in education rests on a genuine insight. For the first time, something approximating a personal tutor, patient, adaptive, and available at midnight, could be within reach of any child with a device and a connection. The Harvard Advanced Leadership Initiative's Social Impact Review argues that access to high-quality one-on-one tutoring, which most families cannot afford, has long been one of the largest barriers to academic success for low-income students, and that generative AI could help close this gap at a fraction of the cost. The broader scholarship is more guarded. In an interdisciplinary review in PNAS Nexus, Capraro, Lentsch, Acemoğlu and colleagues (2024) conclude that generative AI has the potential both to exacerbate and to ameliorate socioeconomic inequalities. In education specifically, they write, it offers personalized learning but may widen the digital divide, and they assign policymaking a central role in tipping the balance. Farahani and Ghasemi (2024)

reach a similar double-edged conclusion. On their account, AI could make education more accessible and affordable, yet algorithmic biases embedded in AI systems can perpetuate discrimination against marginalized communities unless ethical development and responsible governance intervene.

The historical pattern of democratizing technologies is discouraging. They tend to benefit the already-advantaged first and can leave the gap wider than they found it. Commentary on AI tutoring makes the same point: access alone will not close the gap. Avoiding that outcome requires confronting four distinct and compounding fault lines.

The first fault line is class, and it begins with infrastructure rather than software licenses. Commentary on the AI tutoring equity gap cites a figure of roughly nine million American students without reliable home broadband. This is a policy estimate rather than a research finding, but it signals a floor beneath which no tool can help, and the problem is far graver globally. Writing on low- and middle-income countries in Frontiers in Education, researchers (2025) stress that physical deficits, including unreliable electricity and inadequate facilities, severely limit the feasibility of digital tools. Without investment in that foundation, they warn, AI adoption risks remaining a distant aspiration rather than a practical solution. Industry commentary on AI tutoring in developing nations is more upbeat about leapfrogging these constraints. Such claims come from a commercial source, however, and should be read as advocacy rather than evidence.

Governments are beginning to respond. The UK government has announced plans to make AI-powered one-to-one tutoring available to up to 450,000 children from disadvantaged backgrounds, offering personalized support to those who cannot afford private tutors. Whether such programmes narrow the gap or simply layer a new digital hierarchy over existing ones remains unclear. The outcome depends on whether the tools actually reach students with the weakest, rather than the strongest, prior preparation, and on whether those students have the devices, connectivity, and adult support needed to use them well. A 2026 Frontiers in Computer Science analysis of AI and the digital divide frames the issue in the same terms: access, skills, and the quality of use are separate layers of disadvantage, and closing one does not close the others.

The second fault line is language, and the linguistic geography of AI is radically uneven. An analysis published in Undark notes that only about seven percent of the world's roughly 7,000

languages are reflected in published online material. It adds that UNESCO estimates only around 400 languages are fully accessible online. The training data underlying most large language models is therefore a thin slice of human expression. English remains the dominant language of AI development and application, and that dominance can marginalize other languages, limiting access to educational content for speakers of Indigenous languages in particular.

The injury is not only one of access. AI output often reflects a 'WEIRD' perspective, meaning Western, Educated, Industrialized, Rich, and Democratic. This tilt leaves out the perspectives of minority groups and underprivileged communities, effectively reproducing and reinforcing existing social hierarchies (the cultural dimension of this bias is treated in depth at Q019; see Q019). Arora (2024) sharpens the point from a decolonial standpoint. The Global South, she observes, has become a significant player in the data economy because it supplies the majority of users, yet its cultural contributions are rarely acknowledged in how AI systems assign value. She proposes a creative data justice framework, drawing on Indigenous systems of care, that challenges power imbalances in global data governance.

Work on second-language learning complicates any simple story of deprivation. Research on distributed agency in language learning suggests that generative AI can become a genuine resource for learners and teachers. Its usefulness, however, depends on how agency is shared among learner, teacher, and machine, and it is not a property of the tool alone. López-Gazpio (2025) likewise argues that large language models can mitigate barriers of language diversity and cultural difference. He insists, though, that this potential is realized only under instructor-guided deployment that attends to cultural sensitivity. His study is a review of trends rather than an empirical trial, so its optimism should be treated as a hypothesis.

Linguistic bias has a particularly sharp edge in academic integrity enforcement. A widely cited Stanford study, summarized by Berkeley's D-Lab, found that more than 19 percent of essays written by non-native English speakers were unanimously misclassified as AI-generated by seven different detectors. Ninety-seven percent of those essays were flagged as suspicious by at least one detector. The mechanism is revealing. Non-native writers tend to adhere more closely to standard syntax and vocabulary, which produces lower perplexity scores, and low perplexity is exactly the signal detectors read as machine authorship. The result is a significantly higher false positive rate for this population, which reinforces structural inequities in education.

The broader case against detection points the same way. A critical review of generative AI detection in higher education assessment argues that detectors are insufficiently reliable to justify high-stakes decisions, and that their errors fall unevenly across student groups. Legal commentary on academic integrity enforcement adds that students accused on the basis of detector scores often have little procedural recourse. The evidence base on detector bias is not yet large, and detectors continue to change. The direction of the findings has nonetheless been consistent enough that relying on detection as the primary integrity mechanism is difficult to defend on equity grounds (the wider question of integrity when assistance and authorship blur is addressed at Q017; see Q017).

The third fault line is geography, and it reflects where AI is built as much as where it is used. According to the 2025 Stanford AI Index, global AI activity, from model production to investment, is heavily concentrated in a few regions, chiefly the United States, China, and parts of Western Europe. Many non-English-speaking nations lack the technological and economic resources to develop generative AI tailored to their own linguistic and cultural needs. A UNESCO analysis has warned that fully digitalizing education in low-income countries could add 50 percent to the education financing gap those nations already face. That figure should give pause to anyone presenting AI as a cheap substitute for teachers.

Geography also shapes access through regulation. A study of Chinese university students shows them navigating between restricted global generative AI tools and permitted domestic alternatives. Their experience indicates that the tools available to a learner depend on national policy as well as on cost and connectivity, so students in different jurisdictions effectively learn alongside different machines.

The epistemic dimension of this concentration is as troubling as the economic one. Whose knowledge is encoded, and whose is discarded, has profound consequences for what students in different parts of the world are taught to regard as authoritative. Arora's (2024) call to restructure global data governance applies here with particular force, because communities that supply data without shaping the systems built from it are being incorporated on terms they did not set.

The fourth fault line is disability, where AI tools carry assumptions about what normal learning looks like. Foley and Melese (2025), writing in the British Journal of Sociology of Education, draw on Critical Disability Studies, disability justice, and intersectionality. They argue that AI

technologies in education reproduce systemic inequalities by embedding ableist and normative assumptions into their design and use, marginalizing non-normative ways of learning and knowing. Their analysis is theoretical and case-based rather than statistical. It examines chatbots, learning analytics, robotic tutors, and intelligent tutoring systems, and it identifies patterns of sociotechnical ableism, algorithmic marginalization, and limited technological agency. They also reject the view that such harms are inevitable or merely technical, tracing them instead to policy, ideology, and technosolutionist narratives that obscure the contributions of disabled people. Related work on generative AI in higher education describes a similar marginalization of disability knowledge in model outputs.

The promise is nonetheless real, and here the literature genuinely disagrees in emphasis. Adaptive platforms such as Kurzweil 3000 adjust content and pace to identified needs. Text-to-speech and real-time translation tools open courses to students with visual or auditory impairments, and speech recognition can support those with specific learning disorders. López-Gazpio (2025) counts learning disabilities among the barriers that large language models could significantly mitigate. Yet students with disabilities are particularly exposed to AI bias, because diverse user input is largely absent from the training of most models. Students on the autism spectrum face a further indignity. Their structured or literal writing styles may resemble AI-generated text, and in documented cases this has led to false accusations of academic dishonesty. Scholarship drawing on the social model of disability argues that governance should locate the problem in exclusionary systems rather than in individual impairments. On that view, the remedy is to redesign institutions and procurement, not merely to add accommodations at the margins.

What prevention requires follows from these four fault lines, and none of it will be produced by the market alone. The first requirement is investment in foundational infrastructure of electricity, connectivity, and devices. The second is sustained teacher training that builds both technical competence and the critical capacity to evaluate and adapt AI for local pedagogical purposes, a priority emphasized in research on low- and middle-income countries. Tools must also be co-created with the communities they are meant to serve rather than optimized by engineers and delivered downstream. Foley and Melese (2025) make this case for participatory, justice-oriented approaches that centre human variation. Laukkonen and colleagues (2026), writing from within AI alignment research, independently propose design principles of

community customization, contextual grounding, and polycentric governance, meaning many legitimate centres of oversight rather than one.

Oversight must also operate at every stage. Algorithmic bias enters at multiple points, from data collection to institutional policy, and without ethical oversight and accountability at each point, AI systems actively introduce new and opaque barriers to assessment and opportunity. Evidence from a neighbouring field suggests why fragmented governance fails. Van Kessel and colleagues (2026), writing on health systems, argue that legal frameworks, evidence generation, regulation and market access, workforce readiness, and public trust form a cyclical governance chain in which weaknesses cascade across domains. Education is not healthcare, and that analogy remains untested. Still, the logic plausibly carries over: a well-designed tool deployed into weak procurement, untrained staff, and absent evaluation can widen the disparities it was meant to close. Capraro and colleagues (2024) likewise caution that explicit trade-offs make it hard to predict in advance which policies will succeed, which argues for continuous evaluation rather than one-time approval. The obligations this places on developers and vendors are taken up at Q259 (see Q259).

Most crucially, bias can be reinforced through patterns of user interaction, so that inequities compound over time rather than dissipate. The danger is therefore not a single moment of exclusion but a self-reinforcing drift. Reversing it will require active, sustained, and structurally informed intervention. That includes infrastructure funding tied to need, procurement standards that demand evidence of performance across languages and disabilities, the retirement of unreliable detectors from high-stakes decisions, and governance in which affected communities hold real authority.

Q016 What consent can a minor meaningfully give to AI-mediated education?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

A minor can give only partial, context-bound consent to AI-mediated education. Below the age thresholds set in data protection law, a child's agreement carries no legal weight for most online processing. Above those thresholds, understanding what an AI system collects, infers and does is so demanding that consent cannot bear the protective burden often placed on it. What a minor can meaningfully offer is assent and participation: an informed voice in decisions, a genuine say over optional uses, and growing control over their own data as maturity increases. The substantive work of protection has to be done by law, institutional design and oversight.

The question sits where data protection law, developmental psychology and educational ethics meet. It has become more urgent as AI systems spread through schools, collecting, processing and acting on student data in ways that can shape educational trajectories, influence identity formation and create durable digital profiles. The answer is therefore neither a simple yes nor a simple no. It depends on the legal framework, the nature of the AI system, the age and maturity of the child, and the specific processing activity in question.

UNICEF's policy guidance on AI and children helps frame the issue. It treats children as rights-holders whose development, best interests and participation should shape how AI systems are designed and deployed, rather than as users who click through terms of service. That shift matters for everything that follows. It moves attention away from whether a form has been signed and towards whether the system, and the institution deploying it, respects the child.

In the European Union, the General Data Protection Regulation and the EU AI Act together form the most comprehensive legal framework governing AI use with minors in educational settings. Article 8 of the GDPR provides that where consent is the legal basis for information society services offered directly to a child, children under 16 cannot give valid consent themselves and parental or guardian authorisation is required. Member states may lower that age to no less than 13. The AI Act (Regulation 2024/1689), which entered into force in 2024, classifies many educational AI systems as high-risk. These include systems used for admissions, grading and evaluation of learning outcomes, placement, and monitoring of student behaviour during assessment. The classification triggers strict requirements for human

oversight, transparency and documentation. Public institutions that deploy such systems must also carry out fundamental rights impact assessments. The Act goes further for one category, prohibiting emotion-recognition systems in educational institutions outside narrow medical or safety exceptions. For that category, the question of consent never arises.

The EU framework also recognises that consent is rarely the appropriate legal basis for institutional AI deployment in education. Schools typically process student data under the 'public task' or 'legal obligation' grounds. The educational relationship is not voluntary in the way a social media subscription is, and the imbalance of power between institution and pupil undermines the freedom that valid consent presupposes. Bygrave (2024) stresses the legal significance of this distinction. Framing institutional AI use as consent-based is often misleading, because the real governance challenge is not obtaining permission. It is ensuring that processing is lawful, proportionate and subject to meaningful oversight. French-language scholarship in the Revue des droits et libertés fondamentaux (2024) on minors' personal data in educational AI systems takes up the same problem. It examines how protections designed for consent-based services translate, often awkwardly, to compulsory schooling.

In the United States the framework is more fragmented. The Family Educational Rights and Privacy Act protects the privacy of student education records. It requires written consent before personally identifiable information is disclosed, subject to exceptions that include legitimate educational interests. The Children's Online Privacy Protection Act governs data collection from children under 13 and requires operators of websites and online services to obtain verifiable parental consent. The Federal Trade Commission's 2025 amendments to the COPPA Rule strengthened requirements on data retention, deletion and disclosure to third parties. Reidenberg and Schaub (2024) argue that neither statute was designed for AI. In their analysis, both leave significant gaps when applied to systems that continuously infer, profile and generate rather than simply store records.

State legislatures have begun to fill some of those gaps. California's AB 1159, which addresses student data privacy and restricts the use of student data to train AI systems, illustrates a shift in strategy. Rather than asking families to consent to secondary uses, it removes certain uses from the table altogether.

Spain offers a comparable European example. The Ley Orgánica de Protección de Datos y Garantía de Derechos Digitales sets the age of digital consent at 14 and requires explicit

parental consent for younger children. The Spanish data protection authority's guidance on AI in education (AEPD, 2024) requires educational institutions to apply data minimisation and purpose limitation to all processing of student data, including through AI systems. Read together, these regimes show considerable variation in age thresholds and legal bases. Yet they converge on the view that the most consequential protections should not depend on a signature, whether from a child or a parent.

Beyond the legal question lies a developmental one: even where the law permits a minor to consent, can that consent be meaningful? Steinberg (2013) and the broader research on adolescent decision-making consistently find that the capacity for autonomous, informed choice develops gradually through adolescence. Individual variation is substantial, and the capacity is not fully mature until the early twenties. Meaningful consent to an AI system requires understanding what data is collected, how it is processed, what inferences are drawn and what the long-term consequences might be. These demands are unusually heavy. They call for general cognitive maturity and also for a specific AI literacy that most adults, let alone children, do not possess.

This gap produces what scholars describe as a 'pre-consent harm' problem. The LSE evidence review on children's data and privacy online, led by Livingstone, shows that children's understanding of commercial and institutional data flows lags well behind their use of digital services. Some AI systems function as formative environments, shaping attention, preferences and identity through algorithmic reinforcement. Such systems can cause harm before a child is mature enough to understand or resist the influence. On this account the harm lies less in data collection itself than in the cumulative effect of algorithmic shaping on a developing mind. Traditional 'notice and choice' consent cannot address it, because that model assumes a discrete, comprehensible transaction rather than an ongoing and opaque process of influence. How large such effects are over the long term remains unclear (see Q015).

Work on adult autonomy suggests why design matters more than disclosure. Fossa (2024), writing about driving automation, argues that AI's impact on human autonomy is ambiguous. He finds that the literature has treated it at too general a level to yield useful design insights, and calls for applied analysis of specific system functions. Winslow and colleagues (2026), revisiting the human-centred AI grand challenges for generative AI, identify preserving human autonomy as one of the critical new requirements. Experimental evidence from McGuire, De Cremer and Van de Cruys (2024) points the same way. Across two studies of poetry writing,

participants were most creative when working alone. They showed a creativity deficit when editing an AI-generated poem, a deficit that disappeared when they co-created with the AI, with creative self-efficacy as a key mechanism. These findings come from adults and non-educational settings, so extrapolating them to children is speculative. They nonetheless suggest that whether an AI system supports or erodes a learner's agency depends heavily on its interaction design, and no consent form can address that.

Where minors cannot exercise their own data rights, proxies exercise them, usually parents or guardians. This creates three further governance problems. First, proxy rights assume that parents have the knowledge and capacity to decide on their children's behalf. That assumption becomes harder to sustain as AI systems grow more complex and their effects less predictable. Second, proxy consent can conflict with the child's developing autonomy. A teenager may have legitimate interests in controlling their own data that differ from their parents' preferences. Third, the practical mechanics of proxy rights, such as verifying parental identity, managing competing claims and handling disputes, are tasks for which most educational institutions are poorly equipped (Bygrave, 2024).

Recent empirical work deepens the first problem without resolving it. Akakpo and colleagues (2025) applied Communication Privacy Management theory to thematic analysis of 42 interviews with AI experts. They identified six themes: human agency, data use and abuse, transparency and opacity, information weaponisation, cyberbullying, and privacy enforcement. They argue that AI's advance will challenge traditional concepts of privacy ownership. Proxy consent rests on a clear model of who owns a child's information and who may co-own it, so this argument suggests the model itself is under strain, not merely the competence of individual parents.

Khurramov and colleagues (2025) surveyed 341 educators and students in Uzbekistan, Kazakhstan and Kyrgyzstan about AI in legal and science education, using questionnaires and open-ended responses. Participants were substantially optimistic about AI's capacity to personalise learning and strengthen analytical thinking. They also voiced strong concerns about ethical oversight and legal ambiguity, including on consent and data protection. The study measured perceptions rather than outcomes and did not focus on minors. It does suggest, however, that uncertainty about who may authorise what is felt well beyond the Euro-American jurisdictions that dominate the literature. When families object to AI use outright, the proxy problem becomes a question of conscience as well as data (see Q109).

The evidence therefore points towards governance that does not rest primarily on consent, whether from minors or their parents, but builds protection into the design and deployment of AI systems. This 'upstream' approach prioritises system design, data minimisation, purpose limitation and transparency over downstream enforcement through consent mechanisms. It draws support from the LSE evidence review, from UNICEF's guidance and from the structure of the AI Act itself. Its core elements are mandatory fundamental rights impact assessments before high-risk systems are deployed in schools, and data minimisation that limits collection to what the educational purpose strictly requires. It also prohibits profiling that creates durable, consequential records of student behaviour. Qualified professionals must review AI outputs before they affect educational decisions. Students and parents must receive meaningful information about how systems work and what they do. Brandão's (2025) broad synthesis of AI's societal impact reaches a parallel conclusion, calling for proactive governance and ethical frameworks rather than reactive correction, though at a level of generality that offers little specific guidance for schools.

The literature is not fully united here. Rights-based frameworks such as UNICEF's insist that children's participation and evolving capacities must be honoured. Some critics worry that a purely protective, upstream model treats young people as passive objects of governance and delays the development of the very agency that adolescents need. The more defensible position combines the two. Protection that does not depend on consent should set a floor, and children's informed voice should grow above that floor as their maturity increases.

For schools, the practical implications are clear even where the empirical picture is not. Institutions should not rely on consent, parental or student, as the primary governance mechanism for AI. They should conduct impact assessments before deploying AI tools and require vendors to demonstrate compliance with applicable data protection law, an obligation whose enforcement is examined elsewhere (see Q259). They should build data minimisation and purpose limitation into procurement and design, and ensure human oversight of AI-generated decisions that affect students. They should give students and parents accessible information about AI use, framed as a transparency obligation rather than a consent mechanism. Where an AI system is optional rather than integral to the educational programme, genuine opt-out should be available without educational penalty. Within that structure, adolescents should be consulted and their assent sought. Their assent cannot make a harmful system acceptable, but seeking it is how the capacity for meaningful consent is learned.

Q017 How do we preserve academic integrity when the boundary between assistance and authorship dissolves?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

We preserve academic integrity when assistance and authorship blur by relocating integrity from the question of who typed the words to the question of who can account for them. That means demanding human accountability, transparent disclosure, assessment that makes reasoning visible, and the deliberate cultivation of students' own ethical commitments, rather than relying on surveillance tools that cannot bear the weight placed on them. The problem is not, at its core, technological. It concerns what authorship means and why it has ever mattered. Authorship has traditionally implied a cluster of things that travel together: intellectual origination, accountability for error, and the capacity to stand behind one's claims. When a language model drafts the sentences a scholar submits under their name, that cluster begins to come apart, and institutional life has not yet caught up with the consequences.

Recent philosophical and empirical work suggests the unbundling is real rather than rhetorical. Bisenbaev (2026) argues that contemporary large language models exceed the role of a "mute" procedural accelerator. In his account they participate in generating explanatory structures, reframing research problems and reconfiguring the knowledge corpus. He therefore proposes moving the debate away from the ontological dichotomy of "tool versus author" toward an epistemology of contribution. The lived experience of academics points the same way. In a

mixed-methods survey of 109 faculty, Vassallo (2026) found that 35% worried AI undermines their credibility and 26% felt they were "cheating". Respondents' narratives repeatedly returned to the question "are AI-assisted ideas still mine?" Wu's (2026) interviews with twenty-one doctoral students at a large U.S. research university describe careful "boundary work between assistance and authorship". These students separated grammar support, translation, coding help and conceptual orientation from intellectual substitution. Neither study is large, but together they suggest that the people inside academic institutions already feel the authorship cluster fracturing, even where policy treats it as intact.

The current institutional response has settled, for now, on a firm position. Authors are held solely responsible for all content. AI tools cannot be listed as authors or co-authors. Human judgment and verification are treated as indispensable. Thesify's 2025 guide to publisher policies reports that this stance is now effectively universal among major academic publishers: Elsevier, Springer Nature, Wiley, Taylor & Francis and SAGE Publishing all explicitly prohibit listing generative AI or large language models as an author. The justification is straightforward. The fundamental responsibilities of academic authorship include taking full accountability for a work's integrity, managing legal agreements and approving the final manuscript, and only humans or legal persons can fulfil them. Institutional integrity policies surveyed by EyeSift echo this logic at the level of student work: responsibility for submitted content cannot be delegated to a tool.

This consensus rests on a defensible moral intuition, and moral philosophy offers some support for it. Cho (2026), writing from a Thomistic framework, argues that algorithmic systems cannot possess genuine moral knowledge or exercise practical wisdom. On this view, the decisive question is whether a system supports or substitutes for human moral reasoning, never whether it can itself bear responsibility. Accountability, in other words, has nowhere else to land. The consensus is less settled than its uniformity implies, however. Bisenbaev (2026) accepts that authorship must remain compatible with an anthropocentric legal order, yet argues that this compatibility need not mean pretending AI's cognitive participation is negligible. He proposes describing authorship as "distributed epistemic authorship", a network of people, artifacts and algorithms in which legal responsibility stays human while contributions are traced and measured. The disagreement is therefore not about whether a chatbot can sign a copyright agreement. Nobody serious claims it can. It concerns whether the binary of "author or tool" still

accurately describes how scholarly work is produced. Publisher policy answers yes; part of the philosophical literature answers no.

Transparency through disclosure has become the dominant governance mechanism. The Committee on Publication Ethics published formal AI authorship guidelines in 2023, updated in 2025. They hold that AI tools cannot be listed as authors and require that their use be disclosed in the methods section. Thesify's 2025 compilation reports that approximately 70% of journals had established AI usage guidelines by January 2025. That figure comes from a publishing-guidance resource rather than a peer-reviewed census and should be read accordingly. The same source describes a broader trend in academic publishing toward accepting AI tools while requiring disclosure. For students, the practical question of how to document AI use honestly, and how to build habits that carry into professional life, deserves separate treatment (see Q083).

Disclosure requirements, however well-intentioned, face a fundamental enforcement problem. An analysis posted to arXiv (2025) found a significant increase in AI-generated content in academic writing from 2023 onward. Journals with and without AI policies showed parallel growth trends. This suggests that publishing an AI policy has not meaningfully affected researchers' use of AI writing tools. Because the finding is observational, it cannot establish why policies fail. Weak enforcement, ambiguous wording and researchers' unawareness of the rules all remain plausible explanations.

Ambiguity in particular may be underestimated. Ruttenberg (2026) characterises the field as facing a "transparency crisis": researchers wish to use AI responsibly but lack a shared vocabulary for describing what the tools contributed. His AIR framework maps AI involvement across seven research stages and five engagement bands. In a small pilot ($n = 15$ raters, nine scenarios), trained evaluators applied it with substantial agreement (Cohen's $\kappa = 0.72$). Yet the same pilot revealed systematic boundary ambiguities. Ruttenberg also identifies limitations that bear directly on integrity policy. Structured disclosure risks false precision for ambiguous practices. It may stigmatise legitimate high-band use, including AI use related to accessibility and neurodiversity. And it remains vulnerable to adversarial compliance, meaning disclosure that satisfies the letter of a rule while obscuring its substance. Disclosure, on this reading, is necessary but cannot by itself carry the burden of integrity. Ruttenberg's argument that transparency should be treated as an epistemic virtue rather than a procedural box to tick points toward the formative approach discussed below.

This enforcement gap has pushed institutions toward automated detection, with troubling results. California State University Fullerton's Faculty Development Center cautions that the ability to detect AI-generated content is not fully reliable. It also notes a crucial difference from traditional plagiarism detection. A plagiarism checker can document the original source of copied text, whereas AI detection platforms offer no comparable evidence, only a probability. The inequity these tools introduce is especially concerning. Detectors are more likely to flag non-native English writers, because the constrained vocabulary and regular syntax of second-language prose can resemble AI output. One widely cited study, summarised in the Fullerton guidance, found that over half of TOEFL essays were wrongly flagged as AI-generated across all tested detectors. Guidance aimed at students from EyeSift likewise warns of false positives and of students' limited means to contest them. The pattern means that detection-based enforcement risks compounding linguistic disadvantage, a concern that connects integrity policy to the wider problem of AI amplifying educational inequality (see Q014).

The strongest argument against detection-based enforcement is epistemological: probabilistic tools should not make high-stakes determinations about academic conduct. Thesify's 2026 overview of how professors detect AI notes that a 2024 study documented systemic harm arising from enforcement based primarily on detection scores. Evidence on detector accuracy is contested, and vendors' claims frequently diverge from independent assessments. Even so, the burden of proof in misconduct proceedings should not rest on a score that cannot be explained or verified. The social costs of this approach also appear in a large-scale analysis by Yüce and colleagues (2026). They examined 270,000 AI-related posts and comments from 26 education subreddits between November 2022 and April 2026. They describe discourse evolving from an early "detection-and-evasion arms race" into a sustained enforcement regime, which constructive integration only began to challenge in mid-2024. Of threads involving both faculty and students, a third of cross-role contact occurred in the adversarial themes of AI detection and misconduct enforcement. Negative sentiment correlated with higher engagement. That is a correlation in self-selected online communities, not a causal finding about classrooms. Still, it suggests that detection-centred regimes shape the relationship between teachers and students as much as they police it.

The more durable response may lie not in surveillance but in redesigning what is assessed and how. As the Fullerton guidance observes, using generative AI to write an essay may not constitute plagiarism in the classical sense. It can, however, reasonably be judged "false

authorship": the student did not write the essay, which is functionally similar to having a peer write it. The 2025 AWAC Statement on AI and Writing Across the Curriculum, as summarised in EyeSift's review of integrity policies, recommends separating responsible "supporting" use from unethical "substitution". It advises students to retain primary authorship by revising and personalising automated suggestions. The distinction between support and substitution is philosophically sensible but practically elusive, which is precisely why assessment design matters more than detection. Thesify's 2026 guidance recommends that when a detector flags an assignment, instructors hold a structured conversation instead. They can ask the student to explain key paragraphs, justify sources and describe how the draft developed. This shifts the process from "gotcha" enforcement to evidence-based integrity review.

Recent scholarship suggests the support-substitution line can be made more tractable, although none of the proposals is yet validated in classrooms. Bisenbaev (2026) offers operational tests for the threshold between "support" and "creation". These ask whether AI altered the problem space, how much causal or counterfactual weight its contribution carries, whether the work could be independently reproduced without it, and whether its role is traceable. Wu (2026) found that the doctoral students she interviewed already draw similar lines unprompted, and that AI functioned for them as an access infrastructure. It lowered linguistic barriers for some and technical barriers for others. Her title captures a broader shift "from production to verification": what remains distinctively the scholar's own may increasingly be the judgment exercised over a text rather than its first drafting. That is a strong reason to assess process, reasoning and defence alongside products (see Q028).

Evidence from creative professions points the same way while warning against tidy categories. Tsao and colleagues' (2025) scoping review of 57 papers found that professionals consistently position generative AI in early-stage conceptualisation rather than final production. These professionals developed hybrid methods that preserve human judgment in convergent phases, with a broad shift from creation toward curation. Ge's (2026) four-year ethnography of 34 Chinese digital romance writers documents several coexisting modes rather than a single boundary. Writers delegate world-building and error-checking to the model, curate machine prose under platform pressure at the cost of the work's "aura", and refuse AI involvement in the emotional texture they consider beyond its competence. If professional writers negotiate the line case by case, students cannot be expected to find it from a policy sentence alone. Assessment must instead make the negotiation visible and discussable.

Underlying all of this is a deeper unresolved question. A 2024 article in the International Journal of Management and Data Analytics argues that existing authorship models are inappropriate for AI contributions. It calls for revised criteria that address the ethical and legal dimensions of accountability and intellectual property. A cross-sectoral review of AI ethics from 2019 to 2025 by Liapis and colleagues (2026) likewise singles out integrity and authorship as the defining ethical problems of AI in education. Until such criteria mature, institutions will be governing a practice whose conceptual foundations are in flux.

The most promising evidence concerns students' own values rather than rules or tools, though it remains preliminary. A 2025 survey of U.S. university students, reported as a preprint, found that personal ethical beliefs, not institutional policy, were the strongest predictors of whether students used AI in prohibited ways. A related study plan outlined by AI Flow Review sets out to test this relationship further. Predictors are associations, and a single preprint survey cannot settle causation. The finding nonetheless suggests that institutional energy may be better invested in ethical education and policy clarity than in detection-based enforcement. Qualitative work supports the call for clarity. In Alam and Dubey's (2026) thematic analysis of 23 detailed responses drawn from 55 student surveys, participants saw ChatGPT as a supportive tool when used responsibly. They remained unclear, however, about plagiarism rules, authenticity standards and institutional policy, and they worried about dependency.

That worry deserves weight, because integrity concerns the formation of the person as well as honesty toward others. Van Zyl's (2026) commentary on psychologists warns that cognitive offloading and automation bias may erode professional judgment, and that "moral deskilling" can undermine ethical autonomy. The argument concerns a different profession and rests on narrative review rather than direct measurement, but the risk plausibly extends to students whose judgment is still being formed. Vassallo's (2026) faculty found that guilt diminished with use and reported strategies such as boundary setting and transparency. This suggests that integrity norms are learned through reflective practice rather than issued by decree. Academic integrity, in other words, has always depended less on catching dishonesty than on cultivating the conditions under which honesty seems worthwhile. The technology has changed; that underlying logic has not.

Q018 Should there be a "right to a human teacher," analogous to a right to human medical care?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

There is a strong case for something close to a right to a human teacher, but the most defensible version is a rebuttable presumption in favour of human instruction, with automation required to justify itself, rather than an absolute and already justiciable entitlement. The question is less fanciful than it sounds. As AI tutoring systems become more capable and more economically attractive, the pressure to substitute them for human educators will intensify, first in underfunded school districts and then more broadly. Whether students have, or should have, a legally enforceable claim to human instruction is now a live policy question. It also connects in revealing ways to debates already under way in medicine, where the parallel claim to a human clinician has received more sustained philosophical attention.

The structural analogy to healthcare is imperfect but illuminating. Writing in Philosophy & Technology on human responsibility for artificial risks, philosophers of medicine have argued that moral agency belongs only to humans, because AI systems lack the autonomy and sentience on which agency depends, and they have used this argument against fully automated systems in clinical settings. Work in Topoi developing a substantive human rights framework for AI in health care shows how the principle of patient autonomy, which entails a right to receive reasonable explanations and to withhold informed consent, has been invoked to reject what some call "black-box medicine." Similar reasoning applies to education. If a learner cannot interrogate the reasoning behind an assessment or a pedagogical choice, something morally significant has been lost. A recent analysis of how AI knowledge should be governed,

framed in terms of epistemic authority and structural transparency, sharpens the point. When AI performs teacher-like functions such as diagnosing student understanding, planning learning pathways and adjudicating correctness, no expert may be able to examine the basis of those judgments, and intervention becomes impossible when they are wrong. On this account, the case for a human teacher rests partly on accountability: a human can be asked why, can be wrong in ways others can detect, and can be held answerable.

The rights-based case for a human teacher draws on existing international frameworks. An analysis of AI, education and children's rights in Frontiers in Education starts from the United Nations Convention on the Rights of the Child, which establishes children's rights to education, dignity, autonomy and privacy, and to protection from discrimination and economic exploitation. The authors conclude that, in the context of AI, tasks such as teaching, assessment and accreditation should not be delegated to AI systems unless it can be shown that delegation does not violate children's dignity. Even when that high standard is met, they argue, human teachers must remain central to these processes, because they are better equipped to understand and respond to children's emotional and psychological needs. UNESCO's guidance on AI and the right to education takes a similar line. As AI becomes more embedded in education systems, it raises pressing questions about rights to privacy, work, culture and autonomy, and about the right to be heard. A right to be heard implies someone with the standing and capacity to listen.

Developmental theory gives these legal arguments more weight. Navarro (2026) extends neo-ecological theory, itself an adaptation of Bronfenbrenner's bioecological model for the digital age, by conceptualising AI as a "person" within the Process-Person-Context-Time model. On this view AI is an active influence on the proximal processes, the everyday interactions and activities, that drive development. Navarro's contribution is theoretical, not empirical, but the framing clarifies what is at stake. If proximal interactions are the engine of development, then who or what occupies the teacher's place in those interactions is a developmental question, not merely an administrative one.

Pollak, Morrin and Shanahan (2026) raise a related concern. They observe that large language models can sustain long, emotionally salient conversations and induce a potent sense of connection with a human-like entity, even when users know their interlocutor is artificial. For some users, they argue, this produces a "philosophical vertigo," a loosening of the ordinary criteria by which people stabilise meaning, and clinical reports of AI-associated delusions may be sentinel events for subtler population-level effects. Their analysis concerns users generally

rather than children, and its population-level claims remain conjectural. Still, it suggests that a human teacher may matter as an anchor against epistemic destabilisation during formative years. How much weight that should carry, given how little is known about long-term effects on children (see Q015), and how far minors can meaningfully consent to AI-mediated instruction (see Q016), remains unclear.

UNESCO has been the most prominent institutional voice on this question. Its position, endorsed by the Santiago Consensus at the World Summit on Teachers and set out in its reflections on AI and the future of education, is that teachers are irreplaceable and that AI must support, not replace, educators. A paper from the UNESCO Teacher Task Force, as reported by EdTech Innovation Hub, argues that AI can support teaching by automating certain tasks and providing data-driven insights. It cannot, however, replicate the relational, ethical and human dimensions of teaching. The paper adds that framing teachers as replaceable risks undermining professional identity and reducing education to a purely technical process. This is a normative and policy consensus, not an empirical finding. Its strength lies in its breadth of endorsement rather than in controlled comparisons of human and machine instruction.

Adjacent work on caregiving helps explain why the relational argument persists even as AI capability grows. Respess (2026) evaluates social robots against a heuristic of good care drawn from care theory: humble inquiry, inclusive connection and responsive action. He finds that robots can already meet a range of needs and can mirror certain desirable emotional and social traits. They still face pressing challenges in developing tacit knowledge, showing emotional sensitivity and tailoring responses to diverse users. More fundamentally, Respess argues that robots cannot themselves benefit from the moral resources of a care relationship. Their embodied constraints limit their ability to improvise, empathise and mobilise to a degree comparable with humans, and this risks reinforcing "a thinner and unidirectional account of care." Teaching is not identical to caregiving, but the parallel is close. If education involves a reciprocal relationship in which teacher and student both have something at stake, a system that only appears to participate changes the nature of the practice, not just its delivery. Przygoda, Rynio and Kalisz (2025), in a critical-hermeneutic meta-analysis spanning philosophy, education and pastoral theology, likewise centre their concern on AI's impact on persons and personal relationships. This reminds us that the value placed on human presence often has religious and philosophical roots that families may hold deeply (see Q109).

The analogy to medicine also exposes a tension that advocates of a formal right must confront. In healthcare, AI has outperformed human specialists in certain diagnostic tasks. The Topoi analysis records that AI applications have begun to diagnose some types of cancer better than doctors, identify heart rhythm abnormalities as well as cardiologists, and diagnose various eye diseases as well as ophthalmologists. If we would not insist on a human radiologist when an algorithm is more accurate, then the argument for mandatory human involvement must rest on something beyond competence. It must rest on the intrinsic value of the human relationship itself.

The competence picture is more mixed than headline comparisons imply, and here the literature plainly disagrees. Krichevsky and colleagues (2025) compared ChatGPT (version 3.5) with physicians on 70 real-world pharmacotherapy queries submitted to the drug information centre of Hannover Medical School. Three blinded evaluators, with beginner, advanced and expert levels of experience, all rated the physicians' answers higher for quality of information and preferred them. All three also detected factually wrong information more often in the chatbot's responses. This is a single study of an older, openly available model in one specialised domain, so it cannot settle the general question. It does show that superiority in narrow image-based diagnosis does not transfer automatically to open-ended advisory work, which resembles much of teaching. Ong and colleagues (2026), using ophthalmology as an exemplar, add that medical AI models often fail to generalise. Academia, they argue, lacks a systematic science of retraining and maintenance, so performance shown in proof-of-concept studies may not persist in deployment. Both findings complicate any argument that would make the right to a human contingent on human superiority, since measured superiority may be fragile in either direction.

In education, the relational value is more plausibly central than in diagnostic medicine. A review on whether AI will replace or assist teachers argues that effective teaching requires empathy, judgment and the ability to respond to diverse student needs, capabilities it holds cannot be automated. It adds that teachers often help shape students' moral and ethical values by discussing complex issues and encouraging reflection, guidance that AI systems lack the capability to provide. Some scholars dispute whether such limits are permanent. Torrance, Tomlinson and Filippi (2026) describe AI systems that converse fluently, interpret human emotions and, they claim, infer personality traits from subtle cues with superhuman acuity, and they anticipate a "social superintelligence" that may rival or surpass human social abilities. If that trajectory holds, arguments resting on AI's inability to read students will weaken. The case

for a human teacher would then depend more heavily on Respess's point about reciprocity, and on accountability and moral standing, than on perceptual skill. Advocates would be wise to build on those firmer foundations now.

A distributional dimension gives the rights question added urgency. The Center for Democracy and Technology, reviewing the 2025 state legislative session, notes unprecedented federal attention in the United States to accelerating AI deployment in K-12 schools. It also notes growing evidence that this expansion is associated with increased risks to students. That evidence is correlational and still accumulating, but the policy direction is clear. The danger is not that wealthy private schools will replace their teachers with chatbots; they will not. The danger is that AI substitution will be imposed on precisely the students who already receive the least human attention. Capraro, Acemoğlu and colleagues (2024), in an interdisciplinary review of generative AI's effects on socioeconomic inequality, capture the ambivalence. In education, generative AI offers personalised learning but may widen the digital divide. In healthcare, it may improve diagnostics and accessibility but could deepen existing inequalities. They stress that these trade-offs make a priori predictions difficult and that policy choices will largely determine which way the balance tips.

Seen this way, a right to a human teacher is partly a proxy for a right against educational neglect dressed in technological clothing. It would protect not an abstract preference for human contact but a floor of human attention below which no student's education may fall for budgetary convenience. This also bears on the obligations of AI companies toward education systems they disrupt but do not serve (see Q020), and on the duties educators owe to students who cannot or will not use AI (see Q111).

Current consensus does not quite land at a codified right. It lands at something close to a rebuttable presumption: human teachers should remain central, AI should be deployed only where it demonstrably serves learners without violating their dignity, and the burden of proof falls on those proposing automation. That formulation draws together the children's-rights analysis in Frontiers in Education, UNESCO's insistence that teachers are irreplaceable, and the accountability concerns carried over from medical ethics. It also leaves room for the empirical uncertainty described above. A presumption can tolerate evidence that AI performs some instructional tasks well, provided that evidence is robust, maintained over time and does not come at the cost of the relational and accountable dimensions of teaching. In practice it implies

classroom-level judgment about when AI aids or undermines learning (see Q078), and regulatory mechanisms that place real obligations on developers (see Q259).

As UNESCO observes, embedding AI in education systems raises pressing questions about rights to privacy, work, culture and autonomy, and about the right to be heard. Whether those concerns eventually crystallise into a justiciable right to human instruction, as the right to a human clinician may yet do in medicine, remains genuinely open. The strongest version of the case will not rest on claims that machines are incompetent, which may prove temporary. It will rest on claims that human teachers provide answerability, reciprocity and a guaranteed share of human attention that a just education system owes every child.

Q019 How do we address the cultural and ideological biases embedded in models trained predominantly on certain languages and worldviews?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

The cultural and ideological biases embedded in language models cannot be engineered away as incidental impurities. They follow from how these systems are built, trained and evaluated, so addressing them requires measures that are political and epistemological as well as technical: diversifying data, rethinking how alignment is defined, changing who produces the infrastructure, and settling who has the legitimacy to decide which values a model should carry. Every language model is, in a philosophical sense, a theory of the world. Like any theory, it inherits the assumptions of its builders and the evidence they chose to include.

Karpouzis (2024) makes this point through Plato's Allegory of the Cave. Generative systems such as ChatGPT, he argues, see the world through training data produced predominantly by dominant cultural groups, so their picture of human life is limited and distorted. In this framing, bias is a problem of representation, not a defect in an otherwise accurate instrument. The critical data studies literature reaches a similar conclusion from a different direction. Datasets driving machine learning are far from neutral; they reflect histories of exclusion, erasure and cultural dominance. From natural language processing to facial recognition, the question of whose knowledge gets encoded is increasingly unavoidable (Critical Playground).

For education, the stakes are direct. In their systematic review of research on AI models in the classroom, Lin and Su (2024) screened 1,445 publications from 2013 to 2023 and coded 32. Algorithmic bias and discrimination was the most frequently studied of the five ethical implications they identified, ahead of privacy leakage, lack of transparency, decreased autonomy and academic misconduct. That ranking reflects where researchers have concentrated their attention. It does not measure harm. Even so, it shows that bias is already the primary ethical lens through which the field views classroom AI, and cultural bias is among its most consequential forms.

The empirical picture of cultural skew is now well documented and converges across methods. Work on responsible multilingual models for the social sciences and humanities reviews benchmarks comparing Arab and Western cultural contexts. These benchmarks show that both multilingual and Arabic monolingual models are systematically biased toward Western-associated entities. Even when prompted in Arabic about food, beverages or personal names, they disproportionately generate Western responses.

The problem runs deeper than surface vocabulary. The bias persists in models specifically fine-tuned for Arabic. More strikingly, a model may appear culturally competent when evaluated in English yet reveal significant blind spots when operating in the target language itself. This has a methodological implication. Evaluating cultural competence through English-language probes can systematically overstate it, and anyone procuring a tool for a non-Anglophone classroom on the strength of English-language evaluations may be misled.

A complementary line of evidence asks models to describe their own values. Messner, Greene and Matalone (2025) prompted ChatGPT and Bard with value questions derived from the GLOBE project's cross-cultural leadership instrument. The models' cultural self-perception

aligned most closely with the values of English-speaking countries and of countries characterised by economic competitiveness. The design has limits. It examines two commercial systems at one point in time, and self-reports elicited by survey items are not the same as behaviour in open-ended tasks. The direction of the finding nonetheless matches the entity-level results from Arabic benchmarks.

Messner and colleagues add a concern that matters especially for schools. Existing research indicates that humans may unconsciously internalise biases they encounter in these systems, and that such biases can persist after people stop using the programs. If that holds for learners, a culturally skewed tutor does more than produce skewed answers. It may gradually reshape students' sense of what counts as normal, reasonable or authoritative. This raises particular difficulties for the teaching of history, social studies and the humanities outside Western contexts (see Q243).

The ideological dimension is equally concrete, and in some respects more troubling, because it concerns factual claims rather than cultural defaults. Bilingual benchmark research on contested sovereignty questions documents what some analysts call "information cocoons" in multilingual AI: the same query produces different factual claims depending on the language in which it is asked. On contested border disputes, Hindi queries have yielded India-aligned responses and Chinese queries China-aligned responses. This pattern suggests that multilingual models may encode several inconsistent worldviews rather than any unified factual understanding. The difficulty is not cultural flavour but epistemic integrity. A student asking about a disputed territory receives an answer shaped by the language of the question, and nothing signals that a speaker of another language would be told something different.

This inconsistency is not confined to geopolitics. Research on cross-lingual stability in instruction-tuned models for humanitarian NLP raises a parallel concern: model behaviour and bias can shift across languages in settings where consistency matters for vulnerable populations. The evidence base here is still developing. How far such instability reflects the composition of training data, and how far it reflects alignment procedures applied unevenly across languages, remains unclear.

These problems persist partly because standard evaluation is poorly designed to detect them. McIntosh and colleagues (2025) critically assessed 23 state-of-the-art LLM benchmarks with a unified framework built on people, process and technology. They found significant limitations,

including biases, difficulty measuring genuine reasoning, inconsistent implementation, limited evaluator diversity, and neglect of cultural and ideological norms. They argue for moving from static benchmarks to dynamic behavioural profiling. If the benchmarks on which developers optimise largely ignore cultural and ideological variation, then improved benchmark scores reveal little about whether cross-cultural and cross-lingual consistency has improved. A model can climb the leaderboards while its information cocoons remain intact.

Beneath these phenomena lies a structural imbalance in who supplies the data and who builds the systems. Addressing it is not just a technical problem. As the critical data literature puts it, it is a cultural and political challenge that demands a rethink of authorship, representation and participation in AI design. Research on African educational and linguistic contexts observes that many AI systems, rooted in Western epistemologies, fail to account for the linguistic diversity and socio-cultural realities of communities in the Global South. Work on digital colonialism in Global South governance adds that contemporary AI models, founded on Global North notions and data, frequently produce biased outcomes that exacerbate existing inequalities. Bias in this sense is continuous with the wider patterns by which AI can amplify inequalities of language and geography in education (see Q014).

The imbalance extends to the workforce. Ulnicane (2024) analysed four high-profile reports on intersectionality in AI. They frame the problem as a vicious cycle: a diversity crisis in the AI workforce leads largely homogeneous groups of developers and founders to build their own biases into AI systems. The reports note that earlier diversity initiatives have not worked. They call for a holistic approach that addresses culture, power and opportunities for influence, not just headcounts. Ulnicane's evidence concerns how policy documents frame the issue, not a measured causal link between workforce composition and model outputs. That causal claim is plausible but less directly tested than the documentary analysis itself.

At stake is more than representation in outputs. Segun (2024) argues that two values prized across nearly all documented versions of sub-Saharan African ethics may sit in direct opposition to the fundamental motivation of corporate AI adoption. These are Afro-communitarianism grounded in relationality, and human dignity grounded in a normative conception of personhood. Segun notes that little to no literature had examined AI's implications for African ethical values. His argument is philosophical rather than empirical, but it widens the frame. A model that writes fluently in an African language may still carry, in its

design purposes and interaction patterns, an individualist and efficiency-oriented ethic that sits uneasily with the communities it serves. Translation does not fix that.

The standard technical response is to collect more diverse data and fine-tune models to reduce measured bias. This is necessary but insufficient. Research operationalising pluralistic values in alignment finds that current LLMs display far less preference variation than humans across cultural and political lines. The result is an "algorithmic monoculture" that overlooks the diversity of human values. The same work reports trade-offs between safety, inclusivity and model behaviour when pluralistic values are built into alignment, which means pluralism is not a free addition to existing objectives.

The alignment process itself is part of the problem. Organisers of the first workshop on pluralistic value alignment at AACL 2026 observe that existing studies have largely focused on generic safety or on alignment to a single core value. Pluralistic alignment remains underexplored, even though human values are diverse and context-dependent. Alignment is not monolithic, because cultural value systems differ and often conflict.

A more promising direction is pluralistic alignment proper: designing systems that can recognise, hold and navigate competing value frameworks rather than collapsing them into a dominant consensus. Recent work suggests that LLMs internalise culturally specific preferences that shape downstream reasoning. Researchers have proposed two responses. One is culture-conditioned approaches; the other is agentic debates that reconcile competing value targets. This work indicates that cultural priors shape model outputs and that single-objective alignment can obscure equity concerns in high-stakes, cross-cultural contexts. These are early proposals, and whether they generalise beyond the settings in which they were tested remains unclear.

There is genuine disagreement about how far technical intervention can go. Karpouzis (2024) proposes combining data diversification and culturally aware model constraints with reflexive scrutiny of the cultural contexts of AI development. He holds that controlling cultural bias is inseparable from the wider project of equity in AI governance. Naudts and Vedder (2025) are more cautious about formalisation. They treat fairness, justice and equality as essentially contested concepts and examine the limits of techno-solutionism and of attempts to formalise fairness by design. Their central claim is that fair AI is not an insular engineering exercise: the social processes, structures and relationships that co-shape these systems matter as much as

their procedures and outputs. On this view, a culture-conditioned model still embeds a prior decision about which cultures exist, how they are bounded and who speaks for them.

On the data infrastructure side, community-driven initiatives point toward a different model of production. The Masakhane Project is a grassroots research collective across Africa. It develops open-source datasets, models and tools for African languages, in a field where most mainstream NLP systems privilege English and a handful of global languages and sideline hundreds of millions of speakers. Such projects suggest that decolonising AI is less about "fixing" biased systems from outside than about designing infrastructures that begin from different worldviews.

Ofosu-Asare (2024) develops this into a methodology for countering what he calls cognitive imperialism. He proposes participatory co-creation with indigenous communities, ethical protocols for indigenous data governance, and adaptation of AI algorithms themselves. He reports case studies in natural language processing, content moderation and healthcare as evidence of the methodology's effectiveness. The abstract does not report effect sizes or comparative outcomes, however, so how much these approaches reduce measured bias, as opposed to improving process legitimacy, remains to be established.

None of these approaches fully resolves the question of legitimacy, which remains open: who decides which cultural values are encoded, and through what process? The decolonial governance literature holds that fair algorithms require local knowledge and cultural values to be taken into account, with community input central to decision-making. That principle leaves hard cases unsettled. Communities are internally plural. The groups positioned to speak for them may not represent their least powerful members. The firms that control frontier models are not accountable to the communities their products reach. These asymmetries bear directly on what AI companies owe to education systems they disrupt but do not serve (see Q020).

For educators, three practical consequences follow. Cultural competence should be assessed in the language of instruction, not inferred from English-language evaluations. Students can be taught to treat cross-lingual inconsistency as an object of inquiry, for instance by posing the same contested question in different languages and comparing the answers. Institutions should also prefer tools developed with, not merely for, the communities they serve.

As of mid-2026, the field has compelling diagnoses and promising early interventions, but no settled solution. Mistaking technical mitigation for genuine cultural pluralism remains one of the deeper hazards ahead.

Q020 What ethical obligations do AI companies have toward education systems they disrupt but do not serve?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

AI companies that reshape education without serving it owe it obligations proportionate to the disruption they cause. At minimum, they must be transparent about how their systems work and who answers for them, submit to independent audit, provide meaningful access to the populations they would otherwise leave behind, and refrain from setting the terms of educational policy on their own. The question's premise deserves scrutiny first, because the distinction between disrupting and serving carries the argument. To disrupt is to alter the conditions under which teaching and learning occur: rewriting what counts as student work, reshaping the value of credentials, and recalibrating the skills an economy demands. To serve is to bear the costs, meet the needs, and accept accountability for the populations affected. The two are not the same, and the most serious ethical obligations sit in the gap between them.

That gap has widened as AI power and education policy have converged. Leon Furze documents that in July 2025 OpenAI released an "Economic Blueprint" for Australia, a document offering recommendations and advice on Australian government policy across several sectors, including education. A similar pattern appeared elsewhere. In the United States, a June 2025 "Pledge to America's Youth" on AI education was signed by more than sixty organisations. By Furze's analysis, more than half of them were big technology companies or their venture capital funders, among them Amazon, Apple, Google, Meta, Microsoft and

OpenAI. The White House presented these commitments as a mobilisation of major organisations behind AI education. Furze's reading is less charitable: these companies have, in effect, taken it upon themselves to determine the future of AI in American schooling. Whichever framing one prefers, the asymmetry is plain. The entities shaping the terms of educational disruption are the same ones positioned to profit from it.

Wang's (2024) actor-network analysis of AI in smart-city construction offers a useful structural parallel, although it concerns urban infrastructure rather than schools. Wang traces how governments, technology development companies and residents are drawn into a network through problem statement, interest alignment, recruitment and mobilisation. The point transfers to education. Whoever frames the problem tends to define the solution, and residents or students enter late, as recruited participants rather than authors of the arrangement.

The most concrete harm of disruption without service is inequity. The systematic review published in Frontiers in Education argues that the effect of generative AI on digital equity depends on how it is implemented: without guaranteed equitable access, the digital divide could widen. The OECD's analysis of AI's potential impact on equity and inclusion makes the same conditional point. These technologies can support inclusion, but nothing in their design guarantees that they will. Commentary on the rapid commercial expansion of classroom AI goes further. It warns that advanced, expensive tools threaten a dramatic new educational divide, with critics suggesting that students who can afford them may gain "almost superhuman academic capabilities" over peers without access. That phrase is a rhetorical forecast rather than a measured finding, and it should be read as such. Reporting on AI adoption in schools in 2025 describes uneven uptake, especially between urban and rural districts. This is a more modest claim, but it is directly observable.

The Frontiers review leaves two questions open, and both bear on corporate obligation. How should institutions respond to generative AI companies that seek a role in education while pricing their tools beyond reach? And why are academic-use models not more broadly supported or subsidised? These are not questions schools can answer alone. They concern the pricing and licensing decisions of the firms themselves.

Zhu, Sun and Yang (2025) give this concern a firmer conceptual footing. Their systematic review, combined with grounded-theory coding, sorts the ethical risks of AI in education into three dimensions: technology, education and society. In the societal dimension they identify

three risks: the exacerbation of the digital divide, the absence of accountability, and conflicts of interest. The grouping matters. It places inequity alongside accountability and commercial interest as linked features of how AI enters schools, rather than as a side effect of individual tools. Evidence from neighbouring sectors points the same way. Couture and colleagues' (2025) scoping review of 243 articles on AI and big data in population health concludes that positive outcomes remain uncertain and that benefits may be unequally distributed, both within populations and between them. The domain is different, but the structural warning is the same. Whether AI's equity effects in education will turn out net positive or net negative remains unclear, and the evidence base is too young to settle it.

A second cluster of obligations concerns bias and the integrity of pedagogical systems. AIhub's review of the year's major ethics and policy issues observes that algorithmic discrimination remained a significant challenge in 2025, despite advances in dataset auditing and fairness tools. It notes that models used in education continue to mirror historical inequalities. The Frontiers review adds a different kind of harm: cognitive dependence. Excessive use of generative AI may inhibit students' development of critical thinking and autonomy. The empirical base for this claim is still thin and largely short-term, so it is better described as a credible concern than an established effect.

Zhu, Sun and Yang (2025) widen the inventory considerably. In the technology dimension they list privacy invasion, data leakage, algorithmic bias, black-box algorithms and algorithmic error. In the education dimension they list homogenised student development, homogeneous teaching, a crisis in the teaching profession, deviation from educational goals, alienation of the teacher-student relationship, emotional disruption and academic misconduct. Their taxonomy shows that the risks extend well beyond cheating, the concern that dominates public debate (see Q075 on integrity frameworks).

The teaching-profession risk has indirect support from organisational research. Kim and Kim (2024) collected data at three time points from 402 employees across industries in South Korea. They found that AI-induced job insecurity was positively related to knowledge-hiding behaviour, both directly and indirectly through reduced psychological safety. Self-efficacy in AI learning buffered the harmful effect of insecurity on psychological safety. These are associations in workplace samples, not studies of teachers, and should not be read as causal claims about schools. Still, they suggest that disruption imposed on a profession can erode the

collegial knowledge-sharing on which good teaching depends, and that investment in practitioners' confidence may soften the effect.

Taken together, these harms are not technical glitches awaiting a patch. They are structural features of how these systems were built, trained and deployed. That makes them the developer's responsibility rather than the teacher's problem, even though teachers currently absorb most of the cost.

On accountability, current practice falls short of what the moment demands. UNESCO's report on its AI Company Data Initiative argues that, as privately developed systems shape more of daily life, transparency must move beyond technical description to show how accountability actually works. That means showing who makes decisions, how ethical issues are escalated, and what remediation paths exist when things go wrong. On UNESCO's account, responsibility for harms or breaches should be identifiable in practice, not merely in principle. AIhub's review records two related warnings. The ACM cautioned about the manipulative potential of chatbots interacting with minors. UNICEF stressed that AI systems affecting children must be designed with explicit safeguards, transparency and accountability to prevent exploitation and undue influence.

The broader governance literature explains why such demands keep recurring without being met. Marszałek-Kotzur (2025) writes about industrial AI, and her work is a theoretical, literature-based analysis rather than an empirical study. She argues that international legal frameworks for safe and ethical AI already exist, yet new threats keep emerging. Above all, she finds insufficient attention to responsibility when machines are entrusted with autonomy and decision-making. Educational AI that grades, recommends or tutors is exactly such a delegation. Saheb and Saheb (2024) analysed 57 ethical-AI policy documents from 24 countries using text mining and qualitative content analysis. They identified six overarching themes: principles, personal data protection, governmental roles and responsibilities, procedural guidelines, governance and monitoring mechanisms, and epistemological considerations. They also found 31 previously overlooked ethical dilemmas. Their findings suggest that national policy is converging on a shared vocabulary of accountability, while leaving many practical dilemmas unresolved and unevenly addressed across countries.

The health sector offers a model of institutional responsibility that education largely lacks. Stroud and colleagues (2024) describe academic medical centres making decisions about AI

amid uncertainty about risks and no consensus on best practice for managing them. They propose concrete oversight strategies to balance innovation with proactive scrutiny. Schools rarely have comparable institutional capacity. That raises the stakes of vendor transparency, and of the contractual means schools have to enforce it (see Q264).

Some companies have responded with pledges. Among the commitments announced through the White House's September 2025 AI education initiative, xAI committed $10 million to AI education for underserved youth. OpenAI separately announced plans to certify 10 million workers by 2030 through a new skills platform. These are corporate announcements, not evaluated programmes, and their reach and effects remain unclear. The gestures are real, but they are also instructive in what they reveal. They are voluntary, unilateral and difficult to enforce, which is precisely the model of corporate responsibility that critics such as Furze find inadequate.

The disagreement here is genuine and should be stated plainly. Institutions such as the World Economic Forum frame responsible AI in higher education as a collaborative project of building skills, trust and integrity, in which industry partnership is part of the solution. Critical scholars read the same partnerships as a means by which firms secure market position and policy influence while appearing philanthropic. The available evidence does not settle which reading is more accurate, and both may describe different commitments within the same initiative.

What can be said is that the digital divide is increasingly becoming an AI divide, as the OECD's framing of equity risks implies. Pledges calibrated to marketing cycles cannot substitute for structural remedies to that divide. A ten-million-dollar commitment is significant to the communities it reaches. It is small relative to the scale of the access gap the Frontiers review describes, and it gives recipients no standing to demand anything further.

What would genuine obligation look like? The World Economic Forum describes scaling AI literacy as a shared responsibility. On this view, companies working with educators, governments and communities can help produce a generation of learners who engage with AI critically, ethically and confidently. The aspiration is sound, and literacy frameworks from other professions show what structured efforts can look like. Hoelscher and Pugh's (2025) N.U.R.S.E.S. framework for nursing is one example: it pairs understanding of AI fundamentals with recognising pitfalls such as biased data, ethics in practice, and continuing skill

development. But "shared responsibility" cannot become a euphemism for diffused responsibility, the arrangement in which everyone is nominally responsible and no one is actually held to account.

Research on organisational adoption suggests what concrete responsibility involves. Ehsan and Critchlow (2026) interviewed nine business leaders who had implemented AI effectively, drawing also on public secondary data. They identified six themes: structured governance and policy development; data governance and privacy protection; human oversight, AI constraint and quality assurance; phased pilots and use-case prioritisation; workforce training and change management; and continuous monitoring and adaptive improvement. The sample is small and drawn from adopters rather than developers. Even so, the findings indicate that responsible deployment is a set of ongoing institutional practices, not a one-time statement of principles. Firms that expect such discipline from their own customers can reasonably be held to it in the education systems they enter.

EDUCAUSE's ethical guidelines make the related point that educational integrity must be maintained amid growing commercial influence. On the argument developed here, that requires, at minimum, that AI companies accept binding transparency obligations, submit to third-party audits, and provide meaningful access to underserved populations as a condition of market entry. Which regulatory or market mechanisms could enforce such conditions is a separate question (see Q259). It also requires honesty about trade-offs. UNESCO frames one such dilemma starkly: whether to invest in AI platforms that could reach millions, or in the 44 million additional teachers the world still needs. That is a genuine choice, and Silicon Valley should not resolve it alone. Nor should the discussion forget students and families who cannot or will not use these tools. Their position is the clearest test of whether a system serves everyone or only its adopters (see Q111).

The ethical minimum is proportionality. Those who profit most from disruption owe the most to those who bear its costs.

Q109 Is it defensible for a school to require AI use when families object on religious or philosophical grounds?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

Requiring AI use over sincere religious or philosophical objections is defensible only under narrow conditions: when the requirement is tightly drawn, the objection has been fairly considered, accommodation is genuinely infeasible, and the use serves a mandated outcome that cannot be reached any other way. In every other case schools should prefer accommodation to compulsion. The question sits where two legitimate claims meet. One is the school's authority to determine its educational program. The other is the family's right to raise children in accordance with its convictions. Neither claim cancels the other, and the emerging legal and policy landscape supports a presumption toward accommodation rather than a rule for either side.

Religious and philosophical objections to AI are real and substantive, not Luddite reflexes. Families object on several grounds. Some hold that human consciousness and creativity are sacred and that AI use devalues the imago dei. Some believe that machine-generated learning bypasses the moral and intellectual struggle that constitutes genuine formation. Some are concerned about data privacy, surveillance and the concentration of power in technology companies. Others hold convictions about work, integrity and personal accountability that make AI-assisted work feel like a shortcut. Writing in Front Porch Republic in 2026, one commentator makes the case that believers should be offered an explicit exemption option, framing AI use as a matter of conscience rather than mere preference. The scholarly record shows these concerns are being worked out seriously rather than dismissed. Chrostowski's (2026) scoping review of AI in Christian religious education searched Scopus, Web of Science, the Open Digital Theological Library and IxTheo for publications from January 2023 to March

2026. It identified 23 publications addressing AI in educational, catechetical and formative contexts. That is a small corpus, which suggests the theological conversation is substantive but still young. Papakostas (2025) used a critical literature review and institutional case studies. He identifies decision making, data privacy and bias as central ethical challenges of AI in religious education, and these overlap closely with the concerns families voice. Religious communities are not monolithic in their response, either. Andok, Rajki and Dornics (2025) surveyed 133 Hungarian lay religious respondents, predominantly Catholic, between February and March 2025. They used Campbell's Religious Social Shaping of Technology framework to examine attitudes across 15 religious functions. That framework assumes communities accept, adapt or reject technologies selectively, function by function. A school should therefore not assume that a religious family's objection is total, nor that it is trivial.

Whether or not one shares these beliefs, they are the kind liberal democracies have historically protected, because they concern the deepest questions of what a human being is and how a child should be formed. The legal tradition treats sincerely held religious objections as deserving accommodation. The 2025 US Supreme Court decision in Mahmoud v. Taylor reinforced that tradition. As the Congressional Research Service, the University of Washington School of Law and the Free Speech Center at Middle Tennessee State University each explain, the Court held that parents were entitled to notice and the opportunity to withdraw their children from instruction they believed burdened their religious exercise. The Court reasoned that instruction which substantially interferes with children's religious development warrants heightened scrutiny. The case concerned classroom storybooks rather than tools, however. Whether its reasoning extends to compelled use of AI remains unclear, and commentators differ on how far the precedent reaches.

The defensibility of a requirement depends on what is being required, and it helps to distinguish three tiers. The first tier is learning about AI. A school that requires students to understand what AI is, how it works and how to evaluate it is on strong ground. This is general education, comparable to teaching about evolution or the internet, and it does not require the student to adopt any belief. Indeed, a student whose family rejects AI has particular reason to understand it well enough to articulate and defend that rejection.

The second tier is using AI as a tool for one's own work. Here the school is on weaker ground, because it compels a practice and not just knowledge, and the practice is precisely what some families find objectionable. The line between understanding a tool and being made to rely on it

carries moral weight for families who see formation as inseparable from the effort of producing one's own work. That concern also connects to wider debates about where assistance ends and authorship begins (see Q017).

The third tier is submitting to AI-driven assessment, surveillance or profiling. A school that requires this is on the weakest ground of all. It subjects the child to the system in ways that implicate the family's deepest concerns about dignity and control. The ethical challenges Papakostas (2025) identifies, namely automated decision making, data privacy and bias, are most acute at this tier, because the child is not wielding the technology but being acted upon by it.

The defensibility of a requirement therefore varies inversely with the intimacy of the compulsion. AASA, The School Superintendents Association, likewise advises district leaders to look carefully at what precisely a family is objecting to before deciding how to respond. Treating all AI-related objections as a single category obscures distinctions that matter both legally and ethically.

Where a requirement is challenged, the process matters as much as the substance. The school must first determine whether the objection is sincerely held. Courts have historically made this determination expansively, avoiding deep scrutiny of a belief's internal logic provided it is sincerely held. Schools that have developed opt-out policies have had to distinguish religious objections from political or sociological preferences, and the AASA guidance on faith-based opt-outs is candid that this distinction is genuinely difficult. Many families' objections to AI braid theological conviction with privacy worries and distrust of technology firms. Disentangling these strands is neither easy nor obviously the school's business. The breadth of protection the Supreme Court extended in Mahmoud v. Taylor, as the Congressional Research Service and the Free Speech Center describe it, makes aggressive sincerity-testing by schools increasingly hazardous. A school that interrogates a family's theology risks both legal exposure and a breach of the respect that accommodation is meant to express.

The defensible approach is to make the process transparent. Families should know what AI is used, for what purposes and how to object. The school should respond to objections in a timely and respectful way. The burden should not fall entirely on the family to police the curriculum. Families cannot object to practices they do not know about, so transparency about AI use is a precondition of meaningful consent. This links to the separate question of whether teachers

should disclose their own classroom use of AI (see Q101). Guidance written for Texas parents on the 'opt-out trap' illustrates the problem from the family's side. When schools are vague about what happens in classrooms, the family must investigate, identify and contest each specific practice. That labour falls unevenly on households with the time, knowledge and confidence to undertake it.

Accommodation is usually possible and usually preferable. Practitioner writing on AI reluctance in classrooms suggests that most objections can be accommodated without great cost. Getting Smart (2025) discusses how teachers can respond to reluctant students and families with alternative assignments, non-AI pathways and differentiated assessment. This is practitioner guidance rather than systematic research, but it accords with ordinary pedagogical experience. Teachers differentiate routinely for ability, language and disability, and a non-AI pathway is a further instance of the same craft.

The empirical research on AI in schools does little to justify compulsion, because it is early and largely descriptive. Polly's (2026) exploratory study of elementary pre-service teachers found that they considered generative AI helpful for generating ideas to differentiate mathematics instruction. Those with more robust background knowledge made more connections to strategies moving from concrete to pictorial to abstract activities. The finding suggests AI can support differentiation. It also implies that teacher knowledge, not the tool, does much of the work, so a knowledgeable teacher can differentiate for an objecting student without AI. Studies of students are similarly preliminary. Yavich and Davidovitch (2026) examined 207 Israeli middle and high school students using self-report instruments and Pearson correlations. They investigated the relationship between AI use and learning motivation, but correlational self-report data of this kind cannot show that AI use causes motivational gains that an objecting student would forfeit. Józsa and colleagues (2026) conducted a cross-sectional survey of Hungarian elementary and high school students guided by the Technology Acceptance Model. They focused on perceived usefulness and willingness to use AI. The design measures acceptance rather than learning outcomes. At the leadership level, Raptis and Psyrras (2026) surveyed 262 Greek primary school leaders using a 61-item questionnaire covering attitudes, self-efficacy, perceived usefulness and challenges to integration. Their work suggests adoption depends heavily on leaders' own dispositions and capacities. None of this research establishes that AI use is educationally indispensable. Where the evidence for necessity remains unclear, the case for overriding conscience is correspondingly weak.

Where accommodation is feasible, requiring AI use is not merely legally risky but pedagogically gratuitous: the school is compelling a practice it does not need to compel. The strongest argument for accommodation is that it preserves the school's legitimacy. A school that forces AI on objecting families converts a pedagogical choice into a test of authority, and the resulting conflict damages the trust on which education depends. Accommodation also generates duties. A non-AI pathway must be equally rigorous and equally valued, not a lesser track, and that obligation is examined more fully elsewhere (see Q111).

There are limits to accommodation, and these define when a requirement becomes defensible. Three conditions mark the boundary. The first is that the AI use is integral to a state-mandated outcome that cannot be achieved otherwise. The second is that the objection is not sincerely held but is a pretext for avoiding work. The third is that accommodating the objection would impose disproportionate cost or harm on other students. Where one of these holds, a school may defensibly require AI use, subject to the family's right to seek legal remedy. Each condition should be read narrowly. Few current curricular outcomes are achievable only through AI. Pretext is hard to establish given the courts' expansive approach to sincerity. Claims of disproportionate cost must be evidenced rather than asserted.

The sources disagree about how much weight opt-outs themselves can bear. The Front Porch Republic essay treats an exemption option as the natural remedy for believers. AASA's guidance treats opt-outs as a manageable administrative tool when handled carefully. The Texas guidance on the 'opt-out trap' warns that relying on opt-outs can place the burden of resistance on minority families. It can also institutionalize religious preference by making it the parent's job to identify and challenge specific practices. On this view, an opt-out regime quietly endorses the default and leaves dissenters to absorb the costs of departing from it. Their children may also be visibly singled out among peers. These positions are not fully reconcilable. Opt-outs protect conscience, but they can also shift responsibility from institutions onto families least equipped to carry it.

The practical implication is that a school relying on opt-outs should ensure that the default curriculum is itself respectful of the diversity of families it serves. A default that teaches about AI critically, uses it where its value is clear, and avoids intimate forms of compulsion such as AI-driven profiling will generate fewer objections. It will also make the objections that do arise easier to accommodate fairly.

Taken together, these considerations yield a clear but conditional answer. Requiring AI use over religious or philosophical objections is defensible only when four conditions hold. The requirement must be narrowly drawn, favouring knowledge over compelled practice. The objection must have been fairly and transparently considered. Accommodation must be genuinely infeasible. The requirement must serve a state-mandated outcome that cannot be achieved otherwise. Outside those conditions, the defensible course is accommodation: offer non-AI pathways, keep the process transparent, and treat the family's objection as a claim to be weighed rather than a nuisance to be managed.

The legal ground beneath this conclusion is still moving. Mahmoud v. Taylor, as the Congressional Research Service describes it, strengthened parental claims to notice and withdrawal, but it was decided on facts far from classroom AI. How courts will treat compelled use of a tool, as distinct from exposure to content, remains unclear. The educational evidence is equally unsettled. Studies from Greece, Hungary and Israel describe adoption, attitudes and associations rather than establishing that AI use is indispensable to learning. Practitioner guidance such as Getting Smart's suggests that alternatives are workable. A school that cannot point to strong evidence of necessity has little warrant to override conscience. The school's authority to determine its program is real, but it is exercised most defensibly when it leaves room for the convictions of the families it serves.

Q111 What duties do educators have toward students who cannot or will not use AI?

17 citations · 17 sources · 5 cross-references

Claim 1 emerging

Educators owe students who cannot or will not use AI a set of positive duties. It is not enough to tolerate non-use; educators must ensure that non-use never hardens into disadvantage. The question has become pressing as AI shifts from optional tool to assumed infrastructure in schools and universities. The equity and rights frameworks developed by UNESCO and the OECD converge on this position, even where they differ in emphasis.

The first duty is to distinguish two populations, because their claims differ. Some students cannot use AI because of cost, connectivity, disability, language, or institutional policy. They stand on the wrong side of what the OECD's 2024 report on equity and inclusion and the 2024 Frontiers in Education analysis of AI-powered education treat as an emerging AI divide. The duty owed to them is one of equity: the school must not let access to learning depend on access to AI. Other students will not use AI, out of religious, philosophical, or personal conviction. They are exercising a choice, and the duty owed to them is one of respect: the school must not punish or marginalise conscientious refusal. UNESCO's rights-based guidance frames both groups' claims as matters of the right to education itself rather than of technological preference.

Refusal is not a fringe position. Runcan and colleagues (2026) surveyed 675 students across six Romanian universities. Perceived benefits strongly predicted acceptance of AI ($\beta = 0.541$), while skepticism had a modest but significant negative effect ($\beta = -0.113$). The design is correlational, but it indicates that doubt coexists with enthusiasm within the same student body. Aloud, Alotaibi and Al-khalifa (2026) modelled the perceptions of 652 King Saud University students. They treated fear of using generative AI as a construct distinct from awareness and desire to use, and examined whether these perceptions differ by gender, age, academic major, and level of study. Neither study measures refusal directly, so the size of the conscientious non-user population remains unclear. In practice the two duties overlap: both require the school to maintain non-AI pathways that are genuinely equivalent in educational value, not merely available in name.

The second duty is non-discrimination in assessment. AI use may be rewarded through faster completion, higher grades, or implicit expectations about polish and volume. Where it is, students who cannot or will not use it are systematically disadvantaged, and the assessment ends up measuring access to technology rather than learning. The duty is to design assessment so that it measures the learning outcome, not the means of production. The same principle

already governs accommodations for disability: the standard is the outcome, and the pathway is adjusted. Where AI is integral to the curriculum, the school must ensure that non-users can still meet the standard by other means. The disability analogy cuts both ways. Some disabled students find mainstream AI tools inaccessible, while others depend on AI as assistive technology (see Q248).

The burden falls squarely on educators' professional conduct. Chinoracky and Stalmasekova (2025) conducted a thematic review of 42 open-access, peer-reviewed articles published between 2022 and 2025. Drawing on Slovak legislation that defines educators' responsibilities, they classified educators' activities into teaching, scientific research, and other work such as academic management and self-directed professional development. Assessment design sits within the teaching responsibilities that such legislation already assigns. This suggests the duty is an extension of existing obligations rather than a new one.

Evidence on educators' own adoption complicates matters. Bahaw and colleagues (2026) refined the Unified Theory of Acceptance and Use of Technology for entrepreneurship educators. They identified affinity to technology as an individual-level antecedent of adoption and specified boundary conditions under which facilitating conditions lose explanatory power. If teachers' uptake of AI depends partly on personal affinity, their implicit expectations of students may as well. Assessment criteria could then drift toward rewarding AI-assisted products without anyone deciding that they should. Explicit outcome criteria are the safeguard against that drift.

The third duty is to teach AI literacy to all students, including those who will not use AI. UNESCO's rights-based framework treats AI literacy as a universal entitlement. Every student should understand what AI is, how it works, what its risks are, and how to evaluate its outputs, because these are now conditions of participation in society rather than optional skills. A student who declines AI still has to live in a world saturated by it. That student must still be able to recognise AI-generated content, protect personal data, and assess machine-produced claims. The duty is to teach about AI to everyone while requiring use of AI from no one.

Curricula are already being reshaped around AI competence, which makes it important to decouple literacy from use. Adeyemi and colleagues (2025) examined awareness and use of large language models among library and information science undergraduates at Kwara State University. They drew a sample of 306 from a population of 1,479, retrieved 279

questionnaires, and framed their study explicitly in terms of implications for educators. Alemán Ramos and Morales Almeida (2026) ran a mixed-methods study of 49 Social Education undergraduates. They integrated perceived AI use, self-reported learning competencies, and professional knowledge requirements to judge preparedness for AI-mediated practice in a socially oriented profession. Both studies treat competence with AI as something graduates are expected to possess. Neither, as summarised, separates knowing about AI from using it, and that gap is where the duty applies. A course can examine how a language model generates text, why it can fabricate sources, and what happens to data entered into it through demonstration, case analysis, and critique, without requiring each student to operate a tool personally. Miranda's (2025) exploratory survey of 376 teachers, university students, and future educators in the University of Salerno area set AI's promise for personalisation and efficiency against concerns about ethical implications and responsible implementation. That pairing suggests critical understanding is wanted even by those who see value in use. Literacy taught this way serves the refuser and the enthusiast alike.

The fourth duty falls on institutions as much as on individual teachers: if AI is expected, it must be provided. Inside Higher Ed reported in 2025 that half of colleges do not grant students access to AI tools. Where that is the case and coursework nonetheless assumes AI, students are left to secure tools privately. What they can obtain then depends on what they can afford, whether a free tier or a paid subscription, and on whether their devices and connections can support it. The analysis of the new digital divide in education poses the choice starkly, as one between AI as a public capability and AI as a private advantage. When institutions neither provide tools nor design courses that work without them, they default to the second option without having chosen it. Work on the digital divide in AI education makes the corresponding demand for equal opportunities, which in practice means either institutional provision or genuine independence of the curriculum from privately acquired tools.

Access is not only financial. Tabiri and Jones-Mensah (2026) studied Ghanaian tertiary students' use of AI in language learning, including which languages they use it for and at what stage of their studies they adopted it, guided by the Unified Theory of Acceptance and Use of Technology and constructivist learning theory. Their attention to multilingual learning signals that a student's linguistic background may shape how useful a given tool is to them. Nyaaba and Min (2025) tested text-to-video tools for culturally and linguistically responsive teaching with English Language Learners, assessing their capabilities particularly in freemium modes,

which is where budget-constrained teachers and students are most likely to work. The duty that follows is concrete. An institution that builds AI into teaching should supply tools that meet privacy and accessibility standards, check that they serve the languages its students actually use, and keep a non-AI route open for anyone the provision still fails.

The fifth duty concerns the student who will not use AI and is entitled to that position. Respect means more than permitting refusal; it means not making refusal costly in hidden ways. A student who objects to a tool's data practices should not be required to open an account with a commercial provider to complete compulsory work. UNESCO's guidance on protecting learners' rights, together with the overview of AI and the right to education, treats privacy and protection from coercive data collection as part of what learners are owed. Educators should state openly which tasks involve AI, offer an equivalent alternative without requiring the student to justify it at length, and avoid treating refusal as evidence of laziness or technophobia.

Respect also requires candour. Neittaanmäki (2025) surveyed medical students at Gothenburg University about their attitudes toward AI in medicine, its effects on their career plans, and their use of generative AI in their studies. Where a profession is being reshaped by AI, a decision to abstain may carry consequences beyond the classroom, and a teacher who conceals this does the student no favour. The duty is to inform without pressuring: to explain what the field increasingly expects, then leave the decision with the student wherever the curriculum permits. The separation of fear from awareness in the King Saud University model points to a related obligation. Some apparent refusal may be anxiety that better information would ease, while some is a settled judgement. Educators should offer explanation to the first group without treating the second as a problem to be corrected.

These duties have limits, and stating them guards against overreach. Where competence with AI is itself a stated learning outcome, as in some professional programmes, a school cannot exempt a student from the outcome while still certifying it. The duty then shifts to offering the least intrusive means of demonstrating competence, such as institutionally hosted tools with strong privacy protections, and to explaining the requirement clearly before enrolment so that students can choose with full knowledge. The preparedness agenda described in the Social Education study shows why such programmes exist, but it does not license silently extending AI requirements to courses whose outcomes do not include them. Nor do the duties require identical experiences for users and non-users. They require equivalent opportunity to learn and to be judged fairly.

The evidence base remains thin. Most of the empirical work cited here consists of single-institution surveys of attitudes and use, and none of it measures the educational outcomes of non-users directly. The equity analyses identify risks more clearly than they quantify them. The framing in the digital divide literature, that AI either becomes a shared public capability or entrenches private advantage, nonetheless gives educators a workable test. For any practice involving AI, they can ask whether a student without access, or without the wish to use it, could still learn what is taught and show that learning. If the answer is no, the practice needs redesign before it needs defending.

Q101 Should teachers be required to disclose their own classroom use of AI, as the EU AI Act requires of AI systems, even when disclosure weakens the exercise?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Teachers should be held to a transparency standard modelled on the EU AI Act, but not a blanket one. Students should know when they are interacting with an AI system and when the material in front of them is AI-generated. The decision not to disclose AI assistance in designing a particular exercise should rest with the teacher's professional judgment, coupled with a duty to justify that choice afterwards to students and parents. The rest of this answer sets out the reasons.

The benchmark is Article 50 of the Artificial Intelligence Act, Regulation (EU) 2024/1689. Article 50 imposes transparency obligations that apply to AI systems in specified situations, regardless of how those systems are classified for risk. Systems intended to interact directly

with natural persons must be designed so that people know they are dealing with AI, unless this is obvious from the context. Providers of generative AI must ensure that outputs are marked in a machine-readable format and are detectable as artificially generated. Deployers who use AI to create deepfakes, or to publish AI-generated text informing the public on matters of public interest, must disclose that the content is artificial.

These obligations become applicable in August 2026. The European Commission has published guidelines and a voluntary Code of Practice on AI-generated content to support compliance, and practitioner commentary such as Orrick's analysis has begun mapping how providers and deployers will implement them. The question here is whether this standard should extend to a teacher's own use of AI in the classroom, including cases where disclosure might undermine the pedagogical value of an exercise. Answering it requires three steps: distinguishing the separate transparency obligations, examining the special character of the classroom, and weighing the values transparency is meant to serve.

The AI Act's transparency regime is not a single rule but a set of differentiated obligations, each with its own scope, exceptions and rationale.

The first is the interaction obligation, which requires that a person be informed they are interacting with an AI. It applies to systems intended to interact directly with natural persons. It is subject to an exception where the AI's involvement is "obvious from the point of view of a natural person who is reasonably well-informed, observant and circumspect."

The second is the content obligation, which requires AI-generated output to be marked. It applies to synthetic content, with exceptions for systems that perform assistive functions such as standard editing, for example grammar correction, or that do not substantially alter the input data.

The third is the deepfake obligation, which requires disclosure of artificially generated or manipulated content. It falls on deployers. It is reduced, not removed, for evidently artistic, creative, satirical or fictional works, where disclosure need not hamper display or enjoyment of the work. The parallel duty for AI-generated public-interest text lapses where the content has undergone human review or editorial control and a person holds editorial responsibility. That exception matters for teachers, who routinely exercise exactly this kind of control over materials before students see them.

Each obligation protects something different. The interaction obligation protects the autonomy of the person in the exchange. The content obligation protects the integrity of the information environment. The deepfake obligation protects against deception.

The obligations also attach to different actors. Machine-readable marking binds providers of generative systems, not the teacher who uses them. A teacher is, at most, a deployer. Extending the content rationale to classroom practice is therefore partly an argument by analogy rather than a direct reading of the legal text. Applying the regime to the classroom means asking which of the three rationales a given use actually engages, rather than treating "AI use" as a single category.

A teacher's use of AI in the classroom is not the paradigmatic case the AI Act was designed for. Its transparency obligations protect individuals against deception and manipulation by AI systems acting on them: chatbots that impersonate humans, synthetic content that masquerades as real, deepfakes that deceive.

The classroom relationship differs in kind. The teacher is a professional with a duty of care toward students. The interaction is pedagogical rather than commercial. In schools, the students are often minors whose educational interests are the very purpose of the interaction.

None of this removes the transparency obligation. The Act applies to deployers in education as elsewhere, and the Commission's overview of the regulatory framework treats certain educational uses as high-risk, such as systems that determine access to education or score examinations. The classroom's character changes how the Article 50 obligations should be interpreted and applied, not whether they apply.

The practical scope of the question is wide. Cincioğlu, Mutlu Bayraktar and Altan (2026), in a systematic review of teachers' generative AI use in K–12 education, find AI supporting lesson planning, assessment, feedback generation, content creation and classroom support.

They also note that the research is scattered across contexts, methods and theoretical frameworks. A single disclosure rule would therefore have to cover activities that touch students very differently. A lesson plan a student never sees engages none of Article 50's rationales. AI-generated feedback on a student's essay engages several.

How students and teachers understand AI's role in the room also matters. Day (2026) studied 76 preservice teachers on a postgraduate programme in China, using thematic analysis of forum posts. The study explored their views of AI as a "non-human instructor" and whether it could replace human teachers. This confirms that the boundary between AI as interlocutor and AI as tool is something participants themselves actively negotiate, not a settled fact. Jia (2025) surveyed 373 Chinese undergraduates and modelled how the history and frequency of AI use relate to their cultural values and their interactions with teachers. The abstract does not report the direction or size of the effects, so whether AI use reshapes the student–teacher relationship in ways that bear on disclosure remains unclear.

There are four strong arguments for extending the transparency standard fully to the classroom.

The first concerns autonomy and trust. Students and parents have a claim to know when AI is involved in their education, and undisclosed use erodes the trust on which the teacher–student relationship depends.

The second concerns informed consent. The data protection analysis of educational AI presupposes that families know which systems are in use. That analysis rests on the GDPR and on the school-consent models discussed elsewhere in this volume.

The third concerns modelling. If students are to develop AI literacy, they must be able to recognise AI in their environment. A classroom where AI is invisible teaches the wrong lesson.

The fourth is the Act's own logic. The transparency obligation exists because AI interaction can be consequential, and classroom AI is consequential for the students involved.

On this view, the pedagogical value of an exercise cannot justify concealment. The harm of concealment outweighs the benefit: harm to trust, to autonomy, and to students' ability to evaluate their own learning.

Recent evidence on student disclosure sharpens the modelling argument. Qu and Wang (2026) studied 409 undergraduates at a Singaporean university who used generative AI for academic work. Their mixed-methods design was guided by Bandura's social cognitive theory. They report that students frequently conceal their AI use despite institutional disclosure mandates, reflecting ethical uncertainty and relational risk. They also find that willingness to disclose is shaped jointly by cognitive, social and emotional factors, including peer influence.

If disclosure is a socially learned norm, the conduct of the most visible adult in the room plausibly matters. A teacher who requires students to document their AI use while concealing their own undermines the norm being taught (see Q083).

The study's limits should be stated plainly. It sampled a single university, relied on self-report and concerned students rather than teachers. Whether teacher modelling actually changes student disclosure behaviour has not been tested and remains unclear. The reciprocity argument is therefore a reasonable inference, not a demonstrated effect.

The counterargument is that the classroom is precisely where the "obvious from the context" exception and the pedagogical purpose should be read generously. Three examples show why. Consider a teacher who uses AI to generate a Socratic dialogue for a philosophy lesson, a teacher who creates a writing prompt designed to elicit a student's unassisted response, and a teacher who simulates a conversation partner for language practice.

In each case, disclosure at the moment of use could alter the pedagogical effect. Students who know a dialogue is AI-generated may engage with it differently, and the exercise's value may depend on that engagement.

The deeper point is that a teacher's use of AI is not the same as an AI system acting on a student. The teacher remains the accountable agent, and the AI is a tool in the teacher's hands, like a textbook or a film. The obligation that protects against deception by systems is less clearly engaged when the system is not the interlocutor. Here it is the instrument of a human professional who is present, accountable and known to the student. This reading echoes the Act's own exception for content under human editorial responsibility, although that exception is framed for public-interest publication rather than teaching.

The argument rests heavily on professional judgment, and the evidence on that judgment cuts both ways.

Letina, Tomaš and Škugor (2026) surveyed 322 primary and secondary teachers in Croatia. They examined how professional awareness of AI and conceptual beliefs about its educational role contribute to explaining teachers' preferred pedagogical approaches. Teachers, on this account, do not approach AI uniformly; their choices vary with what they know and believe. Polly's (2026) exploratory study of elementary pre-service teachers points the same way. Participants using generative AI to plan differentiated mathematics instruction found it helpful.

Those with more robust background knowledge made more connections to research-based differentiation strategies.

Taken together, these studies suggest that the quality of AI-assisted pedagogy depends on the expertise of the person using it. That supports trusting expert judgment, but it also warns that judgment is uneven. Neither study measured outcomes for students, and neither addressed disclosure directly.

Credible positions therefore disagree. One side holds that professional discretion is the proper safeguard. The other holds that discretion is too variable to replace a rule.

The defensible resolution is a graduated standard that tracks the obligations the AI Act actually imposes.

The interaction obligation should apply. Students should know, at the level of the classroom and the lesson, when they are interacting with an AI system rather than with the teacher. That obligation protects the student's autonomy in the interaction itself. A language-practice chatbot can preserve its value if students are told at the outset of the unit that practice partners will be simulated, without interrupting each exchange. This is how the "obvious from the context" exception is meant to work.

The content obligation should apply, by analogy, to AI-generated materials that students consume as content. Students should be able to tell what is AI-generated, because the integrity of the information environment matters in education as much as anywhere.

Deepfake-style disclosure of every AI-assisted pedagogical act is a different matter. Requiring a label on every AI-generated prompt or every AI-drafted exercise is neither demanded by the Act's rationale nor necessary for its purposes. Here a teacher's professional judgment about when disclosure serves the learning objective should be respected. Where an exercise depends on delayed disclosure, as with the Socratic dialogue, the honest course is to disclose afterwards. The reveal can then become part of the lesson rather than being withheld altogether.

The standard, then, has three parts: transparency about the system, transparency about the content, and professional judgment about the pedagogy. The burden falls on the teacher to be able to justify, to students and parents, why a particular exercise was conducted without disclosure. That burden answers the concern raised by the uneven expertise documented by

Letina and colleagues and by Polly. Discretion is permitted, but it is accountable rather than unreviewable.

Two complementary safeguards would give the standard practical force. The first is a professional code of practice for teachers' AI use (see Q217), which would articulate the justifications schools accept. This could parallel how the Commission's voluntary Code of Practice operationalises Article 50 for providers.

The second is attention to how disclosure practices shape classroom authority and trust once students encounter competing AI explanations of their own (see Q260).

This approach preserves the values the AI Act protects: autonomy, trust and the integrity of information. It also recognises that the classroom is a pedagogical space, not a marketplace, and that the teacher's professional judgment is itself part of what students are learning to trust.

What changed in this edition: This answer is unchanged in Edition 120. Its most recent revision, in Edition 117: Expanded to six sections. Added recent evidence on student concealment, teacher judgment and the range of teacher AI uses. Clarified that provider-side marking duties and the editorial-responsibility exception apply. Added post-hoc disclosure and cross-references. Converted the two bulleted lists into running prose. (1,061 → 2,092 words · 6 new sources)

Q259 What obligations do AI developers and companies owe specifically to the education sector, and what regulatory or market mechanisms might enforce those obligations?

11 citations · 11 sources · 5 cross-references

Claim 1 established

AI developers increasingly treat education as a strategic market, offering free or discounted tools to schools, partnering with teacher organisations, and designing products for students. Education differs from most consumer markets in ways that generate distinctive obligations. Its

users are often children, attendance is frequently compulsory, institutions act on behalf of students who cannot freely choose their tools, and the stakes include long-term intellectual development. These features suggest that developers owe the education sector more than general consumer protections, and a combination of regulatory and market mechanisms is beginning to define and enforce those obligations.

The first obligation is heightened protection of children's data. Students in compulsory education cannot meaningfully opt out of tools their schools adopt, which places a special burden on developers to limit collection and use. In the United States, the Federal Trade Commission's amended Children's Online Privacy Protection Rule, finalised in January 2025, requires separate verifiable parental consent before operators disclose children's data to third parties for purposes not integral to the service, mandates written data-retention policies, and strengthens security requirements. The FTC's 2023 order against Edmodo, which required deletion of data and of models developed from improperly collected children's information, demonstrates that regulators can impose remedies that reach into AI development itself.

The second obligation concerns safety and accuracy. Educational AI systems that produce errors, inappropriate content, or biased outputs affect learners who may lack the knowledge to detect problems. The European Union's Artificial Intelligence Act, Regulation 2024/1689, classifies AI systems used to determine access to education, evaluate learning outcomes, assess the appropriate level of education for individuals, or monitor students during tests as high-risk in Annex III. Providers of such systems must implement risk management, ensure data quality, maintain technical documentation, enable human oversight, and meet standards of accuracy and robustness. The Act also prohibits emotion-recognition systems in educational institutions except for medical or safety reasons. These provisions represent the most comprehensive statutory definition of developer obligations in education to date.

The third obligation is transparency. Schools and teachers need to understand what a system does, how it was trained, what its limitations are, and when it changes. UNESCO's 2023 Guidance for Generative AI in Education and Research called on providers to be transparent about the data and methods used to train models and urged governments to regulate generative AI in education, including through age limits for independent use. Transparency enables institutions to make informed procurement decisions and teachers to calibrate their trust.

The fourth obligation concerns evidence. Products marketed as improving learning should be supported by credible evidence, yet much educational technology has been sold on the basis of developer-funded studies or no evidence at all. Developers can meet this obligation by supporting independent evaluation and publishing results regardless of outcome.

The fifth obligation concerns accessibility and equity. Tools should work for students with disabilities, for speakers of diverse languages, and across socio-economic contexts, rather than delivering benefits mainly to already advantaged users.

The sixth obligation is respect for educator authority. Systems should support teachers' professional judgement, provide override capabilities, and avoid designs that bypass the teacher or encourage dependence on the product.

Market mechanisms complement regulation. Digital Promise's Responsibly Designed AI certification, launched in 2025 after co-design with education stakeholders, evaluates products against criteria covering privacy, security, bias mitigation, transparency, and educator control, giving schools a signal they can use in procurement. Procurement standards adopted by districts, states, and consortia can require contractual commitments on data use, accessibility, and evidence, translating ethical expectations into enforceable terms. Collective purchasing increases bargaining power, particularly for smaller institutions.

Partnerships between developers and education organisations raise their own questions. The American Federation of Teachers' National Academy for AI Instruction, launched in 2025 with 23 million dollars in funding from Microsoft, OpenAI, and Anthropic, illustrates how industry investment can expand professional development while also creating potential conflicts of interest for organisations that may need to advocate for regulation of the same companies. Disclosure of funding and independence of content are important safeguards.

The idea that companies serving schools owe obligations beyond those of ordinary consumer markets has precedents in earlier educational technology regulation. California's Student Online Personal Information Protection Act, enacted in 2014 and widely known as SOPIPA, was among the first laws to impose duties directly on operators of online services designed and marketed for kindergarten through twelfth-grade school purposes, rather than only on schools. It prohibited such operators from using student information for targeted advertising, from building profiles of students for non-educational purposes, and from selling student data, and it required reasonable security measures and deletion of data at a school's request. The law was a

response to concerns that the student-privacy framework then in place, centred on the Family Educational Rights and Privacy Act, regulated schools but left vendors largely untouched. More than a hundred state student-privacy laws followed in the United States over the next several years, many modelled on SOPIPA. The precedent is significant for AI because it establishes that legislators can define a category of education-specific services and attach obligations to the companies providing them. Extending such laws to cover training of AI models on student data, the generation of student profiles by AI tutors, and the disclosure of AI capabilities and limitations would be a natural evolution rather than a novel regulatory departure.

Broader online-safety regimes are also extending to AI services used by children. The United Kingdom's Online Safety Act 2023 imposes duties on providers of user-to-user and search services to assess and mitigate risks to children, including duties to prevent children from encountering certain categories of harmful content, and the communications regulator Ofcom has indicated that generative AI chatbots fall within scope where they enable users to share content or function as search services. These duties are not specific to education, but they apply to many of the general-purpose AI tools students use, and they move regulation from a model of parental consent toward one of provider responsibility for the design of services children are likely to access. The Act has been criticised by some for its breadth and by others for its slow implementation, and its effectiveness in relation to AI has yet to be tested. Its significance for the education debate lies in its premise that companies whose products reach children must anticipate and reduce foreseeable harms, a principle that supports the safety obligation described above.

International human-rights instruments are beginning to address AI directly. The Council of Europe's Framework Convention on Artificial Intelligence and Human Rights, Democracy and the Rule of Law, adopted in 2024 and opened for signature by member states and non-member states including the United States and the European Union, is the first legally binding international treaty on AI. It requires parties to ensure that activities across the lifecycle of AI systems are consistent with human rights, democracy and the rule of law, and it includes commitments on transparency, accountability, non-discrimination, privacy and access to remedies. The Convention applies primarily to public authorities and to private actors acting on their behalf, with parties choosing how to address other private-sector activity. Because public education is a core state function, AI systems deployed by public schools and education ministries fall squarely within its intended scope. Over time, the Convention could provide a

basis for requiring that AI tools procured for public education meet human-rights standards, though its practical effect will depend on ratification and national implementation.

The evidence obligation deserves closer attention because educational research has documented systematic ways in which effectiveness claims can be inflated. Alan Cheung and Robert Slavin, in a 2016 analysis in Educational Researcher, examined 645 studies of educational programmes that met inclusion standards for the Best Evidence Encyclopedia and found that methodological features were strongly associated with reported effect sizes. Studies using measures created by the developers or researchers produced roughly twice the effect sizes of studies using independent measures, and small studies, quasi-experiments and studies published by those with a stake in the programme also tended to report larger effects. These findings imply that a developer's own study showing that an AI tutor raises scores on a test the developer designed should be treated with particular caution. An evidence obligation that is meaningful rather than cosmetic would require independent evaluation, preregistration of outcomes, use of standardised or independent assessments, and publication of null results. Funding bodies and procurement authorities could make such requirements conditions of eligibility, as several have done for other educational programmes under evidence standards such as those introduced in the United States by the Every Student Succeeds Act.

Transparency obligations can draw on documentation practices developed within the AI research community. Margaret Mitchell and colleagues, then at Google, proposed model cards in a 2019 paper presented at the Conference on Fairness, Accountability, and Transparency, describing short documents that accompany trained models and report their intended uses, performance across different demographic and other groups, evaluation data, ethical considerations and known limitations. Model cards and related practices such as datasheets for datasets have since been adopted, in varying forms, by many developers and are reflected in documentation requirements in the EU AI Act. For education, an equivalent would describe how a tool performs for students of different ages, languages and abilities, what content it was evaluated on, how it handles requests for direct answers, what data it collects and retains, and how it changes over time. Such documentation would allow schools and teachers to make informed choices and would provide a basis for accountability when tools fall short. At present, documentation provided to schools is often marketing material rather than technical disclosure.

Market mechanisms face structural limits in education that justify regulatory backstops. Schools are often fragmented buyers with limited expertise, which weakens their ability to

demand high standards. Free or heavily discounted tools can lock in adoption before evaluation, and switching costs rise as tools become embedded in curricula and teacher practice. Network effects and the concentration of foundation-model development among a few large firms mean that many education products are built on the same underlying models, so problems in those models propagate widely. Certification schemes and procurement consortia can partly offset these weaknesses, but they depend on voluntary participation by vendors and on schools prioritising certified products over cheaper alternatives. Regulation that sets minimum standards for all products marketed to schools ensures that the most vulnerable schools, which may lack capacity to evaluate certifications, still receive baseline protections.

Equity considerations reinforce the case for clear obligations. Wealthier schools and systems can negotiate better contracts, hire specialist staff and choose premium products with stronger safeguards, while poorer ones may accept whatever free tools are available, sometimes with weaker protections and terms that permit broader data use. Without enforceable obligations that apply to all education products, the protections students receive will track the resources of their schools. Obligations framed around the rights of students rather than the purchasing power of institutions help ensure that children in under-resourced schools are not exposed to greater risks simply because their schools could not bargain for better terms.

Remedies for students and families form a further gap in most current frameworks. When an educational AI system mishandles a child's data, produces a discriminatory recommendation, or contributes to an unfair disciplinary or grading decision, the harmed party is usually the student, yet contracts are typically signed between the developer and the school, and students are not parties to them. Privacy statutes such as SOPIPA, discussed above, are enforced mainly by public authorities rather than through private lawsuits, which leaves families dependent on regulators' priorities and capacity. One way to close this gap would be for procurement agreements to name students as intended beneficiaries of data and safety commitments, to require vendors to support accessible complaint and correction procedures, and to oblige prompt notification of families when incidents affect them. Another would be for regulators to publish enforcement outcomes in ways that help schools judge vendors' track records. Neither approach has yet been evaluated systematically in education, so its practical effect remains uncertain, but both would align developers' obligations more closely with the people those obligations are meant to protect.

Enforcement gaps remain significant. Regulatory agencies have limited capacity, the EU AI Act's high-risk obligations are being phased in over several years, many jurisdictions lack AI-specific rules, and schools often lack the expertise to monitor compliance. Free products may be offered on terms that schools accept without negotiation. The obligations of developers to education are becoming clearer, but their realisation depends on sustained regulatory attention, institutional capacity, and collective action by the education sector.

Chapter 3: AI's Role in Teaching

15 questions · 246 citations · 236 unique sources · 75 cross-references

Q021 What can AI tutors do better than human teachers, and where do they fall short?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

AI tutors outperform human teachers on a narrow but important set of tasks: delivering structured, well-defined content efficiently, adjusting difficulty moment by moment, and offering patient, on-demand practice at a scale no teaching workforce can match. They fall short, sometimes structurally, wherever learning depends on durable independent mastery, reliable information, emotional support, or the gradual formation of judgement. This is no longer a speculative question. A body of controlled research now exists, and its results are striking enough to demand serious attention and sober qualification.

The contrast between human and machine is also less clean than the question implies. The most informative recent evidence does not show AI tutors simply replacing or failing to replace teachers. It shows their effects depending heavily on how teachers frame, assign, and supervise their use. The comparison that matters most for policy is therefore not AI against teacher but AI with and without teacher involvement. The sections that follow set out where the advantages are well supported, where the evidence conflicts, and where the limits look categorical rather than temporary.

The best-documented advantage is raw instructional efficiency on well-defined content. A randomized controlled trial at Harvard, discussed in the Education Next forum on AI tutoring, found that students learned roughly twice as much in less time with an AI tutor than in the comparison condition, with effect sizes reported between 0.73 and 1.3 standard deviations. That magnitude dwarfs most educational interventions. A separate 2025 randomized trial reported comparable findings: a custom AI tutor outperformed in-class active learning on knowledge gains and time efficiency, and it also raised engagement. Broader syntheses point the same way.

Sevilla and colleagues (2025), reviewing computer-assisted learning and AI-guided tutors, describe meaningful gains in student performance, especially in mathematics, and identify these tools as promising for strengthening foundational skills and closing educational gaps.

Several mechanisms help explain these results. Park University's overview of intelligent tutoring systems describes their capacity to locate and work within each student's zone of proximal development. Such systems can detect within seconds whether a task is too easy or too hard, using error patterns and response latency, and can adjust difficulty in real time. A human teacher with thirty students cannot do this for every learner at once. AI tutors are also constitutionally patient and always available. Commentators at Nuton and Speakerly emphasise that they operate around the clock, do not tire of repeated questions, and adapt continuously to each student's needs. This removes scheduling constraints and the social anxiety some students feel when exposing their confusion to a human tutor. For learners who would otherwise go without help, including those in under-resourced systems, this is a real form of access to patient, personalised instruction.

The advantage is not uniform across subjects. Analyses published in the Journal of Mathematics and in practitioner discussions of language learning agree that AI tutors work best in procedural, knowledge-based domains such as mathematics, coding, grammar, and pronunciation. In these areas correct answers are well defined and errors can be diagnosed algorithmically. The complexity and variability of the humanities and creative fields make an effective system considerably harder to build, because interpretation, argument, and originality resist the tight feedback loops on which adaptive tutoring depends. The domain pattern matters. Most of the strongest efficacy evidence comes from the subjects where AI is structurally best suited, so it should not be generalised to the whole curriculum.

Credible sources disagree about how large the AI advantage really is. A 2025 meta-analysis reviewed in the Cognifying Education mapping study found no significant differences in learning outcomes between AI-generated and human feedback. This suggests that in many ordinary instructional settings the two approaches are roughly equivalent, not that AI is categorically superior. One plausible way to reconcile this with the striking trial results is to look at the comparison condition. Where AI is tested against passive lectures, a large effect may partly reflect the weakness of the alternative rather than any particular genius of AI pedagogy. Where it is tested against skilled human feedback, the gap narrows or disappears. On current

evidence, the honest position is that AI tutoring can be highly effective, but its superiority over good human teaching remains unclear.

Evidence on implementation complicates matters further. Sevilla and colleagues (2025) argue that the impact of these tools depends less on access to devices than on how they are woven into teaching, through curriculum alignment, teacher training, and interactive designs that promote active learning. Using new data from Italy, they show that digital divides in AI adoption persist across schools and regions and reflect wider social and economic disparities. Without careful implementation, they warn, these tools risk widening the inequalities they are often promoted to close. The democratising promise of the patient, always-available tutor is therefore conditional, not automatic.

The largest naturalistic dataset in this field reinforces the point. Bardach and colleagues (2025) analysed about 139 million mathematics problems completed by roughly 194,000 students using an intelligent tutoring system in Germany and the Netherlands between 2016 and 2023. In both countries, students working on teacher-assigned problems consistently dropped out later, stayed active for significantly more weeks, and completed more problems than students who chose their own problems. These are observational associations, not causal estimates, and teachers who assign work may differ in other ways from those who do not. Even so, the pattern is consistent and the sample is very large, which is why the authors titled their paper Intelligent Tutoring Systems Need Teachers. Much of what looks like AI efficacy may in fact be AI efficacy sustained by human structure. That has direct implications for how co-teaching arrangements should be designed (see Q025).

Some of the failures are not inconveniences but structural, and the most damaging evidence concerns dependency. In a large randomized trial in secondary mathematics, students who practised with a general GPT-based tutor performed worse on later exams taken without AI support. They showed no long-term learning gains and substantially overestimated how well prepared they were. Brookings and the critical analysis Do AI tutors empower or enslave learners? both read this as a 'learning penalty' driven by cognitive offloading and an inflated sense of mastery. The 2026 ScienceDirect scoping review of generative AI risks in K-12 education reports the same trial: students using the basic GPT tutor scored 17 percent worse on subsequent non-AI exams than their peers. The review concludes that reliance on generative AI can hinder independent performance and distort self-assessment.

This finding sits uneasily beside the efficacy trials above, and the tension should be stated plainly. Measured during or immediately after AI-supported study, performance can look excellent. Measured later and without the tool, the gains may vanish or reverse. Purpose-built tutors that withhold answers and require students to reason seem less exposed to this penalty than general-purpose chatbots, but evidence on which design features protect durable learning is still thin. Designing systems that strengthen rather than substitute for students' thinking is therefore a central problem, not a technical footnote (see Q030).

Preiss and Sternberg (2025) place this risk in a broader theoretical frame. In a position paper drawing on the theory of adaptive intelligence and the ACCEL model of teaching for active concerned citizenship and ethical leadership, they argue that generative AI challenges basic human cognitive abilities by automating tasks traditionally central to intellectual, creative, and ethical development. They weigh cognitive amplification against cognitive deskilling and warn of an erosion of critical thinking. They also acknowledge real benefits, such as personalised learning and productivity, while cautioning against overreliance and the uncritical acceptance of AI outputs. As a position paper it offers argument rather than new data, but its account fits the empirical dependency findings closely. The scoping review adds that routine use of AI tools can hinder the development of metacognitive skills, independent thinking, and intellectual agency, as students outsource decisions to the machine and risk becoming passive recipients of information rather than critical participants in their own learning.

The hallucination problem compounds the dependency risk. Generative systems produce confidently presented misinformation and perform inconsistently across tasks, a pattern that contributors to the Education Next forum describe as 'a jagged and unpredictable frontier' of capabilities. Kalota's (2024) primer on generative AI for educators explains the underlying architecture of large language models and lists accuracy among the technology's current challenges. The issue is a property of how these systems generate text, not a passing bug that will soon be engineered away.

The pedagogical danger is that learners are poorly equipped to catch these errors. In a study discussed in the 2026 thematic analysis of students' perspectives on AI hallucination, medical trainees detected AI hallucinations with only 55 percent accuracy overall. In complex clinical scenarios that figure fell to 44.2 percent, and detection accuracy declined as cognitive demands rose. AI assistance is thus least reliable precisely where it is most needed. A novice cannot use expertise they do not yet have to audit a tutor that speaks with the same fluent confidence

whether it is right or wrong. A human teacher's errors are also real, but they are usually bounded by professional accountability and visible uncertainty.

Medical education shows both the promise and the caution clearly. Gordon and colleagues' (2024) BEME scoping review synthesised 278 publications on AI in medical education, 68 percent of them from North America and Europe. They mapped applications ranging from admissions and assessment to teaching and clinical reasoning, with roles that span augmenting traditional methods to introducing new ones. Dipaola and colleagues (2024) suggest that natural-language-processing virtual patient simulators could benefit students and practising clinicians learning to manage syncope, while also setting out weaknesses alongside strengths. The pattern across this literature is that AI tutoring is most defensible where outputs can be checked against reliable ground truth, and riskiest where learners must trust what they cannot yet verify. This concern links directly to how students' relationship with truth changes when answers are generated rather than discovered (see Q005).

Then there is the dimension of human formation that no current system reaches. The Cognifying Education study and the Journal of Mathematics analysis both stress that teachers' emotional support is crucial for student motivation and engagement, and that AI has not yet been able to replicate it. Over-reliance on AI risks reducing the face-to-face interaction that builds social skills and rapport, both vital for holistic development. Jafari (2024), interviewing 18 experts drawn from technology and computer science and from the social sciences and humanities, found that human-centred AI design is trying to address the recognition of negative emotions, emotional responsiveness, and fairness and justice. That these are still aspirations in design research, rather than achieved capabilities, shows how far the technology remains from the relational work teachers do. A further social risk is on the horizon. As Brookings reports, OpenAI has cautioned that human-like voice interaction could lead users to anthropomorphise AI tutors and form emotional dependency, and early testing suggested that extended interaction might shift social norms and lead some users to prefer an AI bot to human company.

These limits point toward a division of labour rather than a contest. Nordgren (2026) argues in a viewpoint article, explicitly offering no new empirical evidence, that the strongest case for AI in schools may be relieving teachers of non-instructional and administrative burdens. This would free time for strong relationships with students and more individualised instruction, and could ease the burnout behind global teacher shortages (see Q024). Making that division work requires teachers who understand the tools. Delcker, Heil and Ifenthaler (2024), surveying 480

vocational school teachers, modelled AI competence as six dimensions and found them unequally developed, which suggests that professional learning has not kept pace with deployment.

The honest overall judgement is this. AI tutors are genuinely superior at delivering structured, measurable content gains efficiently and, under good implementation, equitably, giving many more learners access to patient, personalised instruction. But they are categorically unreliable as guarantors of deep learning, accurate information, emotional development, or independent thought. The largest evidence base suggests that their benefits persist best when teachers remain in charge of assigning and framing the work. The technology is powerful enough to matter and flawed enough to be dangerous without careful human oversight.

Q022 How should the teacher's role be redefined — from transmitter of knowledge to what, exactly?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

The teacher should be redefined not as a single successor figure but as a layered professional: a designer of learning experiences, a relational and moral presence, and above all the most experienced asker of questions in the room. The familiar phrase "from transmitter to facilitator" has become so common in education discourse that it risks meaning almost nothing. It is worth pressing on that "what, exactly," because the answer turns out to be multiple, layered, and genuinely contested.

The transmitter model rested on a theory of scarcity. The teacher possessed knowledge the student lacked, and the essential act of schooling was moving that content across the gap. A 2025 China Daily commentary on redefining learning in the age of AI describes traditional education as focused on memorisation and the reproduction of knowledge. It argues that, with the widespread application of AI, mechanical and repetitive tasks are increasingly handled by technology, so learning must shift toward abilities that algorithms cannot replace. When information becomes abundant and freely accessible, the transfer model does not merely become inefficient. For a large class of content, it becomes structurally unnecessary, and the teacher's irreplaceability must be located elsewhere.

The transmitter model also persists in teachers' own sense of competence, which is one reason the shift is harder than slogans imply. Sarmurzin and colleagues (2026) surveyed 589 pre-service primary teachers across six Kazakh universities and interviewed 29 of them. Their title quotes one participant: "I fear they might ask a question I cannot answer." The study concerned gifted education rather than AI. Its qualitative themes of methodological helplessness and fear nonetheless show how firmly the professional self-image is still tied to possessing answers. On their attitudinal and self-efficacy measures, third- and fourth-year students did not differ significantly, and effect sizes were trivial. The authors call this a "Plateau Effect" and attribute it to curricula lacking stand-alone gifted-education modules. If AI makes the teacher's answer-holding role obsolete, that loss will be felt as a threat until teachers are prepared to stand on different ground.

One answer, now close to orthodoxy in policy circles, is the facilitator. Drawing on UNESCO, a 2025 analysis in the International Journal of Social and Educational Innovation describes the teacher's role as moving from knowledge transmitter to facilitator of learning, collaborative knowledge producer, and guide to citizenship in the era of AI. That formulation is richer than it first appears. It implies three simultaneous roles: pedagogical, intellectual, and civic. A 2025 article in the Global Education Journal similarly argues that teachers must now take on a multifaceted role as facilitators, mentors, and digital pedagogues.

The facilitator idea predates AI and has deep roots in educational psychology. A review of the teacher as facilitator stresses that the social and collaborative aspects of learning require environments that support interaction and cooperation between students. It also gives the facilitator a role in emotional support and constructive feedback, which contributes to students'

well-being. The concept therefore carries more than procedural weight. At its best, facilitation is an active and demanding craft, not a retreat to the margins of the classroom.

Recent qualitative work shows what that craft involves. Beer (2026) conducted a phenomenological study of ten student-teachers in heutagogy-inspired courses, which are designed around self-determined learning. These student-teachers came from early childhood, elementary, secondary, and special education programmes. They experienced facilitation as a set of complementary practices, used flexibly as their needs changed, rather than as one technique. Among the practices identified were designing an autonomous learning space, constructing cognitive and structural scaffolding, and providing psychological and emotional anchoring. The title phrase, "It's not my safe zone," signals that learners' readiness for self-direction varied and that facilitation had to respond to that variation. The sample is small and drawn from a single setting, so the findings are illustrative rather than general. They do suggest that facilitation, properly understood, already contains elements of design and relational care. That overlap becomes important when the alternatives are set side by side.

A second, more technically precise answer comes from researchers working where AI meets pedagogy. A 2026 paper on generative AI and science literacy argues that integrating generative AI requires rethinking instructional design as co-authorship between educators and intelligent systems. In this view, educators are epistemic designers. They work with AI to curate, interpret, and adapt AI-generated resources so that those resources promote scientific reasoning and inquiry. The epistemic designer is meaningfully different from the facilitator. Design implies intentionality, judgement about what is worth knowing, and accountability for the architecture of learning experiences. Facilitation, in its thinner sense, implies only easing a process that students lead themselves.

Empirical support for the designer framing is beginning to appear, though it remains qualitative. Ngo (2026) interviewed 13 university teachers of English as a Foreign Language from 13 Vietnamese universities. The study also analysed 88 policy and governance documents: 10 national, 7 ministerial, and 71 institutional. Teachers' professional reasoning developed through continual negotiation between classroom realities and multi-level AI governance. Participants moved beyond their traditional roles as language experts to become learning designers, pedagogical facilitators, critical mentors, and ethical guides. They set context-appropriate boundaries for AI use and reframed ethics in terms of transparency. The finding matters because no single label emerges. The same teachers combined design,

facilitation, mentoring, and ethical guidance, which supports a layered account of the role rather than a replacement metaphor.

A more radical framing comes from Elsayed (2026). His conceptual framework, "Pedagogical Symbiosis," treats the learner as a post-human entity whose cognition is hybrid and distributed across biological and artificial systems. It builds on Vygotskian mediation, the extended mind thesis, critical posthumanism, and distributed cognition. Elsayed argues that TPACK and the SAM model retain instrumentalist limitations, treating technology as a tool rather than a cognitive partner. He proposes a "Cognitive Choreographer" teacher role, supported by a five-module professional development structure and a portfolio assessment rubric. The proposal is conceptual, not an empirical test, and the paper itself engages counterarguments about autonomy, techno-determinism, and epistemic opacity.

The literature disagrees here, and the disagreement should be stated plainly. The epistemic-designer view keeps the teacher as the accountable author of learning, with AI as collaborator. The symbiosis view locates cognition partly in the human-AI system and casts the teacher as orchestrating a distributed process. How these two positions should be reconciled in practice remains unclear (see Q025).

A third answer starts from what AI conspicuously cannot do. A 2025 case study asking whether AI can replace teachers concludes that AI improves instructional efficiency, personalisation, and access to education. It also concludes that AI cannot fully replicate the emotional intelligence, empathy, and social interaction found in effective teaching. This points toward the teacher as a relational and moral presence. The review of the teacher as facilitator reaches a compatible conclusion from a different direction. It emphasises the teacher's role in providing emotional support and constructive feedback and in building environments where students interact and cooperate.

On this view, what teachers uniquely offer is not content, and not even method, but presence. This means attentive witness to a student's development, which no system can simulate in the full sense, because simulation lacks the stake that a person has in another person's growth. Beer's (2026) finding that student-teachers valued psychological and emotional anchoring adds some weight. Even in courses explicitly designed to give learners autonomy, learners wanted a human anchor while they ventured outside their "safe zone." Ngo's (2026) participants likewise

described themselves as critical mentors and ethical guides, roles defined by judgement and relationship rather than information.

The relational case has limits. Much of the evidence is a single case study, a review, or small interview samples, and claims about what AI "cannot" do may age poorly as systems become more conversational. The more durable argument is normative rather than technical. Even if a system could imitate empathy convincingly, a school has reasons to keep a responsible adult accountable for each child's moral and social formation. Presence also has a practical side. When AI tools give students competing explanations, the teacher's standing as a trusted interlocutor becomes part of instruction itself (see Q260).

There is also the question of identity and will. A 2025 study in the Journal of e-Learning and Knowledge Society finds that many teachers are already redefining their roles as learning designers and adopting reflective, student-centred pedagogies. Their ability to fully realise this shift, however, depends on institutional support, curriculum demands, and access to professional development. The authors describe the transition as a profound pedagogical and identity shift rather than a technical adjustment, one that requires agency, collaboration, and systemic alignment. The redefinition, in other words, cannot be mandated from above; it has to be inhabited.

Ngo's (2026) Vietnamese data make the same point at the level of policy. Teachers' reasoning was shaped through negotiation with national, ministerial, and institutional governance documents, not simply by personal conviction. New roles were improvised within constraints that teachers did not choose.

Quantitative work points the same way, though its designs warrant caution. Filiz and Gür (2026) surveyed 381 mathematics teachers. They found a statistically significant, moderately positive relationship between technology acceptance and self-efficacy for technology integration ($r = 0.541$; $\beta = 0.42$; $p < .001$). Because this is a correlational survey modelled with structural equations, it shows association, not that positive attitudes cause confidence. The authors themselves conclude that positive attitudes alone are not enough for effective integration. They argue that teacher education should strengthen practical skills and pedagogical approaches to technology use, and that contextual factors such as infrastructure also matter.

Gökbulut (2026) offers a more targeted intervention. Over a 10-week applied training period, 31 pre-service teachers developed digital materials around the Sustainable Development Goals using AI and AI-supported Web 2.0 tools. Their AI-TPACK scores rose significantly in pedagogical knowledge, AI-technological knowledge, pedagogical content knowledge, and overall AI-TPACK. Content knowledge showed no significant change. Interviews described more engaging learning environments and greater digital self-confidence. With a single small cohort, the result is suggestive rather than definitive. Its pattern is nonetheless telling: training improved how teachers teach with AI but not what they know about their subject. Preparation for the redefined role is therefore largely pedagogical and dispositional, which bears directly on how teacher education should change (see Q026).

What, then, is the teacher becoming? The China Daily commentary argues that future student development should centre on the ability to ask meaningful questions, think critically, and drive innovation. If that is what students need, the teacher's redefined role is to model exactly those capacities. Teachers should do this not by lecturing about them but by exercising them visibly and in relationship with students. Each of the competing accounts contributes something to that role. The facilitator brings the craft of building conditions for learning. The epistemic designer brings judgement about what is worth knowing and accountability for how AI-generated material enters the classroom. The relational account brings the presence that makes intellectual risk feel safe. The more speculative "Cognitive Choreographer" brings the recognition that some student thinking will now happen in partnership with machines and must be orchestrated rather than ignored.

The fear expressed by Sarmurzin and colleagues' pre-service teacher, of being asked a question one cannot answer, shows clearly what must change. In an AI-saturated classroom, students can always find an answer; what they need is help judging which answers deserve trust and which questions are worth pursuing. A teacher who can say "I don't know, so let's find out how we would know" is not failing. That teacher is demonstrating the very capacity the curriculum should cultivate. The evidence for this reorientation is still largely conceptual and qualitative, and the balance between design, facilitation, and presence will vary by subject, age, and institution. The best short answer may still be this: the teacher moves from being the source of answers to being the most experienced asker of questions in the room.

Q023 What pedagogical models (Socratic, constructivist, mastery-based) does AI enable at scale for the first time?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

AI enables three demanding pedagogical models to operate at scale for the first time: Socratic dialogue, constructivist knowledge-building, and mastery-based progression. None of them is new, and none is guaranteed to work in machine form. The novelty lies in economics and logistics. For most of educational history the most powerful models of teaching have also been the least scalable. The Socratic method needs a patient interlocutor who will withhold answers, ask probing questions, and tailor each question to one student's particular confusion. Constructivism requires learners to build knowledge through exploration rather than receive it passively. Mastery learning holds that no student should advance until genuine competence has been shown.

All three ideals share one structural problem. They are labour-intensive and individualised, and therefore expensive. The well-resourced university tutorial, the one-to-one Montessori session and the personalised mastery curriculum have historically been luxuries. A systematic review of personalised learning trends published in Frontiers in Education (2026) observes that traditional approaches, limited by classroom instruction and available resources, have long struggled to individualise learning at scale. Dartmouth researchers (2025) report evidence that AI can now deliver personalised learning at that scale.

The argument of this answer is that AI is removing the cost constraint. It is not removing the human and evidential conditions that decide whether these pedagogies succeed. The gap

between what is genuinely enabled and what is merely promised therefore runs through every section that follows.

The Socratic method is the most dramatic case. Its classic move is to answer a student's question with another question. This is not obstruction. It redirects the student toward insight they generate themselves. In a 2025 comparative study in Frontiers in Education of ChatGPT and human tutors, the authors describe Socratic tutoring as rooted in the philosophy of Socrates and centred on dialogue and questioning. By drawing students into structured conversation, it fosters deeper understanding and asks learners to articulate their reasoning. In doing so it develops higher-order skills such as analysing, evaluating and synthesising information. The difficulty has always been arithmetic: a human tutor using the method can work with only one student at a time.

AI systems now implement the approach through deliberate design constraints. Khan Academy's Khanmigo is built on GPT-4 and, according to an industry case study, has been fine-tuned across 842 courses. That figure comes from a commercial blog rather than peer-reviewed research and should be read accordingly. Khanmigo's core design principle is that it never gives the answer.

In an exploratory randomised controlled trial in UK classrooms, released as a 2025 preprint, Google's LearnLM was prompted to draft concise Socratic responses. These were designed to guide students toward correcting specific misconceptions without revealing the answer. The authors conclude that such tutoring can be delivered safely and effectively. The trial is described as exploratory, and the paper has not yet passed peer review. A practitioner overview of AI Socratic tutors also reports a Georgia Tech initiative that used AI to scale the viva-style oral examination. That format has traditionally been too resource-intensive for large cohorts, and the initiative used it to probe the depth of students' reasoning. The examination question itself is treated more fully elsewhere (see Q028).

The model is also spreading into fields where dialogue is central to formation. Papakostas (2025) reviews AI in religious education through a critical literature review and institutional case studies, including Harvard Divinity School and the Oxford Centre for Digital Theology. He identifies AI-mediated dialogic simulations as a didactically grounded opportunity. He also warns of overreliance, theological distortion and epistemic conformity, and argues that AI must not replace the relational and formational side of teaching.

The limits of AI Socratic tutoring are real, and the literature disagrees about how serious they are. The first limit concerns the student. The practitioner analysis of AI Socratic tutors notes that the method collapses if the student does not bring genuine cognitive effort. What remains is a chatbot asking questions of someone who has checked out. The method's power depends on intellectual reciprocity, and AI cannot compel it.

Sánchez (2026), writing a viewpoint in JMIR Medical Education, sharpens this into two named failure modes. He grants that delivering Socratic dialogue at scale is plausible. Such dialogue would be personalised, always available and lower-stakes, and human educators cannot logistically provide it. He nonetheless argues that the promise remains unproven.

The first failure mode is the "mimicry trap". A system that fluently generates Socratic-sounding questions can appear to cultivate reasoning while functioning only as interactive content delivery. Sánchez frames this as an educational instance of the ELIZA effect and of the proxy-outcome problem. In his view, separating conversational mimicry from genuine metacognitive gain is still an unresolved evaluation problem. The second is the "Panopticon Paradox". The data collection that makes AI tutoring effective may erode the psychological safety that Socratic inquiry requires. Learners may then shift toward performative rather than authentic engagement, much like the gaming behaviours documented in intelligent tutoring systems.

Sánchez is careful about the status of these claims. He presents the second construct as a testable causal model with falsifiable predictions, not as an established finding. He also notes that the evidence base consists mostly of proof-of-concept tools, cross-sectional surveys and short-term evaluations.

The UK trial's positive conclusion and Sánchez's scepticism are therefore not strictly contradictory. The trial asks whether AI tutoring can work under controlled conditions. Sánchez asks whether current measures could tell genuine Socratic learning from its imitation. Until evaluation frameworks address that second question (see Q094), claims that AI delivers Socratic pedagogy at scale should be treated as contested.

Constructivism holds that knowledge must be built rather than transmitted, a view associated with Piaget and Vygotsky. It maps naturally onto what adaptive AI systems do best. Richter and colleagues (2025), writing on marketing education, ground three commonly implemented features in constructivist learning theory: adaptive content sequencing, learner-controlled pacing and personalised feedback. That theory treats learning as an active construction of

knowledge, shaped by prior experience and context. In practice, an AI platform can scaffold a student's encounter with new material so that each concept extends something already understood rather than arriving as an arbitrary imposition. Strielkowski and colleagues (2025) argue that analysing individual learning patterns and adapting content keeps students working at an optimal level of challenge, which promotes deeper learning and retention. What is genuinely new is that this process can be personalised for thousands of learners at once. No human teacher or fixed curriculum could attempt that.

Recent work adds needed precision about what kind of scaffold AI should be. Ren and colleagues (2026) present a mini review of anaesthesia education. They conceptualise AI not as an autonomous teacher or objective assessor but as a contingent, temporary scaffold. On their account, it should be adapted to learner performance, progressively faded, and followed by an assessment of whether learners can transfer the skill independently. Human supervisors remain essential. Their evidence review is candid. Anaesthesia-specific studies of AI-assisted regional anaesthesia training, ultrasound interpretation, virtual patients and simulation analysis show feasibility or task-specific benefits. They do not yet establish gains in clinical reasoning, competence or entrustment. The fading principle is the constructivist answer to cognitive offloading (see Q030).

Other studies are empirically promising but rest mainly on perceptions. Ruiz Viruel, Sánchez Rivas and Ruiz Palmero (2025) surveyed 300 teachers across primary, secondary and higher education. Those teachers rated AI-enhanced project-based learning significantly higher than project-based learning without AI, with a Cohen's d of 1.30. They credited greater autonomy, responsive feedback and adaptive personalisation. This measures teacher perception rather than student learning.

Wang, Pan and Zhu (2026) conducted a constructivist case study of 12 teachers and 201 students across six Chinese classes. They found that four reform orientations each improved outcomes, but in different ways and at different costs. Technology-development approaches increased the burden of learning AI. Thinking-development approaches strengthened critical thinking but depended on teachers guiding students.

The student side of the picture comes from Yang and colleagues (2025). Their qualitative study of 45 translation students found appreciation for efficiency and accuracy alongside concerns about overreliance and eroded creativity. Students' readiness and self-efficacy varied widely

depending on their prior training. Constructivist AI, in short, appears to amplify the teacher's design choices rather than replace them.

Mastery-based learning may be where AI's structural advantage is clearest. The classical criticism of time-based schooling, that it advances students by the calendar rather than by competence, is well documented. Mastery models require demonstrated understanding before progression. They solve this problem in theory, but in practice they created an administrative and logistical burden that overwhelmed most institutional attempts.

An eLearning Industry overview (2025) describes AI-powered adaptive systems as offering a bespoke experience. On this account, the system adjusts dynamically to each student's pace and comprehension, anticipates areas of difficulty, and offers targeted resources to secure mastery. Its illustration is a student who struggles with fractions but excels at geometry. The system detects the discrepancy and supplies extra practice or alternative explanations aimed at the gap. The same source frames adaptation partly around "learning styles", a construct with weak empirical support. Its account should be read as a description of design intent, not as evidence.

On outcomes, a systematic review in the International Journal of Education and Humanities reports a strong result. It finds that adaptive systems can reduce learning time by 30–50% while improving outcomes by 15–25% compared with traditional instruction. These ranges are striking, and they aggregate heterogeneous studies. They should be read as indicative rather than as reliable estimates of effect.

A broader systematic review of adaptive techniques in Discover Education (2025) is more cautious. It records progress in personalisation methods and flags persistent challenges in model interpretability, data privacy and scalability, especially in low-resource settings. Dartmouth researchers (2025) found that AI can deliver personalised learning at scale. They also warn of an "illusion of mastery", in which students outsource their thinking to AI and progress without genuinely learning. That warning strikes at the heart of mastery pedagogy. A system that certifies progression on the basis of AI-assisted performance may make the calendar problem worse rather than solving it. This is why mastery-based AI depends on formative assessment that tests independent understanding (see Q230).

An honest accounting across all three models must acknowledge the problems that come with the promise. Traditional approaches, constrained by classroom instruction and resources, have historically struggled to individualise learning at scale, as the 2026 Frontiers review notes. AI

does not automatically dissolve every one of those constraints. The Discover Education review's warnings about interpretability, privacy and low-resource scalability apply equally to Socratic, constructivist and mastery systems. Equity of access, algorithmic bias and the Dartmouth "illusion of mastery" remain live concerns that the evidence has not resolved.

Alqurni (2026) adds an institutional dimension. His survey of 280 university students, analysed with structural equation modelling, examined sustainable adoption of AI and Metaverse technologies. Environmental factors, such as energy-efficient systems, and social factors, such as inclusive access and student acceptance, showed stronger associations with sustainable adoption than governance factors did. Faculty readiness influenced adoption only indirectly. These are correlations from self-report data, not causal findings. Still, they suggest that scale depends on inclusive access as much as on technical capability.

The human dimension matters just as much. Khodi, Curle and Parra-Guinaldo (2026) offer a perspective grounded in professional observation and explicitly intended to open discussion rather than settle it. They argue that teachers need "pedagogical prompting" more than technical mastery. In their account, teachers must be able to make AI serve teaching, learning and student participation. They do not need to keep learning new technical systems. Implemented through deliberate prompting, every one of these models depends on that capacity, which bears directly on how teacher education must change (see Q026).

What is nonetheless historically significant is that the structural ceiling has been lifted. Socratic, constructivist and mastery models can now reach millions of learners simultaneously. Whether that reach produces the learning these pedagogies were designed for remains unclear. The answer depends on rigorous evaluation, inclusive deployment and the judgement of teachers. Whether institutions and educators use this opening intelligently is a separate, and still open, question.

Q024 How can AI support teachers (planning, assessment, feedback) without deskilling or replacing them?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

AI can support teachers without deskilling or replacing them when it takes on the mechanical, time-consuming parts of planning, assessment and feedback, while teachers keep authority over the decisions those tasks feed into and keep practising the judgment that makes them professionals. This is not only a technical question. It concerns the nature of professional expertise itself, and the evidence gathered over the past few years points to a clear but demanding answer. AI is most valuable when it frees the cognitive and emotional energy that the irreplaceable work of teaching requires. It is most dangerous when it quietly takes over that work.

Planning shows both the promise and the caveat. Lesson design has long consumed hours that teachers might otherwise spend with students. The University of San Diego's survey of classroom tools describes platforms such as MagicSchool.ai and Eduaide.AI that produce customisable lesson content aligned to learning goals. Indiana Wesleyan University's account of AI-assisted planning identifies the generation of well-structured, standards-aligned lesson plans as one of AI's most practical strengths. Teachers enter objectives, link them immediately to state or national standards, and receive suggestions that highlight skill gaps, without hours of manual research. The same source cautions that these outputs are strong starting points but may need refinement to fit a school's pacing guides or curricular frameworks. Professional judgment therefore remains the final editor of anything a machine produces.

Rakshit's (2026) review of AI in teacher education offers a broader frame for that caveat. It concludes that AI's transformative potential depends on implementation that is pedagogically grounded, ethically governed and professionally mediated. The same review lists deskilling, algorithmic bias and data surveillance among the main unresolved concerns. Its evidence base is a thematic synthesis of journals, websites and books rather than new empirical data, so it

describes conditions for success rather than demonstrating outcomes. What happens to professional identity when the materials themselves are machine-generated is a separate and pressing question (see Q114).

Formative assessment makes a particularly strong case for AI because speed matters so much there. SchoolAI, a vendor, describes exit tickets (brief end-of-class checks for understanding) as one of the best-evidenced formative strategies. It cites a 2019 meta-analysis reporting an average improvement of 0.4 standard deviations in learning outcomes. The underlying study is not identified in that source, so the figure should be treated with caution until it is traced to its origin.

The practical bottleneck is easier to accept. A teacher with 90 students across three sections receives 90 exit tickets per lesson. Reading and sorting them has traditionally taken 30 to 45 minutes, and AI tools can now reduce that analysis to seconds. OpenEduCat reports that teachers using AI-powered evaluation tools save approximately 44% of their time on administrative tasks. This is a vendor figure without a disclosed methodology, not a research finding, and it should be read as indicative at best.

The limits matter as much as the gains. EdTech Hub's analysis argues that AI is most reliable for formative assessment of constrained tasks. Using it to grade, for instance, final examinations in philosophy would be plainly inappropriate.

Teachers themselves appear wary of crossing that line. Vinci and colleagues (2026) surveyed 662 trainee teachers in qualifying programmes at the Universities of Foggia and Bergamo. They found what they call a 'conscious resistance': respondents reported reasonable technical comfort, yet their pedagogical trust in AI for assessment was low, averaging 4.83 out of 10. Their correlational analysis revealed a training paradox. Trust was more strongly associated with the perception of concrete support ($\rho = 0.57$) than with the technical training received ($\rho = 0.36$). These are associations in a single cross-sectional sample, not causal effects. Still, they suggest that confidence in AI-assisted assessment grows from institutional backing more than from technical instruction. Respondents also raised concerns about dehumanisation and asked for a principle of subsidiarity, under which AI handles only what humans need not.

Assessment design is also shifting in response to AI. Yang (2026) found that 80% of surveyed geography students used ChatGPT, mainly for brainstorming (63%). The same students favoured project-based assessment (70%) and fieldwork or internships (70%). Yang's response

was a project-based model built on data collection, oral presentations and peer assessment. That approach depends on more teacher judgment, not less (see Q028; Q230).

Timely feedback is among the most powerful interventions in learning, and AI greatly shortens the lag between submission and response. OpenEduCat notes that students can receive detailed feedback on the day they submit their work. Corrections then arrive while the material is still fresh, which supports faster improvement. Educators Technology describes how Gradescope goes further by using AI to group similar student answers. A teacher can then write a comment once for a common mistake, and the note applies automatically to every student who made that error. This design deserves attention because it keeps the teacher as the author of the feedback. The machine organises the work, but the teacher still diagnoses the error and composes the response.

The evidence for caution is uneven but cannot be dismissed. HTL International School cites a 2025 MIT study reporting lower cognitive engagement among students who relied heavily on AI while writing. That finding reaches this chapter second-hand, through a school's commentary rather than the original publication. Educators Technology relays teachers' reports that AI grading accuracy is around 50 to 55% when a rubric is provided and falls to roughly 33% without one. These figures are practitioner testimony, not controlled measurement. Even so, they point the same way: unsupervised automated grading is not yet trustworthy for consequential judgments.

The theoretical literature explains why the risk extends beyond accuracy. Chow, Ng and Sadasiv (2025) present a conceptual roadmap from medical education. They argue that AI can scaffold inquiry and reshape assessment through blueprint-aligned items and predictive analytics. They also stress its double-edged nature: it risks undermining integrity, encouraging cognitive deskilling and bypassing productive struggle, which they define as purposeful, scaffolded difficulty that feels effortful yet achievable. Aboodi (2025) argues in Educational Theory that no 'artificial consultant', however strong its track record, could justifiably be trusted to rule out misleading guidance in high-stakes situations. Human critical thinking therefore keeps its value on outcome-based grounds alone. Both are conceptual arguments rather than empirical findings. They imply that fast AI feedback helps learning only when it prompts student thinking rather than replacing it (see Q030).

The risk of deskilling is real and should not be minimised. Ferdman (2025), writing in AI & Society, begins from the observation that many AI tools replace, or stand to replace, human activity through automated decision-making, recommender systems and content generation. The more AI replaces valuable human activity, the more it risks deskilling people of their capacities. Her distinctive contribution is to treat this as a structural problem rather than a matter of individual discipline. She introduces the concept of 'capacity-hostile environments': settings in which AI mediation impedes the cultivation of human capacities.

Drawing on the philosophy of skill and on social epistemology, Ferdman argues that skilling means acquiring agential control over a capacity through long, gradual habituation. That habituation depends on learning from others, both the know-how of the skill and a shared understanding of why it is worth having. For teaching, the implication is uncomfortable. A school that routes lesson planning, marking and feedback through AI may erode the conditions under which novice teachers acquire those skills, even if each individual teacher means well. The concern is especially sharp for novice and under-qualified teachers, who have the least expertise in reserve (see Q116).

The systematic review in Education Sciences on teacher autonomy and pedagogical automation makes a parallel point for education specifically. The risk is not automation as such but pedagogical deskilling through disuse. When teachers are less involved in core instructional decisions, the knowledge and judgment those practices sustain may gradually erode. A subtler threat, discussed in recent work on teachers' meaningful work, is 'reverse adaptation'. Here educational ends are adjusted to fit machine-readable means, rather than the reverse. Teachers become conditioned to anticipate what the system will approve rather than what the situation calls for.

Other professions offer an instructive comparison. Goyal and colleagues (2026) note that computer-aided detection in endoscopy raises adenoma detection rates while also raising questions about the balance between enhancing and eroding endoscopists' skills. Teaching faces the same tension, in a domain where the outcomes are harder to measure. How large the deskilling effect actually is in classrooms remains unclear, because longitudinal studies of teachers' skills under sustained AI use do not yet exist.

What protects teacher expertise, then? The UNESCO Teacher Task Force's 2025 position paper on teacher agency gives the clearest institutional answer. AI can automate tasks, support

learning and improve efficiency, but it cannot replicate the relational, ethical and creative dimensions at the heart of teaching. Protecting those dimensions requires treating AI literacy not as an optional extra but as a professional obligation.

The systematic review on teacher autonomy specifies what that literacy involves. Teachers must be able to identify algorithmic bias and keep AI integration ethical, so that technology does not alienate them from their own practice. They must also develop the discernment to know when AI supports their intellectual autonomy and when it undermines it. Vinci and colleagues (2026) reach a compatible conclusion from their trainee-teacher data. The 'AI-literate' profile their respondents described is defined less by technical fluency than by ethical and relational judgment, and by the expectation that AI should play a subsidiary role.

Governance matters as much as individual competence. EdTech Hub argues that AI assessment tools should be designed and implemented together with teachers. Teachers should be empowered to review results so that validity is protected, and teacher-centred design should be treated as essential to both effectiveness and uptake. This connects to Ferdman's (2025) structural argument. If capacity-hostile environments are created at the level of systems, they must also be prevented at that level, through procurement, workflow design and assessment policy, not left to teachers' private resolve. Rakshit's (2026) emphasis on professionally mediated implementation points the same way.

The practical principle is that AI should prepare decisions and teachers should make them. Gradescope-style clustering, AI drafts of lesson plans that teachers revise, and exit-ticket summaries that teachers interpret all fit this pattern. Unreviewed grading of open-ended work and auto-generated curricula adopted without scrutiny do not. Where students meet AI explanations that compete with the teacher's, keeping that authority becomes harder still (see Q260).

Expert and stakeholder opinion broadly supports augmentation rather than replacement, though opinion is not evidence of outcomes. Forbes reports a 2024 World Economic Forum finding that 78% of education experts believe AI will augment teachers' work rather than replace it. HTL International School cites research surveying university teachers and students that found consensus on one point: AI cannot replace the human qualities essential to students' competency development and personal growth. Low pedagogical trust among Italian trainee teachers (Vinci and colleagues, 2026) suggests the profession largely shares this view.

That consensus is encouraging, but it will not fulfil itself. Whether augmentation actually happens depends on whether schools invest in professional development, and on what kind. Forbes reports that 50% of teachers received professional development on AI in fall 2025, up from 13% in 2023. The more important question is whether such training builds critical judgment or merely passive adoption. Ibrahim and colleagues (2025) studied 1,007 adults in general, not teachers. They found perceived usefulness to be the strongest predictor of attitudes towards AI use (β =.34). This is a reminder that adoption can be driven by convenience rather than by careful assessment of what a tool does to one's practice. Vinci and colleagues' finding that trust tracks concrete support (ρ = 0.57) more closely than technical training (ρ = 0.36) suggests that tool tutorials are not enough. Professional learning should include sustained collegial support and explicit discussion of when to say no.

The literature does not fully agree. Practitioner and vendor sources emphasise time savings and efficiency. Philosophical work such as Ferdman's (2025) and Aboodi's (2025) warns that efficiency gained by giving up judgment may cost more than it saves. That tension is not yet settled empirically. The teachers least at risk of being diminished by AI are those who understand it well enough to know, at any given moment, exactly what it should and should not be allowed to decide.

Q025 What does effective human–AI co-teaching look like in a real classroom?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Effective human–AI co-teaching in a real classroom looks less like a robot standing beside a teacher and more like a continuous negotiation. The AI system takes on work that demands speed, scale or pattern recognition across large amounts of data, while the teacher keeps authority over judgement, relationships and the moral texture of the room. It is not a single model but a continuum of arrangements. The evidence from actual classrooms, as distinct from design proposals, is promising, uneven and still being worked out in practice.

The best-documented form of co-teaching rests on a clear division of labour. AI has made significant inroads into intelligent recommendation, automated grading and learning analytics. It is increasingly reaching core aspects of teaching as well, including instructional design, classroom management and student assessment. The bibliometric analysis by Ivanova, Grosseck and Holotescu (2024), drawing on five years of Scopus and Web of Science records for "artificial intelligence and teaching," documents rapid growth in this research. That literature is produced largely by collaborative, often international teams and concentrates on machine learning, deep learning and conversational tools such as ChatGPT. Growth in publications is not the same as growth in classroom practice, however.

In practice, teachers rarely hand tasks over wholesale. Field studies of how teachers negotiate generative AI's place in their work show them doing ongoing interpretive labour. They evaluate AI outputs, reconcile them with classroom contexts and adapt them to students' diverse needs. The AI proposes and the teacher disposes. Cukurova (2024) gives this arrangement a theoretical frame. He argues against the narrow view of AI as a tool and distinguishes three conceptualisations: AI as externalisation of human cognition, AI models internalised into human mental models, and tightly coupled hybrid systems that extend human cognition. He warns explicitly against approaches that replace human learning rather than extending it. Co-teaching at its best belongs to the third category, although most classroom deployments still sit closer to the first.

The division of labour becomes clearer when one looks at planning, where much co-teaching actually begins. One of the more carefully studied implementations is the Culturally Responsive Lesson Planner, a GPT-powered tool observed in science classrooms. It does not issue generic outputs. Instead it draws teachers into a structured dialogue: the AI asks targeted questions specific to the context and culture, and teachers answer with their content knowledge, classroom expertise and understanding of their students' cultural assets. As teachers refine the

AI's drafts over several rounds, the process activates pedagogical decision-making, cultural reasoning and anticipatory judgement.

The cognitive demands on the teacher rise rather than fall. Teachers critique AI drafts, generate cultural examples, evaluate scientific coherence, adjust difficulty levels and confirm conceptual accuracy. Together these tasks show that AI-assisted teaching is not a passive activity. This cuts against the popular assumption that the main benefit of AI is time saved. Where the design is good, the teacher's expertise is called on more intensively.

Teachers' own accounts support this picture, though the samples are small. Ticar (2026) interviewed ten public secondary English teachers in the Davao region of the Philippines and identified four themes: Augmented Efficiency, Ethical Agency, Pedagogical Mediation and Future Readiness. The teachers reported improved workflow, support for personalised learning and richer assessment. They also raised concerns about academic integrity, the accuracy of AI outputs and digital inequities among students, and they insisted on keeping authentic teacher–student interaction. The study's "Analyze-Change-Transform" method describes almost exactly the critique-and-revise loop seen in the lesson-planner work. A phenomenological study of ten participants cannot establish prevalence, but its convergence with the science-classroom findings suggests that mediation is the core co-teaching skill. What happens to professional identity when materials are increasingly machine-drafted is a separate question (see Q114).

Inside the lesson itself, co-teaching takes a different shape. Here the AI's contribution is usually orchestration and monitoring rather than drafting. Billings and colleagues (2024) offer one of the clearer classroom tests. They used natural language processing to identify grade 7 students' ideas in written science explanations, formed discussion groups from those ideas, and supplied a question bank grounded in Knowledge Integration pedagogy to guide peer chat. The tool was embedded in an earth science unit and tested in two classrooms at one school. The result was instructive in both directions. The similarity of students' ideas limited the value of grouping students to maximise variety, but the question bank did help students use knowledge integration processes. The pedagogical scaffold, designed by humans around a learning theory, did more work than the algorithmic grouping. Effective co-teaching may therefore depend less on AI sophistication than on how well AI functions are tied to sound pedagogy.

At the more technologically ambitious end, Saini, Sharma and Sengupta (2026) present AI-TEACH, which they frame as a "co-teacher paradigm." It fuses audio and video from

classroom cameras to detect and score student distraction and reports results to an instructor dashboard. The authors report 90% accuracy and 92% recall in distraction detection, based on a curated dataset of recordings and a controlled experiment with 200 students in experimental and control groups. These are detection metrics. They do not show that teachers used the dashboard well or that learning improved. Surveillance-based monitoring also raises questions of trust and consent that the abstract does not address. Whether such systems sit comfortably alongside a teacher's own reading of the room remains unclear.

The tension between these two examples is real. One treats the AI as a support for student-to-student thinking (see Q030). The other treats it as an instrument for watching students. Both describe themselves as partnering with teachers.

Whatever the tool, co-teaching arrangements change over time, and the early evidence suggests they remain unstable for a while. At the junior-high level, a case study of a hybrid intelligence classroom with forty students and one teacher applied a Synergy Degree Model to the human–AI partnership. It found that the order degree between the human teacher and the AI systems stayed at a moderate level while changing dynamically. The finding captures how unsettled early co-teaching arrangements are. With a single teacher, it cannot tell us how typical that moderate synergy is. It does suggest that a well-functioning partnership should not be expected from the first week.

The partnership is not static. Teachers and systems adjust to each other across weeks and months. Research on university teachers' continued use of an AI teaching assistant integrates task–technology fit, technology acceptance and expectation-confirmation models. It treats AI integration as a dynamic process in which confirmation, satisfaction and continuance behaviour probably evolve as teachers gain experience and as systems are updated. That work also notes the limits of a cross-sectional snapshot for a phenomenon that unfolds longitudinally.

The human co-teaching literature offers a sobering parallel. Goulet and Ross (2026) followed one pair of secondary science co-teachers implementing new standards. The partners lacked parity, or equal status, because they had not been prepared for the partnership, the content was complex, and they had too little time and structure to plan together. Role disparity grew as a result, although each partner's respect for the other's work increased over the year. If two trained professionals struggle to reach parity without preparation and planning time, the same structural conditions are likely to matter even more when one partner is a system whose

behaviour the teacher cannot fully inspect. The analogy has limits, since an AI has no status to claim. But it points to time, preparation and role clarity as preconditions rather than optional extras.

A persistent structural problem is that AI tools designed outside the classroom often fail to match the realities inside it. Reviews of teacher–AI co-design in learning task design identify a gap between design innovations and their sustained use in classrooms. Tools fall short when they are not meaningfully aligned with pedagogical objectives or with the dynamics of real lessons. Topali and colleagues (2024) quantify part of the problem. Their systematic review of 47 empirical studies in human-centred learning analytics and AI in education found that more than two-thirds involved stakeholders in designing the solutions. Fewer involved them during ideation and prototyping, and most reported no evaluation at all. Few studies explicitly adopted existing human-centred design guidelines. The authors attribute limited adoption in authentic settings partly to neglect of stakeholders' needs, weak pedagogical contextualisation and low trust in new technologies.

Teachers in field studies report that a minority of AI suggestions are inconsistent or overly generic. A minority still matters a great deal when a teacher has to decide, mid-lesson, whether to trust a system's recommendation. An occasional error from a planning assistant can be caught at the desk. An occasional error delivered live to thirty students is harder to recover from. This is why maintaining instructional authority when AI and teacher may offer competing explanations deserves separate treatment (see Q260). Interview evidence on how teachers negotiate generative AI frames the stakes as relief or displacement. The same tool can free time for relational work or quietly shift professional judgement away from the teacher, depending on how it is introduced and governed.

The literature does not fully agree here. Design-oriented work tends to treat misalignment as a fixable engineering and co-design problem. Teacher-experience studies more often describe it as a lasting feature that teachers must manage through vigilance. Both readings have support, and the current evidence does not settle which is closer to the truth.

Teacher agency is therefore central to whether co-teaching works at all. Work on teacher–AI co-design argues that incorporating diverse AI tools depends on teachers' professional agency, and that this agency is seriously lacking in most educational development. Where institutional support is strong and teachers feel genuine ownership of the technology, the picture shifts

markedly. A survey study found that teacher–AI collaboration significantly and positively predicted teaching engagement. That finding is a predictive association from survey data, not proof that collaboration causes engagement. More engaged teachers may simply collaborate more readily.

Building agency appears to depend on involving teachers in shaping both tools and competencies. Filo, Rabin and Mor (2024) co-created an AI competency framework with teachers. It names four skills: identifying how AI mechanisms operate, effective and informed use, "AI agency" understood as proactive and value-generating use, and ethical use. The authors acknowledge that assessment indicators and assimilation models are still needed. The teachers in Ticar's (2026) study likewise called for institutional policies and continuous professional development. Which development programmes actually build this capacity, and with what measured effects, is a question the evidence has only begun to answer (see Q254).

Taken together, the evidence presents effective co-teaching as a practice of continuous negotiation rather than a fixed configuration. Emerging models of hybrid human–AI pedagogy frame AI as a collaborator that expands human capacity rather than a replacement, in line with Cukurova's (2024) case for tightly coupled hybrid intelligence over substitution. In the classroom, the teacher sets the values, reads the room and holds the relationships. The AI extends the teacher's reach into data, personalisation and feedback at scale, whether by drafting culturally grounded lessons, scaffolding peer discussion or flagging patterns a single adult might miss. Neither works well without the other. On current evidence, which is still dominated by single cases, small interview samples and detection metrics rather than learning outcomes, neither yet works perfectly with the other either.

Q026 How should teacher training change so educators can critically use, evaluate, and challenge AI tools?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

Teacher training should be rebuilt so that critical judgement about AI sits at its centre and operational skill at its periphery: educators need to understand how these systems work, evaluate what they produce, reason about their ethical consequences, and keep the authority to refuse them when they fail learners. Generative AI has exposed a structural gap in how teachers are prepared. Qualitative work with K-12 teachers reports that many professional development initiatives concentrate on technical skills rather than pedagogical integration, which leaves teachers unsure how to incorporate AI meaningfully into their practice. The result is educators who can operate AI tools but cannot reason about them. That competence is fragile, because the tools change every few months and button-level knowledge loses its value almost as soon as it is acquired.

Adoption research points to a further reason why technical training alone falls short. Bahaw, Sadiq, Sookhai and colleagues (2026) studied entrepreneurship educators using the Unified Theory of Acceptance and Use of Technology. They identified affinity to technology as an individual-level antecedent of whether educators take up generative AI, and they specified boundary conditions under which facilitating conditions lose explanatory power. Their sample is a single disciplinary community, so generalising from it should be cautious. Still, the finding suggests that supplying access and infrastructure, which is the usual institutional response, does not by itself explain why or for what purpose teachers use these tools. If adoption depends partly on individual dispositions toward technology, training that only removes practical barriers will tend to favour enthusiasts. It will not cultivate discernment across the whole profession.

The most persuasive emerging consensus holds that teacher training should be organised around three interlocking demands: technical understanding, critical evaluation, and ethical reasoning. Studies of training interventions argue that educators need a working degree of AI literacy to integrate these technologies into pedagogy and curriculum while keeping a critical perspective on their use. This is a precondition for responsible teaching rather than an optional enrichment, since teachers are increasingly expected to shape their students' own AI literacy.

The critical dimension is the one most often underemphasised. Work on language teachers' collaborations with ChatGPT and assessments of AI literacy in professional settings describe AI literacy as the ability to evaluate AI outputs and tools critically. That means judging their quality, appropriateness and potential biases. It also means understanding ethical principles, data privacy, bias embedded in AI systems, and the broader social and environmental impacts of the technology. These are not peripheral concerns for specialists. They are core competencies for any teacher who intends to integrate AI meaningfully, because each one shapes what a classroom use of AI actually does to students.

Ahmed and Alreiahy (2026) sharpen this argument in a conceptual analysis of teacher preparation. They observe that preparation programmes have adopted AI tools quickly, while the ethical, social and environmental dimensions of that adoption receive comparatively little attention in how future educators are trained. Their response is to integrate AI competence, sustainability education and ethical technology use into one coherent framework, rather than running three parallel add-ons. As a conceptual contribution, it offers no outcome data, and whether integrated designs outperform modular ones remains unclear. Its value lies in naming the structural problem precisely. When critique is taught separately from use, novice teachers learn to treat it as a separate activity rather than as part of using AI well.

The international policy community has begun to codify what these competencies should look like. UNESCO published its AI Competency Framework for Teachers in August 2024 in response to technological advances in AI and their impact on education. Summaries of the framework describe it as defining the foundational principles, values, knowledge and critical skills teachers should develop. These are meant to help teachers understand AI's role in education and use it in an ethical, effective, safe and responsible way. The framework covers five areas: fostering a human-centred mindset; understanding the ethics of AI, including privacy, data protection and the avoidance of algorithmic bias; building technical knowledge of AI foundations; integrating AI tools into pedagogy; and using AI for teachers' own professional development. The ordering matters. Mindset and ethics come before technique, which reverses the emphasis that the qualitative K-12 study found in much existing professional development.

The framework is also notable for its explicit warning about professional erosion. As summarised by Educational Evidence, UNESCO cautions that AI could soon replace data-driven educational decision-making. The risk is that teachers who rely too heavily on AI may lose key competencies. The framework therefore emphasises maintaining human agency and

ensuring that AI serves as a supportive tool rather than a substitute. This concern connects directly to debates about what happens to professional identity when machines generate curriculum materials (see Q114).

Frameworks of this kind carry real normative weight, but they are statements of aspiration rather than evidence of effect. Teachers become critical users of AI only if training programmes are redesigned to put these principles into practice, and that redesign is where the harder work lies.

Evidence from recent training interventions suggests that structured, hands-on engagement matters a great deal. Studies of in-service and pre-service training describe programmes that let teachers integrate new technologies in a controlled way, within secure environments and under expert guidance. These programmes encourage teachers to use AI tools while giving them feedback and opportunities for self-reflection. The pedagogical logic is that critical judgement develops through guided exposure, including exposure to failure, rather than through abstract warnings.

A graduate-level programme piloted across 2024 and 2025 through professional partnership inquiry reported that structured engagement increased candidates' awareness of both the affordances and the risks of AI in education. It also supported their ability to evaluate AI-generated outputs critically, assess alignment with educational standards, and articulate implications for their own instruction. These are encouraging results, but they come from a pilot. Without larger samples and comparison conditions, they cannot yet show that such gains last once candidates enter classrooms.

Other studies show what disciplined evaluation looks like in practice. Nyaaba, Min and Choi (2025) examined AI text-to-video tools for culturally and linguistically responsive teaching of English Language Learners, set against growing linguistic diversity and a shortage of bilingual educators. Their two-phase qualitative case design began with functional testing of VEED.io and CapCut. They assessed the tools' capabilities in generating visuals, audio, captions and multilingual content, specifically in freemium modes. Evaluating a tool's actual capacities under the conditions teachers will realistically face, before adopting it, is exactly the habit training should cultivate.

Preparedness also cannot be assumed among students who use AI routinely. Alemán Ramos and Morales Almeida (2026) used a convergent mixed-methods design with 49 undergraduate

Social Education students, combining perceived AI use, self-reported learning competencies and professional knowledge requirements. The small sample and reliance on self-report limit any inference. Even so, the study reflects growing recognition that socially oriented professions have been underexplored in AI preparation, and that critical, ethical and responsible use has to be taught deliberately.

Training delivered with AI raises its own questions. Chelouche-Dwek and Fonagy (2026) conducted what they describe as the first systematic synthesis of AI tools used to train caregivers, educators and therapists in psychological approaches relevant to child and adolescent mental health. They frame AI as a possible scalable, low-cost response to severely limited and inequitable access to such training. The promise is real. However, teachers trained through AI tools need the same critical lens they are asked to apply in their classrooms.

The ethical dimension of this training cannot be treated as an add-on module. Research on generative AI in vocational education and on AI literacy needs in professional settings highlights several hazards. Generative AI can produce hallucinations that sound plausible but are incorrect or outdated. It also raises concerns about bias in training data, unequal access to advanced models, and privacy where student data is stored. These problems require urgent attention, and teachers who do not understand these failure modes cannot protect their students from them. The co-design evaluation also documents a slide from productive co-design toward what it calls metacognitive laziness. Here AI use substitutes for thinking rather than supporting it, which is a risk for teachers as much as for learners.

The ethical problems also differ across the many kinds of work teachers do. Chinoracky and Stalmasekova (2025) conducted a thematic review of 42 open-access, peer-reviewed articles published between 2022 and 2025 in Web of Science and Scopus. Drawing on Slovak legislation, they classified university educators' activities into teaching, scientific research, and other work such as academic management and self-directed professional development. Their framework is rooted in one national legal context and in higher education. Its broader lesson is that ethics training tied only to classroom instruction misses the ethical decisions educators make when they use AI for research, administration or their own learning.

Assessment is where these concerns become most concrete. Newton and Jones (2025) review evidence that, for assessments such as essays and multiple-choice exams, concerns about validity are legitimate. ChatGPT can complete such tasks to a very high standard, quickly and

cheaply. They consider alternative ways to assess learning and stress the importance of keeping assessments of foundational core knowledge. Teacher education should therefore prepare candidates to redesign assessment, not simply to police it, a task explored further in work on AI-supported formative assessment (see Q230).

Together these strands support the position of Ahmed and Alreiahy (2026). Ethical reasoning must be built into practical work with AI: inspecting outputs, deciding what to delegate, and judging what a task is meant to develop. It should not be delivered as a separate lecture.

An unresolved tension runs through this research between depth and adaptability. AI evolves rapidly, and studies across disciplines argue that curricula must emphasise continuous learning and adaptability and promote a culture of lifelong learning. Yet effective integration of AI tools appears to require systematic training and ongoing technical support. Research cited in the K-12 study and the co-design evaluation notes that current teacher training systems may not meet the needs of this new kind of technology. It also notes that limited resources for ongoing professional development prevent teachers from engaging in long-term learning. The literature does not resolve this conflict. Advocates of adaptability favour short, renewable training cycles focused on transferable dispositions. Advocates of depth warn that critical evaluation requires sustained conceptual grounding, which brief workshops cannot provide.

Subject-specific reviews show why neither side can be dismissed. Wang and Wang (2024) describe how AI in physical education can contribute to designing teaching strategies, tracking teaching processes and evaluating outcomes, and they propose teacher training strategies accordingly. Such domain-specific uses imply that generic AI literacy needs to be supplemented by disciplinary judgement about what counts as good evidence of learning in a given field. That kind of knowledge takes time to develop.

The reform required is therefore structural, not merely additive. Inserting an AI module into existing pre-service programmes will not be enough. Teacher education must cultivate a disposition of productive scepticism. This means the capacity to use AI tools fluently while questioning their outputs, scrutinising their embedded assumptions, and keeping the pedagogical authority that no algorithm is equipped to exercise. In practice, it means preparing teachers to make lesson-level decisions about when AI helps learning and when it undermines it (see Q078). How such dispositions are best developed, and whether they persist under the time pressures of real classrooms, remains unclear. That uncertainty is the strongest argument

for treating teacher preparation for AI as a continuing research programme rather than a settled curriculum.

Q027 Can AI meaningfully teach non-cognitive skills — empathy, collaboration, resilience, character?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

AI can meaningfully help students practise non-cognitive skills such as empathy, collaboration, resilience and character, but there is not yet convincing evidence that it can develop them in the durable, transformative sense that moral and character educators mean. The answer depends on a distinction the research community has not resolved: *practising* a non-cognitive skill versus *developing* it. AI can plainly scaffold the first. Whether it can reliably produce the second remains genuinely open, and the honest scholarly position is to hold these two claims apart rather than let enthusiasm for the first stand in for evidence on the second.

The field is growing quickly, but it is still young. Wang, Cui, Zhang and colleagues (2026), in a scientometric analysis of 465 Web of Science publications on AI for social–emotional learning (SEL) between 2004 and 2025, report a notable rise in output. They identify three dominant research domains: machine learning–based emotion recognition, immersive technologies for SEL, and AI chatbots for emotional support. Laviola, Cucari and Novic (2024) find a parallel trend in workplace learning. Their bibliometric review of 151 human resource development papers published between 2002 and 2022, drawn from Scopus alone, identifies "AI in soft skills

development" and "AI coaching with chatbots" as two of five main research clusters. Mapping exercises of this kind show where scholarly attention is going. They do not show what works. A rising publication count is evidence of interest, not efficacy, and neither study reports outcome effects. The comparative work that would settle the matter remains scarce. A study in *Interactive Learning Environments* comparing real, virtual and AI-driven methods of teaching empathy starts from the premise that empathy is a fundamental skill whose most effective methods of cultivation are still an open question.

The most credible case for AI in this domain rests on simulation and scale. Building on work in game-based learning, more advanced AI systems can create dynamic, personalised social simulations. These offer students diverse scenarios that adapt in real time to their responses, so they can practise empathic moves and receive immediate feedback. The comparative empathy literature treats AI-driven simulation as a distinct third method alongside real and virtual encounters, not as a replacement for them. That framing matters: it positions AI as one route among several, to be judged against human alternatives rather than against no instruction at all.

The promise is most tangible for populations with specific developmental needs. Work published in *Computers* on a new AI framework for children with Autism Spectrum Disorder builds on evidence that emotion-aware technologies implemented in serious games can help these children develop social-emotional skills and emotion awareness. As AI grows more capable, such tools increasingly function as teaching instruments in their own right rather than as passive aids. Prospective practitioners appear receptive. Çotuk, Kaya and Arslan (2026) used an interpretive phenomenological design with 14 pre-service special education teachers who had taken AI-based courses and projects. Participants saw AI not merely as a tool for individualising instruction but as a potential agent that could transform pedagogical roles. They believed it could support social interaction, independent living skills and decision-making for learners with special needs. The same participants also raised the risk of social isolation. This is a small, qualitative sample of perceptions, not outcomes, but it previews the tension that runs through the whole literature.

For neurotypical learners, the claims are broader but no less hedged. Work on integrating AI into SEL argues that AI systems can support better emotional regulation and focus by tailoring learning experiences to students' emotional and cognitive needs. Zong (2025), studying English-as-a-foreign-language students, reports that an AI-enhanced social–emotional learning framework was associated with greater engagement and emotional well-being. The study

suggests such frameworks can create a more emotionally supportive environment overall. These are context-specific findings from particular implementations. They indicate that AI can shape the affective climate of learning, but not that students left with more empathy or resilience than they would otherwise have developed.

AI also offers something genuinely scarce in human pedagogy: tirelessness. An AI system does not become impatient or burned out. As the *Cognifying Education* mapping study observes, it can offer around-the-clock support with endless patience, which is valuable for students who need steady reassurance or a non-judgmental listener. AI systems can also track a student's emotional patterns over time. In principle, this lets them flag declines in engagement or signs of distress that a busy teacher might miss, enabling earlier intervention. Whether such flags are acted on well depends on how monitoring is integrated into teachers' formative practice. That design problem connects directly to the question of feedback that strengthens rather than substitutes for self-regulation (see Q230).

The most systematic synthesis of this terrain is a review in the *Journal of Research in Innovative Teaching & Learning* covering virtual reality, chatbots, sentiment analysis and wearable devices. It concludes that integrating AI technologies into SEL programmes offers unique opportunities to personalise learning, provide real-time feedback and support students' socio-emotional growth at scale. The technology categories it covers map closely onto the emotion recognition, immersive and chatbot domains that Wang and colleagues (2026) later identified bibliometrically. Taken together, the two studies suggest a stable research agenda is forming.

Evidence from outside education adds an important qualification. Lytle and Gopinath (2026) conducted a PRISMA-guided systematic review of 480 studies, selected from 6,058 records across psychology, business and human–technology interaction. They found that AI's effects on eudaimonic well-being span six interconnected domains: mental health, cognitive development, physical health, personal growth, autonomy and social connection. Benefits and risks often extend across these domains, and outcomes depend on design, use and context. For educators, the implication is that the patience and availability that make AI attractive as an emotional support may, under different design choices, also affect autonomy and social connection. There is no design-neutral version of an AI emotional companion.

The honest reading of this literature is that most of these gains are proximal: better engagement, a more supportive climate, more practice opportunities. They are not evidence of deep character formation. Philosophical and empirical critiques converge on this point. An analysis in the *Journal of Moral Education* of AI as a moral mentor identifies three limitations: diminished human autonomy, insufficient mechanisms for deep moral revision, and neglect of the emotional and transformative experiences through which moral growth occurs. On this view, teaching must model intellectual and moral virtues that AI cannot supply. A mentor matters not only because of the advice they give but because of who they are and how they live.

A particularly acute concern is what the authors of the *Cognifying Education* study call "social deskilling." They warn that without intentional design promoting high-fidelity interaction, such as live video or virtual-reality-based collaboration, students may lose capacity for empathy, negotiation and non-verbal attunement. The worry parallels cognitive offloading in the intellectual domain, where delegating effort to a machine can erode the capacity the effort was meant to build (see Q030). If students rehearse social repair with an endlessly accommodating partner, they may become less practised at the real thing, which is rarely accommodating.

Credible scholars disagree about whether these limits are intrinsic or a matter of current design. Laukkonen, Krier, Bakalar and colleagues (2026) propose a research agenda they call "Positive Alignment": AI systems that actively support human and ecological flourishing in a pluralistic, context-sensitive and user-authored way while remaining safe. They argue that failures such as engagement hacking, loss of human autonomy and low epistemic humility might be addressed in part by deliberately cultivating virtues and maximising flourishing. This is a position paper that sets out technical directions and open questions. It does not report empirical results. Still, it shows that some AI researchers treat virtue-supportive design as achievable, whereas moral educators tend to locate the deficit in what AI is, not in how it is tuned. Whether better alignment could close the gap the moral-mentor critique identifies remains unclear.

A further problem is authenticity. The narrative review in the *Journal of Computers in Education* on integrating social-emotional competencies into AI literacy notes growing doubts about the validity of machine empathic responses and how they might shape students' emotional learning. It also notes that cross-cultural variation in emotional expression may limit the suitability of AI-generated emotional feedback, which calls for culturally responsive design. An emotion recognition model trained on one population's expressive norms may misread

another's. When such a model gives feedback on empathy, it risks teaching a culturally narrow script under the authority of apparent objectivity.

Even researchers sympathetic to AI-based SEL tools acknowledge a prevalent psychological concern: whether machine empathy constitutes genuine emotional support. Work on integrating AI into SEL raises this alongside its more optimistic claims, and the SEL technologies review likewise treats authenticity and ethics as open problems rather than settled ones. The pre-service teachers studied by Çotuk and colleagues (2026) expressed the same ambivalence in practical terms: hope for greater independence among learners with special needs, alongside worry about social isolation. The disagreement is not simply between enthusiasts and sceptics. It runs through individual researchers and practitioners, who see real affordances and real dangers in the same tools.

The authenticity question also bears on trust in the classroom. When an AI system offers students emotional validation or moral framing that differs from what their teacher offers, the teacher's role as a model of character becomes harder to sustain. This connects to wider concerns about instructional authority and pedagogical presence when machines deliver competing messages (see Q260).

The emerging consensus among character educators is that the co-curriculum, meaning communities of practice, service and shared responsibility, should be treated as a central site of formation. A 2026 article in the *British Journal of Educational Studies* on "educating what AI cannot" makes this case for higher education. It argues that civic and moral virtues are actually exercised and strengthened in these human contexts, and that institutions should invest in them precisely because AI cannot replicate them. Practitioner research points the same way. Wall, Bedford and Redmond (2025), drawing on a reflexive iterative cycle of professional practice in Australian secondary history classrooms, propose three principles for generative AI use. The third is to "teach for the whole human," alongside teaching students to use AI tools and fostering discernment and critical thinking. In business education, the essays curated by Fukami, Hamilton, Rivers and colleagues (2025) ask how teaching can remain human-centred as AI spreads, and encourage faculty to cultivate a mindful relationship with the technology rather than either reject or surrender to it.

On this view, AI is better understood as a rehearsal space than a formative one. It can help a student practise the moves of empathy or resilience: rehearsing a difficult conversation,

receiving feedback on tone, regulating frustration during a hard task. Character in the classical sense, however, is forged through genuine stakes, genuine relationships, and the kind of friction that only other people provide. The practical implication is a division of labour in which AI extends practice and monitoring while teachers and communities carry responsibility for formation. Making that work requires co-teaching arrangements that are deliberately designed rather than allowed to drift (see Q025).

The evidence does not yet show which methods most effectively cultivate empathy, even among human-led approaches, as the comparative empathy literature makes clear. That uncertainty applies with compounded force to any system that cannot itself feel what it claims to teach. Until longitudinal and comparative studies follow students beyond the simulation into their actual relationships and communities, claims that AI teaches character should be read as claims about practice, not formation.

Q028 How do we assess learning authentically when AI can complete any traditional assessment?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

Learning can be assessed authentically in an age of capable AI by moving away from evidence that a machine can simply produce and toward evidence that a learner must perform, explain, or build over time. That shift depends on deliberate design rather than surveillance. The question of how to assess learning when AI can complete virtually any traditional assignment is, at its core, a question about what assessment was always supposed to do. Monash University's

guidance on AI and assessment frames the proliferation of AI in education as an opportunity to reconsider why students are being assessed, what is being evaluated, and how evidence of learning is gathered. What the generative AI moment has exposed is not a new vulnerability but an old one: a great deal of conventional assessment measured compliance with a task format rather than the presence of genuine understanding.

The scale of the problem is not in dispute. Newton and Jones (2025), reviewing the evidence for educators in the biomedical sciences, conclude that concerns about the validity of essays and multiple-choice examinations are legitimate, because ChatGPT can complete both to a very high standard, quickly and cheaply. Their review is framed around the professional regulations governing biomedical scientists in the United Kingdom, but the authors argue that it applies broadly across higher education. Northeastern University's Center for Advancing Teaching and Learning Through Research takes a similar starting point, treating AI as ubiquitous rather than exceptional and asking what assessment must become under that condition. The productive response to this exposure is not to defend the old formats more aggressively. It is to ask again which kinds of evidence would show that learning has actually taken place.

The rapid adoption of generative AI among university students is reshaping traditional assessment methods. A systematic review of academic integrity strategies published in AI and Ethics (2025) reports survey evidence that 40% of UK students agreed AI-generated content could achieve a good grade in their subject. The same review finds that essays and take-home assignments are increasingly susceptible to AI-assisted plagiarism, which makes a re-evaluation of assessment strategies necessary. That student perception aligns with the capability evidence assembled by Newton and Jones (2025). What students believe AI can do and what reviewers find it can do are converging.

The instinctive institutional response has been to reach for detection tools, outright prohibition, or a return to invigilated paper examinations. This response is understandable, but its reach is limited. The University of London's guidance on ensuring that assessment survives AI cautions that attempts to block remote access to technology can often be bypassed easily by students. It adds that efforts to use other technology to detect such behaviour are unlikely to be either effective or sustainable. Research on English for Academic Purposes provision in Scottish higher education (2025) documents institutions moving beyond reactive policing toward redesign, although unevenly and under practical constraints. The deeper problem with detection-first strategies is conceptual rather than technical. Even a perfect detector would only

protect the validity of a task whose validity was already doubtful. The boundary between legitimate assistance and authorship, which detection tools implicitly try to police, is itself dissolving, and that difficulty is examined separately in this volume (see Q017).

A more principled response begins by distinguishing between what AI can produce and what it cannot perform. Faculty training workshops on AI-resistant assessment reported in Frontiers in Education (2024) describe authentic assessments as differing from traditional tests in one key respect. They require students to apply knowledge in practical, context-rich scenarios that reflect the complexities they will meet in professional settings. No AI can attend a seminar and defend a position under cross-examination, conduct a supervised clinical consultation, or improvise in a live design critique. Work on simulating oral examinations with large language models (arXiv, 2024) argues that oral examinations offer a comprehensive method of assessing learning in higher education. Their advantage lies in evaluating a range of skills and competencies that matter in academic and professional settings, including depth of understanding and critical thinking, in ways that written tests may not. The same study's aim of using AI to help students rehearse for such examinations is a reminder that AI can serve oral assessment as well as threaten written assessment.

The relationship between generative AI and authentic assessment is therefore not purely adversarial. Salinas-Navarro and colleagues (2024a, 2024b) explore how generative AI tools might support experiential learning for authentic assessment. They argue that these tools can move beyond acting as agents-to-write or agents-to-answer and can instead become agents-to-support reflective thinking, hands-on learning and genuine assessment within a constructively aligned design. Their method has an important limit. It relies on "thing ethnography" and incremental prompting, which in one study meant semi-structured interviews with ChatGPT 3.5 itself. The findings are therefore conceptual and illustrative rather than evidence of effects on student learning. More empirically grounded is the study by Thandla and colleagues (2024) at Case Western Reserve University. They recruited 54 graduate students from a global health course to compare their own required research papers with papers generated by ChatGPT-4o from the same assignment prompt, evaluating adherence to section guidelines, narrative elements and references. Designs of this kind turn the comparison between human and machine work into a learning exercise in information literacy.

Two frameworks have shaped much of the institutional thinking in this period, and they differ in instructive ways. The first, the "Two-Lane" model developed at the University of Sydney

and adopted by Australia's national higher education quality agency, has been widely discussed in practitioner and scholarly accounts. These include a 2025 overview of AI-era curriculum and assessment and a framework for vocational assessment in Frontiers in Education (2026). This validity-centred design recognises that different learning outcomes require different assessment approaches. Foundational knowledge and skills that must be verified as genuinely human capability call for supervised environments such as proctored examinations, oral presentations or in-class demonstrations. Professional capabilities that involve tool use call for assessments in which AI engagement is transparent and the human contribution can be measured. The logic is candid. Rather than pretending AI does not exist in professional life, the model distinguishes between competencies that must be held independently and competencies that will, in practice, be AI-assisted. Newton and Jones (2025) reach a compatible conclusion from the regulatory side, stressing the importance of retaining assessments of foundational core knowledge even as other formats change.

The second framework, the AI Assessment Scale (AIAS) of Perkins, Furze, Roe and colleagues (2024), takes a more graduated approach. It offers educators a set of levels from which to select the appropriate degree of generative AI use according to the learning outcomes being assessed. The authors argue that it provides clarity and transparency for students and staff and serves as a fair, equitable policy tool, while recognising that AI is sometimes neither pedagogically appropriate nor necessary. In a 2025 revision, Perkins, Roe and Furze report that the scale has been implemented in hundreds of institutions and translated into 30 languages. Those figures indicate adoption, not demonstrated effects on learning. The revision grounds the scale in social constructivist principles and repositions it explicitly as an assessment redesign framework intended to enhance validity. It also redraws its visual assets to be inclusive and non-hierarchical, and it adds a new level, "AI exploration." The revision is partly a response to critiques that a scale of permitted use can be read as a set of unenforceable rules.

The two models agree on several points: validity should be central, AI use should be transparent, and some outcomes must be secured under supervision. They disagree on whether a binary or a graduated structure better reflects that reality. The comparative evidence on which structure produces more valid judgements remains unclear.

A parallel movement emphasises process over product. The study of Scottish English for Academic Purposes provision (2025) found that authentic assessments such as real-world tasks and projects, process-oriented assessments such as portfolios, and assignments requiring

higher-order thinking were the approaches most frequently mentioned for adapting to the disruption caused by generative AI. The 2025 systematic review in AI and Ethics similarly identifies a broader shift in the literature toward learning processes rather than final products alone. Portfolios, staged drafting, in-class checkpoints and reflective journals are increasingly promoted as ways to protect validity and to foster genuine assessment for learning. This logic connects summative assessment to formative practice, where the aim is to strengthen feedback and self-regulation rather than invite task substitution (see Q230).

Su, O'Dea, Wood and colleagues (2026) push the concept further. Drawing on a rapid review, they argue that authenticity itself should be reconceptualised as hybrid and relational. On this view, authenticity is realised through students' transparent and purposeful interactions with AI, and assessment practices should value insight, context and co-constructed meaning. They illustrate the argument with four scenarios: a social science task integrating generative AI, AI-assisted language education, a computer science database assignment, and AI-enhanced assessment design in medical education. They also insist that AI literacy among both staff and students is a precondition. Their scenarios are illustrative designs rather than tested interventions. Empirical comparisons are only beginning to appear. Omeh (2026) used a quasi-experimental, non-equivalent pretest–posttest design with 63 undergraduates across two universities in a developing country, comparing an AI-assisted assessment model with a traditional one over roughly ten weeks in a web design course and measuring competence and cognitive load. Non-randomised allocation by existing class groups limits how far such findings can be generalised.

AI can also support the people who design assessments. Nguyen and Hayward (2024) found that multimodal large language models could critique K-12 science assessments against the three dimensions of the Next Generation Science Standards. The models' annotations overlapped with those of educators, and few-shot prompting generally produced higher-scoring, more detailed critiques than zero-shot prompting. Teachers interviewed in the study reported that the annotations supported reflection on their practice and on assessment revision. The broader question of whether such support augments or deskills teachers is addressed elsewhere in this volume (see Q024).

Caution is warranted, however, about treating any single format as a solution. The 2025 systematic review in AI and Ethics notes that portfolio-based assessment, frequently suggested as a forward-looking option, faces an obvious concern. Generative AI can also produce

outlines, drafts and reflective commentaries, which undermines the authenticity the format is meant to secure. Staged drafting can be simulated, and process can be fabricated as easily as product. The University of London's guidance observes that some research appears to support authentic assessment as a way of reducing academic misconduct, but the evidence is unclear. The likely success of the approach will depend heavily on how it is implemented in its particular context and conditions. Supervised formats carry costs of their own. Monash University's guidance points out that handwritten and oral examinations are known to significantly disadvantage students with physical or mental disabilities. The oral examination literature, including the 2024 prototype for LLM-simulated examinations, is partly motivated by the resource burden of scaling viva-style assessment fairly. A retreat to the examination hall, or a wholesale turn to the viva, would trade one validity problem for an equity problem.

The defensible position is that no single assessment format is AI-proof. What institutions can build instead is a more deliberately designed ecology of assessments that collectively make learning visible. Some components would be supervised and verify independently held foundations. Others would be transparent about AI use and test judgement in authentic, tool-rich conditions. Still others would capture process in ways that are hard to fabricate wholesale. Northeastern University's Center for Advancing Teaching and Learning Through Research argues that assessment quality, not cheating prevention, should drive reforms in the AI era. On this argument, institutions should invest in redesigning assessments to secure validity rather than in AI detection tools. Frameworks such as the Two-Lane model and the revised AIAS are best understood as scaffolds for that redesign rather than as finished answers. Their effects on learning remain to be demonstrated, and so does the hybrid authenticity proposed by Su and colleagues (2026). Such an ecology also depends on designing AI use that strengthens rather than replaces student thinking (see Q030). Read this way, the disruption is not a crisis to be managed but a long-overdue invitation to ask what it actually means to know something, and to design the conditions under which that knowledge must be shown, not merely produced.

Q030 How do we design AI systems that strengthen rather than substitute students' thinking (avoiding cognitive offloading)?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

We design AI systems that strengthen rather than substitute students' thinking by building in deliberate restraint: hint-first tutoring that will not hand over solutions during active learning, scaffolding that responds to the learner and then fades, friction placed where effort produces learning, support routed through teachers where possible, and careful decisions about where in a learning sequence the tool appears at all. Each of these principles answers a single underlying problem. AI in education is not inherently hostile to learning. The difficulty is that the path of least resistance runs against the grain of how learning works.

When a student asks a chatbot for an answer and receives one instantly, something cognitively significant is lost. That something is the effortful struggle through which understanding is built. Cognitive science calls this productive struggle. Learning happens only when the student does the effortful part: retrieving, connecting, testing and revising ideas under some strain.

The analysis of AI and productive struggle in "The Effortless Trap" frames the risk as an illusion of learning. Fluent, polished output feels like understanding to the person reading it, even though the person did none of the work that produces understanding. The Stanford AI Lab's discussion of productive struggle as the future of human learning makes the complementary point. In a world where answers are abundant, the experience of working something out becomes the scarce educational resource. Designing AI systems that protect rather than preempt that struggle is therefore the defining pedagogical challenge of the moment. Meeting it requires decisions grounded in learning science rather than in marketing convenience, because the features that make a product attractive to users are frequently the ones that remove the struggle.

The empirical case for concern is substantial and growing, although it is less settled than public commentary often implies. Gerlich (2025) surveyed 666 participants across diverse age groups and educational backgrounds. The study, discussed in the review of AI-overdependence and cognitive decline, found a significant negative correlation between frequent AI tool use and critical thinking ability, mediated by increased cognitive offloading. Because the design is correlational, it cannot establish that AI use causes the decline. Students who already think less critically may simply reach for AI more often.

A laboratory experiment using neural imaging, also reviewed in the analysis of AI over-dependence and cognitive decline, found that cognitive activity decreased when participants relied on external tools. In the same experiment, self-reported ownership of essays was lowest in the group writing with a large language model and highest in the group writing unaided. These findings are suggestive, but a single laboratory study should be read cautiously.

The University of Technology Sydney briefing on cognitive offloading and the essay on productive struggle both describe a phenomenon researchers have termed "metacognitive laziness." When learners rely excessively on AI-generated outputs, they may not experience the cognitive difficulty needed to trigger deeper metacognitive processes. Over time, reliance on external resources diminishes engagement in self-regulation. Özer, Tanberkan and Perc (2025) advance a parallel argument in conceptual rather than experimental terms. They contend that offloading key tasks reduces cognitive load in ways that weaken memory retention and active engagement, producing an overreliance that they treat as a medium- to long-term threat to students' capacity to question information and evaluate sources.

The evidence does not point uniformly in one direction, and the disagreement should be stated plainly. In a questionnaire study of 200 students at the University of Ouargla, Ziani and colleagues (2025) found that most respondents reported awareness of AI errors and biases. Those students said they verified generated content, and the authors conclude that generative AI can enhance critical thinking when used in a guided manner. Zhang and Liu (2025) note an increasing number of studies reporting benefits for college students' critical thinking. They investigated the question in open learning environments through questionnaires, interviews and mediation analysis, drawing on self-regulated learning and motivation theory.

Hu and colleagues (2025) found positive associations between AI literacy and critical thinking among Chinese undergraduates. The effect sizes, however, were uniformly small ($|r| < .10$), and

the authors themselves caution against reading practical significance into them. Most of this evidence, on both sides, rests on self-report and cross-sectional designs. The reconciling hypothesis, that outcomes depend on how the tool is used rather than whether it is used, is plausible. It remains insufficiently tested (see Q033).

There is also a structural equity dimension that is often overlooked in these debates. The UTS briefing and the essay on productive struggle both observe that the cognitive risks of AI, including metacognitive laziness and the illusion of competence, fall disproportionately on novices and on students with weaker self-regulation skills. If that pattern holds, unstructured AI use could widen existing equity divides. The students who most need to build independent reasoning capacity are precisely those most vulnerable to having it quietly eroded. Students with strong prior knowledge can use an answer-giving tool to check their work. Students without that knowledge are more likely to use it to replace their work. This asymmetry is the strongest argument for building restraint into the system itself rather than relying on individual students to exercise it.

What does better design look like? The research converges on several principles. None is simple to implement, but all are grounded in learning science.

The first principle is that the tool must refuse to do the student's thinking. The design case of PeteChat, a guardrailed assistant for higher education, sets out a "tutor, not solver" stance. Its key features are hint-first tutoring, automated detection of assessment-relevant prompts, refusal of direct solutions during active assignments, and redirection toward conceptual explanation or strategy rehearsal. This is not merely a policy choice; it can be built into the architecture.

Work on rule-integrated large language model tutoring in primary mathematics shows how explicit pedagogical rules can constrain a model's otherwise open-ended behaviour. The aim is to "tame the black box" so that the tutor follows a defined problem-solving pedagogy rather than improvising. Third Space Learning describes its own AI tutor as one that cannot give the answer because it is designed not to, which the company presents as a structural response to both hallucination and cognitive outsourcing. That description comes from the provider itself, not from independent evaluation, and should be weighed accordingly. Even so, the architectural idea it illustrates is sound and appears in the independent design literature. Constraints embedded in a system are harder to bypass than instructions students are merely asked to

follow, although determined users may still attempt to circumvent them through prompt manipulation.

The second principle is that scaffolding must be contingent and must fade. Contingent scaffolding is a concept drawn from decades of educational psychology. It holds that support should respond to the learner's current state, offering assistance only when it is needed and withdrawing as competence develops. A well-designed AI system should not offer the same level of support at every moment. It should actively shrink its own footprint as a student's competence grows.

The Frontiers study of agentic AI acting as both lecturer and teaching assistant in university English-as-a-foreign-language courses frames this in terms of learner autonomy, self-regulated learning and intrinsic motivation. The authors conclude that educational AI should support students' autonomy needs while actively fading its own scaffolding. A tutor that is always maximally helpful trains dependence. A tutor that calibrates and then withdraws trains independence. In practice, the system must track not only whether a student answers correctly but how much help each correct answer required. This kind of modelling is harder than generating fluent explanations, and few general-purpose chatbots attempt it.

The third principle is that friction can be a feature rather than a bug. Research on "desirable difficulties" demonstrates that tasks experienced as effortful can improve learning and the transfer of knowledge and skills, even though learners often fail to appreciate those benefits. Retrieval practice is the canonical example. It is significantly more effective than re-reading, despite demanding greater cognitive effort. This is among the better-replicated findings in learning science. Its implications for AI design are drawn out in the analysis of over-reliance and decreasing knowledge and in the essay on productive struggle.

The practical translation is less well tested. Rate-limiting or introducing delays before help is provided may preserve productive struggle. If students must wait before seeing a hint, or can request help only a set number of times per session, they are more likely to attempt problems independently first. Whether such mechanisms improve outcomes at scale, or simply push students toward unconstrained tools elsewhere, remains unclear. Friction has to be calibrated: enough to prompt an attempt, not so much that it provokes abandonment (see Q185).

The fourth principle is that AI can strengthen the teacher rather than replace them. One of the more promising design directions uses AI to support the human tutors working with students

rather than to tutor students directly. Stanford's Tutor CoPilot, described on the SAIL blog, provides live suggestions to human tutors on how to foster productive struggle. It generates expert-like moves such as asking a guiding question or offering a hint. This keeps the cognitive labour where it belongs, with the student, while giving tutors real-time support at precisely the moments when they would otherwise default to supplying the answer. The model is especially attractive where tutors are less experienced, because it builds pedagogical judgment in the adult rather than displacing the student's reasoning.

Teacher capacity, however, cannot be assumed. Le and colleagues (2026) conducted design-based research on generative AI literacy training for teacher education students. They piloted a workshop with 14 master's students and then evaluated it with 29 teacher education students. They report significant gains in participants' self-efficacy regarding AI competence and in their attitudes toward generative AI. The samples are small and the outcomes are self-reported. The study nonetheless indicates that structured preparation can shift how future teachers approach these tools.

Classroom-level designs point in a similar direction. Benali Taouis and Díaz García (2026) chose not to restrict AI in an academic communication course. Instead, they built activities around critical digital pedagogy: explicit expectations for AI-assisted work, reflective assessments evaluating AI outputs, and tasks in which students rephrase, question, edit or elaborate on concepts with AI. Their results suggest that students developed a more nuanced understanding of AI's capabilities and limitations, using it as a support rather than a shortcut.

Zhong, Duan and Wang (2026) propose a conceptual teacher–student–AI collaborative framework for K-12 education. It combines scaffolded project-based learning, AI agent-supported feedback, and process-oriented, transfer-sensitive assessment. Their argument is that what gets assessed shapes whether AI substitutes for thinking or prompts it (see Q230). These are frameworks and small-scale studies rather than definitive trials. Taken together, they nonetheless indicate that the human design surrounding the tool matters as much as the tool's internal guardrails.

The fifth principle is that the AI's role within the learning sequence matters enormously. Analysis reported by Knowledge at Wharton argues that answer-giving at the point where a student should be struggling is what harms learning. Guarded designs deployed at the same point do not appear to cause the same harm. The potential upside is just as design-dependent.

For institutions, the practical question is therefore not whether to permit AI, but where in the learning sequence the tool is placed and what cognitive job it is assigned there.

The review of AI across design thinking by Mirzaei and colleagues (2026), which synthesised 205 studies, offers a useful analogy from a different field. They found that the weight of evidence supports hybrid intelligence: assigning divergent exploration largely to AI while reserving convergent selection and ethical judgment for humans. Transposed cautiously to education, this implies that AI may legitimately widen the space of possibilities a student considers. The acts of judgment, justification and synthesis that constitute the intended learning should stay with the student.

The hardest design challenge is what researchers have named the autonomy–accessibility paradox, a tension identified in the study of agentic AI as lecturer and teaching assistant and echoed in the essay on productive struggle. The features that make AI support pedagogically effective, namely immediate availability, adaptive calibration and frictionless engagement, may at the same time weaken the productive struggle through which deeper understanding forms. Making an AI that is genuinely useful without being cognitively substitutive requires deliberate constraint. It means building systems that are, in a meaningful sense, less convenient by design, even when users and markets reward convenience.

The disagreement in the evidence discussed earlier does not weaken this conclusion; if anything, it reinforces it. If critical-thinking benefits appear mainly under guided use and harms mainly under unstructured offloading, the decisive variable is design, and design is within educators' control. That discipline of intentional restraint is the clearest line separating AI tools that build minds from those that quietly hollow them out.

Q114 What happens to teacher expertise and professional identity when curriculum materials are machine-generated?

13 citations · 13 sources · 5 cross-references

Claim 1 emerging

When curriculum materials are machine-generated, teacher expertise is not erased but relocated. The authority to decide what is taught moves partly toward the system and its vendor, and the teacher's professional identity has to be rebuilt around judgment rather than authorship. Whether that rebuilding strengthens or hollows out the profession depends less on the technology than on how it is introduced and who controls it. The most visible change is in the artifacts of teaching: lesson plans, worksheets and assessments. The deeper change is in the teacher, in their expertise, their sense of who they are professionally, and their place in the educational division of labor. Recent scholarship converges on one central tension. AI can make teachers more capable, or it can make them redundant in the very tasks that once defined their expertise.

The first and most fundamental effect is a shift in the locus of expertise. A teacher's professional identity has traditionally rested on being the author of their curriculum: the person who decides what to teach, how to sequence it and how to represent it to particular students. When materials are generated by a machine, that authorship moves, at least in part, to the system and the company behind it. The 2026 analysis in the International Journal of Innovation and Education Research reports that teachers experience this as a redefinition of their role from "gatekeeper of information" to "facilitator of AI-mediated learning." That redefinition is not inherently a loss, since facilitation is a legitimate and demanding professional role. Yet the same work, together with the 2026 study of AI-driven curriculum change in Educational Management Administration & Leadership, documents genuine uncertainty among teachers about what constitutes their unique expertise in an AI-saturated setting. If the machine can write the lesson, what is the teacher for? The answer that emerges is that expertise shifts from production to judgment. The teacher evaluates the machine's output, adapts it to specific

students and decides what is worth teaching at all. This shift feels empowering only if teachers actually exercise that judgment, and that in turn depends on whether the system and the institution leave room for it. Černý (2026) offers a conceptual frame that widens the question beyond technique. Writing about Christian teachers, he identifies five areas in which professional identity can and should change under AI: the teacher's relationship with themselves, their relationships with others, their relationship to society and environment, and two areas framed in a metaphysical perspective of meaning and truth. His argument is normative and confined to one faith-based context, so it does not show how identity actually changes. It is nonetheless a useful reminder that what is relocated is not only a skill set but a sense of purpose.

The second effect is the risk of deskilling. The concept comes from labor process theory and describes what happens when the cognitive content of a job is automated and the worker is left with execution. When AI takes over grading, assessment, content delivery and lesson design, the teacher can be positioned as the operator of a system rather than as a professional. Each of those tasks was central to what teaching expertise meant. The 2026 IJIER analysis and the 2026 Educational Management Administration & Leadership study both locate the danger most acutely in top-down implementation. Three conditions recur in that account: AI tools imposed without meaningful teacher input, vendor discourse that frames teachers as the bottleneck to be optimized, and teachers treated as "instrumental objects" of the technology rather than participants in its design.

The psychological costs of this positioning are beginning to be measured. The 2025 study in Frontiers in Public Health describes "AI education anxiety," an occupational stress rooted in concerns about professional irreplaceability and about skill deficits. It links that anxiety to weakened professional identity and lower wellbeing, and the broader discussion connects it to burnout and resistance. These are associations drawn from survey-based designs. They show that anxiety and diminished wellbeing travel together, not that AI adoption causes either. Deskilling should therefore be read as a well-theorized and plausible risk rather than a demonstrated outcome of machine-generated curricula. How teachers respond collectively, through unions and professional associations negotiating the terms of adoption, is a separate question with its own evidence base (see Q255).

The third effect concerns professional identity and autonomy more directly. Research on teacher identity in the AI era finds that identity is being actively reconstructed. The 2026 IJIER

analysis describes teachers moving from "digital immigrants" to "AI natives," and from transmitters of knowledge toward designers and ethical guides, a trajectory that bears directly on how the teacher's role should be redefined (see Q022). This reconstruction is not automatic, and it requires institutional support.

The 2025 Frontiers in Public Health study and the 2026 Educational Management Administration & Leadership study report that professional wellbeing is positively correlated with three things: instructional autonomy, teacher-student relationships and a sense of professional competence. Wellbeing is negatively correlated with feeling marginalized by automated systems. Again, these are correlations. They are consistent with the view that autonomy protects identity, but they cannot rule out the reverse, in which teachers who already feel secure claim more autonomy. The implication most consistent with the evidence is that machine-generated materials do not, by themselves, destroy teacher expertise. They relocate it, and the relocation can go badly if teachers lack the authority to review, refine and reject AI-generated recommendations. The 2026 Educational Management Administration & Leadership study is explicit on this point: teachers must retain the authority to reject the machine's output, and that authority must be real rather than nominal. A right of refusal that carries professional penalties, or that the workflow makes impractical, is not authority.

This matters beyond the planning stage. Once AI-generated content reaches students directly, teachers face the further task of keeping their pedagogical presence and classroom trust alongside a machine that offers its own explanations (see Q260). Černý's (2026) emphasis on the teacher's relationships with others, rather than on technical proficiency alone, points in the same direction. It suggests that identity under AI is anchored in relational rather than informational expertise, though this remains a conceptual claim rather than an empirical finding.

The fourth effect is on the quality of the materials themselves and on the teacher's relationship to them. A teacher who writes a lesson knows its assumptions, its gaps and its intended audience. When a machine generates the lesson, the teacher must reconstruct that knowledge through review, which is a different and often underestimated cognitive task. Work on English language arts teacher education in the CITE Journal and on teachers' self-directed professional development in TechTrends (2025) finds that teachers who treat AI as a "creative thought partner" report positive experiences. In this pattern the machine produces drafts that the teacher then evaluates and adapts. The positive accounts include novice teachers who are still forming

their professional identity. The danger is the "set-it-and-forget-it" pattern, in which materials are adopted without critical review. That pattern erodes both the quality of instruction and the teacher's sense of ownership. These findings come mostly from self-report and small qualitative samples, so they show what productive use looks like more convincingly than how common it is.

One proposed remedy is "curriculum-informed AI," meaning systems aligned with high-quality instructional materials and research-backed practices. The case is that the alternative is generic output that reflects neither the teacher's professional voice nor the school's pedagogical goals. This framing is promoted by Imagine Learning, a curriculum vendor, and should be read as industry advocacy rather than independent research. The underlying concern about generic output is reasonable, but no evaluation in the sources reviewed here establishes that curriculum alignment preserves teacher judgment. An instructive parallel comes from medical education. Feigerlova (2026) argues that as AI becomes ubiquitous in clinical workflows, clinical teachers must be prepared not only to use AI tools but to "interpret, appraise and oversee their outputs safely and effectively." She adds that curricula have not kept pace with adoption, so structured AI education remains sparse or inconsistent across institutions. The analogy is imperfect, but it captures the same move from producing artifacts to supervising machine-produced ones. It also warns that the preparation for that supervisory role tends to lag behind deployment.

The fifth effect is on the profession as a whole. If machine-generated materials become the norm, the apprenticeship structures of teaching change. Novice teachers no longer learn their craft mainly by writing lessons and having them critiqued; they learn by evaluating machine output. This can be an efficient induction. The 2025 study in Frontiers in Education finds that generative AI can support novice teachers' emerging professional identities by enabling them to implement innovative task designs successfully. It also carries a risk of producing teachers who are skilled evaluators of AI output but less skilled authors of curriculum. The profession's collective expertise in curriculum design was built over generations of teachers authoring and sharing materials. That expertise may atrophy even as individual teachers become more efficient. This is a long-horizon risk that no current study is designed to detect, and whether it materializes remains unclear.

The readiness of teacher preparation to manage this transition is itself in doubt. Kelley and Wenzel (2025) observe that many teacher candidates remain unaware of AI's presence in daily life despite the rise of generative AI and its influence on personal and professional spaces. They

propose professional partnership inquiry as a route to building AI literacy in teacher education. Mutelo and Yakobi (2026) add a structural caution. Limited empirical research has examined how teacher education institutions in developing-country and resource-constrained contexts can sustainably integrate AI. Many existing frameworks assume levels of infrastructure, institutional capacity and digital readiness that do not reflect the realities of higher education in the Global South. The relocation of expertise from authorship to judgment may therefore unfold very differently across systems. Where preparation is thin, teachers may be more likely to default to uncritical adoption. The evidence base is also narrow. Baizhanov and colleagues (2026) scoped 33 peer-reviewed articles published between 2022 and 2026, identified through a bounded Web of Science search. Their review explicitly set out to describe the extent and nature of the evidence linking AI to teacher competence, not to evaluate whether interventions work. The field has mapped the territory more thoroughly than it has tested what improves outcomes. That gap bears directly on how teacher training should change (see Q026).

Taken together, machine-generated curriculum materials do not automatically deskill teachers. They do relocate expertise from production to judgment, and that relocation is risky. The sources reviewed here point to three conditions on which the outcome depends. First, teachers must retain real authority to review, adapt and reject machine output. Second, implementation must be collaborative rather than top-down. Third, professional development must build critical AI literacy, which the CITE Journal recommendations describe as the capacity to evaluate algorithms, datasets and the power structures embedded in AI platforms. The first two conditions rest on correlational and qualitative evidence from the 2026 Educational Management Administration & Leadership study and related work. The third has broad support but limited evaluation.

The professional development pathway is itself being automated, which introduces a recursive twist. Leitgeb and Leitgeb (2025) deployed an AI-based chatbot in Austrian higher education to provide context-sensitive, personalized professional development recommendations at scale. Their aim was to address traditional programs' neglect of individual needs, subject-area demands and career stages. Their mixed-methods evaluation indicates that AI may help tailor teacher learning. It also raises the prospect that the judgment teachers are meant to exercise over AI is increasingly cultivated by AI. Which programs for building AI literacy have actually been formally evaluated, and with what results, is taken up separately (see Q254). Here it is enough to note that Baizhanov and colleagues (2026) found a literature oriented toward

description rather than effectiveness. Claims that any particular form of training secures teacher judgment should therefore be treated as provisional.

Where the three conditions hold, AI can make teachers more capable and their professional identity more secure. Where they fail, teachers are positioned as operators of systems they do not control, and the profession's expertise is gradually transferred to the machine and its vendor. AI will change teacher expertise; the open question is who will hold the judgment that remains.

Q116 What effect does AI support have on novice, substitute, and under-qualified teachers specifically?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

AI support appears to have a distinctive and largely positive effect on novice, substitute, and under-qualified teachers. It offers expert-level scaffolding on demand, turns substitutes from supervisors into instructors, may shorten the novice induction curve, and supplies subject-matter support to teachers working outside their preparation. That effect is conditional, however, and the evidence for it is thinner than the enthusiasm around it. These three groups face a different problem from experienced teachers. Their question is not how to save time on work they already know how to do, a question taken up in the discussion of workload and burnout (see Q212). It is how to do work they do not yet know how to do. For a veteran, an AI-generated lesson plan is a draft to be judged against years of classroom knowledge. For a novice, a substitute or an out-of-field teacher, the same plan may be the only expert input

available, and the teacher may lack the means to judge it. AI can therefore act as a powerful equaliser for those who need the most help. The same feature also makes them the most exposed to its failures.

The benefits depend on three things: how tools are designed, how teachers are trained to use them, and whether human mentorship is kept in place. Much of the supporting evidence comes from practitioner accounts, perception surveys and small qualitative studies rather than from controlled measures of teacher development or student learning. The overall picture is best described as emerging. Different strands of research point in different directions on several key questions, and the account below says so where it applies.

For substitute teachers, the most immediate effect falls on the emergency lesson. Substitute shortages have pushed schools to rely on paraprofessionals, administrators and under-qualified adults to cover classrooms, often with no prepared plan. Birch Education's account of the shortage describes AI tools that can produce structured lesson plans, worksheets and activities in seconds, matched to grade level and subject. EduStaff, a substitute staffing organisation, describes similar uses, including laboratory experiments for science and discussion prompts for the humanities.

The intended result is to turn a substitute from a supervisor into a teacher of record, at least for the length of the lesson. Both organisations report that AI-generated plans help substitutes provide meaningful learning even without subject-matter expertise. They also report that AI can scaffold complex discussions and suggest classroom-management strategies. If this holds, AI narrows the instructional gap that opens when a teacher is absent. That gap falls hardest on students in under-resourced schools, where substitute shortages are most severe.

These sources are practitioner and vendor accounts, not research. They show what the tools are being used for and what their promoters claim. They do not measure whether students covered by AI-supported substitutes learn more than students covered by unsupported ones. No systematic evaluation of that question appears among the sources reviewed here. Whether the shift from supervision to instruction actually occurs therefore remains unclear.

For novice teachers, the effect falls on induction. Early-career teachers face a steep learning curve that covers planning, classroom management, differentiation and a large volume of administrative work. A 2026 study of early-career teachers and AI-mediated induction describes AI as an "expert-level guide" that could shorten this curve in two ways. It can give

real-time feedback and pedagogical suggestions. It can also automate the repetitive tasks, such as grading, tracking and parent communication, that take up so much of a novice's time.

The same work finds that early-career teachers use AI for self-directed professional development with high levels of self-management and self-monitoring. A 2026 analysis in Discover Education of generative AI in teacher professional learning sorts its affordances into four categories: functional affordances, meaning instructional design and content co-creation; cognitive affordances, meaning higher-order thinking and knowledge construction; social affordances, meaning human–AI partnership; and reflective affordances, meaning the building of self-efficacy through iterative feedback.

For novices, the reflective affordance may matter most. AI can bring together information about a teacher's own practice and support the kind of self-directed growth that induction programmes often lack the staff to provide.

The most careful empirical work, however, presents AI as a participant in professional learning rather than a replacement for it. Jin and colleagues (2025) brought generative AI into an online professional learning community of novice and experienced teachers, drawing on the idea of a community of practice. They studied knowledge co-construction among the AI, the novices and the experienced teachers, using topic modelling, sentiment analysis and qualitative content analysis. They are frank that teachers face real challenges in using generative AI for professional learning. Although AI is expected to transform teacher learning, they describe its impact as still "subtle." That caution is a useful counterweight to accounts of AI as a ready-made expert guide.

Novices' own understanding of AI's role also matters, because it shapes how they will use it. Day (2026) analysed online forum contributions from 76 preservice teachers in a postgraduate programme in China through the TPACK framework. The study asked how they saw AI as a non-human instructor and whether they thought it could replace human teachers. The abstract does not report the balance of their views. The study shows, though, that the next generation of teachers is entering the profession already asking where AI's role ends. That question bears directly on what AI tutors can and cannot do compared with human teachers (see Q021).

For under-qualified teachers, meaning those teaching out of field, on emergency credentials, or in shortage subjects such as mathematics and science, the effect falls on competence. AI can supply some of the subject knowledge these teachers lack, including explanations, worked

examples and content on demand. Tutorela's blog on the mathematics teacher shortage presents AI as an "evidence-based" support that helps under-qualified teachers deliver instruction they could not otherwise manage. That description comes from a commercial source and should not be read as independent research. If the claim holds, the benefit is real. A teacher's lack of formal preparation would do less damage to students, a genuine equity gain in systems that cannot place a fully qualified teacher in every classroom.

The research base for this claim is indirect. Kim (2025) studied teachers in a master's-level elementary science methods course. These teachers used a large language model to design lessons that build students' environmental science agency, an approach to making science relevant to students' lives. The study drew on surveys, lesson design documents, AI chat logs and field notes. It shows that AI can be built into the demanding work of science lesson design within a structured course, alongside explicit teaching of the pedagogical idea. That setting is very different from an isolated out-of-field teacher using a chatbot alone.

Akendita and colleagues (2025) surveyed 380 pre-service teachers at a College of Education in Ghana and analysed the results with structural equation modelling. Their perception of AI was positively associated with their mathematics interest ($\beta = 0.366$) and their mathematics performance ($\beta = 0.560$). Because the design is a cross-sectional survey, these are associations. They do not show that AI use improves teachers' subject knowledge. Positive views of AI may simply go along with stronger mathematical dispositions.

Teachers in shortage subjects are themselves divided. Cheah and Kim (2025) collected 48 responses from STEM teachers in Idaho, who were mostly White, female and working in rural schools. Views on generative AI's impact were split almost evenly between positive and negative. The small, regionally specific sample limits how far this can be generalised. Even so, it is a reminder that the teachers AI is supposed to help do not all accept it.

The research also identifies serious risks specific to these groups.

The first risk is cognitive over-reliance. Novice and under-qualified teachers are the most likely to accept AI output without enough pedagogical judgment, precisely because they lack the expertise to evaluate it. A 2026 study of early-career teachers' adoption of generative AI argues for this reason that "critical scaffolding" is needed, so that teachers question outputs rather than simply consume them. The research also shows what can be called a descriptive–operational gap. Many studies describe what AI can do, but few measure whether it builds professional

competence. That gap is a warning that AI support can produce dependence without development. A novice who learns to teach by accepting machine-generated plans may never develop the curriculum judgment that experienced teachers rely on. This is the teacher-side version of the cognitive offloading problem discussed for students (see Q030). It also links to the broader question of how AI can support teachers without deskilling them (see Q024).

The second risk is the loss of the apprenticeship model. Work on tacit knowledge describes a "pipeline problem." When entry-level cognitive work is automated, the structures through which expertise passes from one generation to the next are disrupted. In teaching, this means AI support for novices must not replace the human mentor. A 2026 study of professional learning communities and AI integration for early-career teachers reports that teachers who work alongside experienced human mentors outperform those who rely only on AI tools. The reason given is that mentors provide context, emotional support and pedagogical guidance that AI cannot replicate.

The design of Jin and colleagues' (2025) professional learning community points the same way. AI was placed inside a community of novices and experienced teachers rather than offered to novices alone. The effective model is a hybrid one, in which AI provides the scaffolding and the mentor shapes the teacher's development. How far mentorship protects against over-reliance has not yet been measured over time, so the strength of the hybrid model remains a well-reasoned claim rather than an established finding.

The third risk is equity in reverse. AI support for substitutes and under-qualified teachers is most needed in under-resourced schools. Those are the schools least likely to have the devices, connectivity, training and support systems that make AI use effective. Research on the AI divide warns that if AI support is available only where infrastructure and training already exist, the technology will widen rather than narrow the gap between well-staffed and under-staffed schools.

The rural Idaho teachers surveyed by Cheah and Kim (2025) identified specific support needs for integrating generative AI. This suggests that even willing teachers in the settings with the worst shortages cannot simply adopt these tools unaided. The effect of AI on novice, substitute and under-qualified teachers is therefore not a single effect. It depends on the conditions in which these teachers work.

The fourth consideration is training. The working consensus is that AI tools are only as good as the training around them. Without professional development, substitutes and novices either misuse the tools or underuse them. Schools that deploy AI for these groups without training are likely to see the tools fail, and may wrongly conclude that the technology does not work.

Alsuhaymi and Eltantawy (2026) surveyed 173 principals, supervisors and teachers in special education settings in Riyadh. They examined whether perceptions of AI differed by professional role, years of experience and AI-related training. That choice of variables reflects a growing assumption that experience and training shape how AI is received.

Amouri and colleagues (2025) used the Technology Acceptance Model 2 to study the factors behind pre-service teachers' acceptance of AI for teaching students with ADHD. They argue that successful integration depends heavily on whether teachers still in initial training accept the tools.

The evidence on institutional support is not straightforward, however. Guo, Lu and Gao (2026) surveyed 512 teachers at Chinese open universities. Teachers' AI literacy was positively associated with open education teaching practice, partly through their innovative behaviour. Unexpectedly, school support negatively moderated this pathway. The study is cross-sectional and set in higher education, so it cannot be applied directly to school induction. Still, it cautions against assuming that more institutional support always helps. Poorly designed or prescriptive support may crowd out the teacher initiative that makes AI use productive.

Taken together, AI support can scaffold novices, equip substitutes and back up under-qualified teachers. Its value depends on training, on infrastructure, on keeping human mentorship in place, and on guarding against cognitive over-reliance. Used well, AI is a force multiplier for the teachers who need the most support. Used carelessly, it can produce dependence without development and widen the very gaps it promises to close. The test is whether AI support builds these teachers' capacity or merely compensates for its absence.

Q227 How is generative AI changing pedagogy, authorship, and assessment in creative arts education?

21 citations · 21 sources · 5 cross-references

Claim 1 disputed

Generative AI is changing creative arts education in three linked ways. It turns the technical production of images, sound, text and motion into something a student can delegate. That shift moves pedagogy toward ideation, selection and critical judgement. It makes authorship a matter of degree rather than a yes-or-no question. It also pushes assessment away from the finished artefact and toward the creative process behind it. The technology bears with particular force on the arts because it works directly on their core activities: image creation, music composition, narrative writing, design and performance. On all three fronts the evidence is nascent, concentrated in higher education and methodologically limited. It is nonetheless sufficient to identify the main pedagogical opportunities, the principal risks and the questions that remain open.

Research volume has grown quickly since 2023, and synthesis work is beginning to map it. Slimi (2026) conducted a systematic critical review of 54 peer-reviewed studies published between 2023 and 2025, alongside six international policy documents. Slimi characterised the effects of generative AI on authorship, pedagogy and integrity as contested terrain rather than settled ground. Dhakal (2025), in a scoping review of the generative AI and pedagogy nexus in higher education, observed that systematic analysis of this literature had until recently remained under the radar. Neither review is specific to the arts. Two reviews of the creative sector come closer. Bervar, Bertoncel and Pejić Bach (2026) applied PRISMA 2020 and keyword mapping to 119 peer-reviewed articles on generative AI in the creative industries published between 2023 and 2025, and placed authorship, ownership and the future of creative labour at the centre of the field. Tsao and colleagues (2025) scoped 57 mainly empirical papers from 2022 to 2025 on how creative professionals perceive and integrate these tools across four domains: visual art and design, writing and literature, performing arts, and environmental and spatial design. Both

concern professional practice rather than education, but arts programmes prepare students for exactly these fields.

The arts-specific educational studies show how early the field still is. Designs are typically single-site, short and uncontrolled. Shen, Lee and He (2026) linked prior course performance, final creative-performance assessment and post-project questionnaires for 133 undergraduates in a single art course, which makes theirs one of the larger datasets available. Mao (2026) used design-based research across a five-week experimental animation course. Weatherly (2026) followed one music teacher in Macau through a school year. Such studies build theory and document practice but cannot yet support confident causal claims about learning gains, and the field's shift from theoretical commentary toward empirical and mixed-methods work is incomplete.

A useful heuristic distinguishes three roles that generative AI can play in arts teaching. As a facilitator, it supports brainstorming and initial concept generation while the creative work remains the student's. As a collaborative partner, it takes part in production, enabling rapid prototyping and the exploration of styles. As an autonomous generator, it produces outputs with minimal human intervention. This third role is the least defensible in classrooms, where developing the student's own agency is the point. The heuristic is an analytic convenience rather than an empirically validated taxonomy, but recent design studies map onto it.

Mao's (2026) animation course illustrates the collaborative-partner role. It combined generative AI with "vibe coding", an approach in which students direct code generation through natural-language prompts. Mao frames the pedagogical challenge as preserving media experimentation, authorial judgement and generative unpredictability against a tendency toward automation. Gusain (2026), writing from the humanities, argues toward a related stance. She proposes treating AI as material for interpretive inquiry rather than as an efficiency tool, on the grounds that its default fluency works against productive ambiguity.

Claims that AI improves outcomes when integrated through intentional instructor design deserve careful reading. The outcomes usually cited are creative confidence, personalised feedback and engagement. The creative-confidence argument holds that AI lowers technical barriers, so students can concentrate on visual thinking and aesthetic judgement. The barrier-lowering mechanism is plausible. Istrate (2026) argues that generative tools sharply reduce the time and expertise needed to produce multimodal content, a democratisation with significant

pedagogical implications (see Q095). Weatherly (2026) documents generative AI helping a music teacher with planning, shifting learning objectives and bridging gaps among students, which suggests benefits for differentiation at K-12 level.

The psychological pathway has also attracted quantitative attention. Hwang and Wu (2025) surveyed 121 design students at universities in southern China. They tested a chain mediation model in which self-efficacy and reduced anxiety connect AI use to creative cognition. The design is cross-sectional and self-reported, so it cannot show that AI use causes creative growth. Ansone, Zālīte-Supe and Daniela (2025) took a closer look at practice. After a lecture on composition principles, ten bachelor's-level art students completed a composition task with both traditional methods and generative AI. The researchers observed them and collected questionnaire reflections. The study was prompted by educators' concern that text-to-image generators could serve as unethical shortcuts. With ten participants, it documents how students approach the tools rather than measuring effects. None of the available abstracts reports effect sizes for creative confidence, engagement or personalised feedback. Whether these benefits are durable or generalisable remains unclear.

Teacher adoption is itself uneven. In entrepreneurship education, Bahaw and colleagues (2026) identified affinity to technology as an individual-level predictor of educators' acceptance of generative AI. They also found that institutional facilitating conditions lose explanatory power under certain boundary conditions. Arts faculties should therefore expect wide variation in how far, and how thoughtfully, instructors build AI into studio teaching (see Q024).

Authorship is the most contested issue in AI-assisted arts education. When a student uses AI to generate an image, compose a melody or draft a narrative, it is genuinely unclear who the author is. The question is not merely philosophical. It bears directly on assessment, on intellectual property and on the educational purpose of arts disciplines, which have traditionally treated the making of the work as the site of learning.

The literature does not support resolving authorship with a single rule, and credible positions diverge. Islam and Greenwood (2024) offer the most critical account. They argue that generative AI draws on a "hypercommons" of collectively produced inputs and labour that is largely invisible or untraceable. In their view, automating the exploitation of that commons risks a crisis of authorship that erodes the moral agency involved in creative and scholarly production. Their essay addresses academic authorship, but the argument transfers readily to

studio practice, where the provenance of style and technique matters. Slimi's (2026) review, by contrast, presents authorship as one dimension of a multifaceted and contested impact rather than as a settled loss. Bervar and colleagues' (2026) mapping shows that the same questions of authorship and ownership dominate research on the creative industries. Students therefore enter professions where the issue is equally unresolved.

Shen, Lee and He (2026) frame the empirical difficulty precisely. They note that the educational value of generative AI is contested because creative support, output generation, authorship and skill development become intertwined in AI-supported coursework.

What can be said is that human creative contribution varies enormously across AI-assisted work. At one end, a student accepts an AI output with minor modifications. At the other, AI is one tool within a complex process involving substantial human judgement, selection and refinement. Policies that treat all AI-assisted work as equivalent, whether permitting or prohibiting it, fail to capture this range. Elkhodr and Gide (2026) observe that universities are already moving beyond blanket prohibition. Institutions increasingly distinguish restricted from permitted contexts, require acknowledgement of tool use and introduce verification mechanisms to protect authorship and understanding.

Acknowledgement rules depend on students actually disclosing, and here the evidence is sobering. Qu, Loo and Wang (2025) studied how undergraduates at a large Singaporean university decide whether to disclose generative AI use. They found that many institutional guidelines remain vague and ineffective, which leaves students to interpret disclosure obligations on their own. They introduced the concepts of strategic and conceptual non-disclosure to describe the outcomes. Although the study was not arts-specific, a disclosure regime that students do not understand cannot carry the weight of authorship attribution in a studio. The pedagogical question is therefore how to make the human contribution visible, and this is where assessment design becomes decisive.

Emerging assessment approaches distinguish process from product. They evaluate the final creative output and also the process that produced it. That process includes the student's ability to articulate creative decisions, to evaluate AI-generated options and to integrate AI assistance into a coherent creative vision. Process-sensitive approaches are more demanding but more pedagogically defensible than product-only grading, which AI can increasingly satisfy without much student learning (see Q028). Goldmeier and Mota (2025) give a broader rationale. They

argue that traditional teaching built on predictability, knowledge transfer and memorisation is increasingly inadequate, and that pedagogy rooted in metacognition, self-knowledge and learning how to learn is the most effective response to AI. Their article is conceptual, but its emphasis aligns with assessment that asks students to account for their own creative reasoning.

The strongest recent support comes from creative arts assessment research that predates the AI question or runs alongside it. Burke and colleagues (2025) conducted a collaborative autoethnographic study across six Australian universities in initial teacher education, using document analysis and thematic analysis of student survey data. They identified three characteristics of effective praxis-focused creative arts assessment: meaningful context, embodied arts engagement and critical reflection. Together, these helped integrate theory and practice. Although the study does not concern AI, embodied making and critical reflection are precisely the elements that generative tools cannot easily substitute, which makes the model a credible template for AI-era redesign.

General higher-education guidance points the same way. Lye and Lim (2024) note that assessment concerns about generative AI have centred largely on academic integrity. They argue that redesign must also address two further problems: models trained on internet data can produce biased and discriminatory outputs, and the underlying language models hallucinate. Applied to the arts, this means students should be assessed on whether they noticed and corrected what the tool got wrong, not only on whether they used it.

Elkhodr and Gide (2026) add a structural observation. Much institutional policy is stronger on governance, permission, disclosure and assurance than on pedagogy. Publicly visible approaches rarely provide structured, student-facing workflows that guide responsible AI use while an assessment is being completed. Their proposed framework aims to fill that gap but is untested in studio disciplines. Qu and colleagues' (2025) findings suggest why such workflows matter: where expectations are vague, students decide for themselves what to reveal.

Whether process-based assessment actually improves artistic skill, as opposed to making skill more visible, remains unclear. Shen, Lee and He (2026) linked baseline performance to final creative assessment for exactly this reason. Designs of this kind, extended with comparison groups, are what the field needs to evaluate assessment reform rigorously (see Q230 on formative uses).

A significant concern is aesthetic homogenisation. If students across institutions use the same tools with similar prompts, the diversity of creative output may narrow. The underlying worry is that models reproduce the preferences embedded in their training data, which are often characterised as predominantly Western, contemporary and commercially oriented. Students who rely on generation without critically engaging these defaults may then produce work that is technically competent but aesthetically undifferentiated. Direct evidence of a decline in the diversity of student creative output remains thin.

Adjacent evidence makes the concern credible. Cooper and Tang (2024) critically examined images that DALL-E 3 produced through ChatGPT, focusing on depictions of science classrooms and educators. They raised ethical and pedagogical concerns about the tools' potential to reinforce biases and perpetuate stereotypes. Their subject was science imagery, not fine art, but the finding shows that image generators carry representational defaults that users may not notice. Gusain (2026) identifies a related tendency at the level of meaning: in common classroom use, generative AI favours fluency, plausibility and resolution. In the arts, a pull toward the plausible and the resolved comes close to a definition of aesthetic convergence. Lye and Lim's (2024) warning about biased and discriminatory outputs points in the same direction.

Arts educators have responded by treating critical AI literacy as a core competency. This means the ability to recognise and interrogate the aesthetic and representational assumptions built into AI tools. It includes understanding how training data shapes a model's preferences, developing prompting strategies that push against default aesthetics, and evaluating AI-generated work critically rather than accepting it. Such literacy requires technical grounding of the kind Kalota's (2024) primer offers non-specialist educators on machine learning and large language models.

Gusain's (2026) proposal to treat AI outputs as material for interpretive inquiry offers a pedagogical form for this literacy. Instead of polishing what the machine produced, students analyse what it produced and why. Mao's (2026) emphasis on preserving generative unpredictability is a studio-based counterpart. Whether such interventions measurably protect stylistic diversity has not been studied.

The copyright status of AI-generated creative work remains legally unsettled in most jurisdictions, and this has practical consequences for arts programmes. In the United States, the Copyright Office has stated in its registration guidance that material generated purely by AI is

not eligible for copyright protection, because copyright requires human authorship. Works containing sufficient human creative contribution may be protected, for example through the selection, arrangement or modification of AI-generated material. Applicants are expected to disclose AI-generated content when registering. The threshold of human contribution is not yet clearly defined, and the Office indicates that it will be assessed case by case.

In the European Union, the AI Act's transparency requirements for AI-generated content, including the labelling of synthetic media, have implications for arts education. The copyright framework for AI-assisted creative work there is still developing. Legal and educational definitions of authorship are therefore converging on a similar intuition: what matters is demonstrable human creative control. This gives process-based assessment a rationale beyond pedagogy.

Islam and Greenwood's (2024) hypercommons argument highlights the ethical side of the problem. Generative outputs are built from collectively produced inputs whose creators are largely invisible or untraceable, so questions of ownership attach to the training data as well as to the output. Students may also unknowingly produce work that infringes copyright in material the model was trained on, a risk that is difficult to detect from the output alone.

Arts educators therefore need working knowledge of how copyright applies to AI use in student work. That knowledge extends to students' own intellectual property rights in AI-assisted portfolios and graduate work. Because the legal ground is shifting, institutions are best served by guidance that teaches students to document their creative contribution, rather than guidance promising a certainty no jurisdiction provides. In the arts, as elsewhere, generative AI is less a solved problem than a standing invitation to make the human part of creative work visible, assessable and defensible.

Q230 How can educators design formative assessment with AI that strengthens feedback, self-regulation, and learning rather than task substitution?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

Educators can design formative assessment with AI that strengthens feedback, self-regulation, and learning by treating AI output as raw material for student thinking rather than as a finished correction. In practice this means tying every piece of machine feedback to an explicit learning goal, requiring students to explain and justify what they change, combining AI comments with teacher, peer, and self-assessment, assessing the process of revision rather than only the final product, and deliberately handing the work of monitoring and judgement back to the learner over time. These principles follow from what is already known about why formative assessment works, and they target the specific way AI can undermine it.

Formative assessment is the ongoing process of gathering evidence about student learning and using that evidence to adjust teaching and learning. It is one of the most powerful tools available to educators, and the case that high-quality formative assessment improves outcomes is among the strongest in educational research. AI appears to promise more of what makes it effective: feedback that is more frequent, more personalised, and more timely than a single teacher can provide to a full class. The same capability, however, introduces a serious risk. AI-assisted formative assessment can slide into task substitution, in which students improve a submitted product without acquiring the skill the task was meant to build. Newton and Jones (2025), reviewing the evidence for educators, show that generative tools can complete essays and multiple-choice examinations to a very high standard, quickly and cheaply. Any formative design that rewards the polished artefact alone is therefore vulnerable, because the artefact no longer reliably indicates what the student can do. The design question is not whether to use AI feedback, but how to keep the learner doing the cognitive work that feedback is supposed to provoke.

The foundational evidence comes from Black and Wiliam's landmark 1998 review, which reported effect sizes of roughly 0.4 to 0.7 for high-quality formative assessment, placing it among the largest effects documented in educational research. Subsequent syntheses have broadly supported the conclusion that formative practice benefits learning, although later reanalyses have debated the precise magnitude of the effect and the quality of some underlying studies; the direction of the finding is more secure than any single headline number. What this body of work demonstrates most clearly is not that any feedback helps, but that feedback helps when it is embedded in a particular kind of classroom practice.

The tradition that grew out of Black and Wiliam's review identifies the key mechanisms. Effective formative assessment gives students information about where they currently stand relative to a learning goal, what they need to do to close the gap, and how to take the next step. Equally important, it develops students' capacity for self-assessment and self-regulation, meaning the ability to monitor their own learning and adjust their strategies accordingly. Feedback, on this account, is valuable less as information about a specific piece of work than as a means of building the learner's own judgement about quality. A comment that fixes an error without changing how the student perceives and evaluates their work has, in formative terms, done little.

This distinction matters directly for AI. Machine feedback can be excellent at the first element, locating where work falls short, and reasonably good at the second, indicating what should change. It is the third element, and especially the longer-term development of self-regulation, that is most easily lost. If an AI system always identifies the gap and always proposes the fix, it occupies precisely the role the student is meant to grow into. The research base therefore supplies not only a reason to be optimistic about more frequent feedback but also a criterion for judging AI tools: do they leave students better able to assess their own work without the tool?

AI can provide formative feedback at a scale and frequency that human teachers cannot match. Writing feedback tools can return immediate, detailed comments on grammar, style, structure, and argumentation. AI mathematics tutors can identify specific misconceptions and offer targeted explanations. Coding assistants can detect errors and suggest corrections in real time. These capabilities address one of the most stubborn constraints on effective formative assessment: the time required for teachers to give detailed, personalised feedback to every student on every draft. Shaw (2024), writing for music educators, makes a parallel argument from a performance discipline, suggesting that AI may open new directions for assessment and

differentiation even as it disrupts traditional grading practices, and urging teachers to approach these possibilities with attention to both effectiveness and ethics.

Empirical evidence on whether these capabilities translate into learning remains limited. Omeh (2026) compared an AI-assisted assessment model with a traditional assessment model in a web design and development course, examining effects on outcomes and on students' cognitive load in a context where conventional assessment was seen as weak at promoting higher-order thinking. Studies of this kind are a welcome move beyond self-report, but they are small, situated in single courses, and difficult to generalise. Vo (2026), studying 17 students in a lighting design classroom, notes that existing literature on generative AI in design pedagogy lacks a clear roadmap and relies mostly on self-reported data, which limits its practical implications. That observation applies well beyond design education.

AI feedback also has recognisable limitations. Critics argue that it tends to concentrate on surface features such as grammar, syntax, and code correctness rather than on deeper learning such as conceptual understanding, quality of argumentation, and creative thinking, although how far this holds for current systems remains unclear and likely varies by tool and prompt. It can be generic rather than genuinely personalised, offering plausible advice that does not engage with what a particular student was trying to do. Most consequentially, it can allow students to improve a product without understanding why an improvement was made. Vo's (2026) study is instructive here because its value lay in sequencing: generative AI was used for ideation and virtual reality for revision, an arrangement designed to promote lateral and vertical thinking within a defined design problem space. Whether the technology helped depended on how and when it was integrated, not on its availability. Similar reasoning underpins broader debates about using AI to support teachers' feedback work without deskilling them (see Q024).

The central risk of AI in formative assessment is task substitution. A student who uses AI to correct grammar may produce a grammatically correct essay without developing grammatical competence of their own. A student who uses AI to debug a program may end up with working code without understanding the underlying programming concepts. In each case the formative evidence, the improved draft, overstates what the student has learned, and the feedback loop that Black and Wiliam's (1998) review identified as the engine of improvement is short-circuited, because the student never has to perceive the gap or decide how to close it.

The empirical evidence on how large this effect is remains thinner than the concern it generates. Earlier versions of this argument were often supported by claims that students receiving AI writing feedback without reflection gain less than those who engage actively with it; the logic is consistent with the formative assessment tradition, but robust, replicated studies isolating this effect for generative AI are not yet available, and the claim should be treated as a well-motivated hypothesis rather than a settled finding. Newton and Jones (2025) establish the precondition, that AI can complete many conventional assessment tasks to a high standard, but completion capacity alone does not show how students actually use feedback tools when they have them.

The risk has also been framed in ethical rather than purely instrumental terms. Smith (2026) argues, using the concept of formative epistemic injustice, that a wrong is done to students when instructors encourage them to farm out literacy learning tasks to generative AI, because doing so deprives them of the opportunity to develop as knowers. This is a philosophical argument, not an outcome study, but it sharpens the stakes: substitution is not only inefficient, it may deny students something they are owed. Not everyone draws the same conclusion. Vo's (2026) design classroom deliberately asked students to use generative AI for one phase of their work, and Shaw (2024) sees genuine opportunities for differentiated assessment. The disagreement is real and unresolved. One reasonable reconciliation is that the line falls between delegating the competence a task exists to develop, which substitutes for learning, and using AI to stimulate or scaffold work the student still performs, which may support it. Where that line sits depends on the learning goal, which is why the question of avoiding cognitive offloading more generally deserves separate treatment (see Q030).

Several design principles follow from this analysis, and the first three concern how feedback is framed and used. The first is to connect feedback to learning goals. AI feedback should be explicitly linked to the objectives of the task, helping students understand not just what to change but why the change matters for their learning. A comment that a paragraph lacks evidence is more formative when it is tied to a stated goal about constructing arguments, because it invites the student to recognise the same weakness next time without prompting. Teachers can achieve this by giving the AI tool the success criteria, by asking students to map each piece of feedback onto a criterion, or by restricting feedback to the goals currently being taught.

The second principle is to require explanation and reflection. Students should be asked to explain the changes they make in response to AI feedback, showing that they understand the feedback rather than merely implementing it. A short revision rationale, a comparison of before and after versions, or a brief oral account of why one suggestion was accepted and another rejected converts passive correction into active judgement. Rejecting AI advice for good reasons is itself evidence of learning and should be valued as such.

The third principle is to combine AI feedback with human, peer, and self-assessment. AI feedback appears most useful as one component of a multi-source system rather than as a replacement for it. The most developed evidence here comes from work on formative and shared assessment, in which students participate in assessing their own and others' work alongside the teacher. Fuentes-Nieto, Aparicio-Herguedas and López-Pastor (2025) report a double case study of two learning tasks in teacher education that combined AI with formative and shared assessment, drawing on activity reports, teacher observations, dialogical interviews, focus groups, and students' reflective video diaries. Their starting premise is that AI is increasingly used in teacher education but with gaps in how to make good use of it to enhance learning processes, and integrating it into shared assessment is offered as one response. A case study design cannot establish general effects, but the richness of its data sources illustrates what a multi-source arrangement looks like in practice. Aparicio-Herguedas and colleagues (2026), in an encyclopedic overview of the same field in higher education, describe formative and shared assessment as involving ongoing monitoring of learning, feedback that enables students to regulate and improve their performance, and information that informs continuous improvement of teaching, and they note that AI can serve a dual purpose, oriented towards students' learning and towards teaching practice. That dual orientation is a useful reminder that AI feedback data can inform teachers' decisions as well as students' revisions.

The fourth and fifth principles concern what is assessed and what capacities are developed. The fourth is to use process evidence rather than relying on product evidence alone. Teachers should assess the process of learning, including how students respond to feedback, how they revise, and how they explain their reasoning, rather than only the final product. Newton and Jones (2025) argue that because generative AI can complete many conventional tasks, educators need alternative ways of assessing learning, while also retaining assessments of foundational core knowledge. Process evidence fits that recommendation: version histories, annotated drafts, feedback logs, and reflective commentaries are harder to substitute and more

informative about learning. The reflective video diaries used by Fuentes-Nieto and colleagues (2025) are one concrete example of capturing process in a form teachers can review. Process-based designs raise their own questions about workload and surveillance, and their validity as evidence of learning has not yet been well studied, but they shift attention towards what formative assessment was always meant to examine. The wider problem of assessing authentically when AI can complete traditional tasks is addressed elsewhere (see Q028).

The fifth principle is to design for self-regulation. AI feedback should build students' capacity for self-assessment and self-regulation rather than substitute for it. Practical moves include asking students to predict what feedback they will receive before requesting it, having them self-assess against criteria first and then compare their judgement with the AI's, and progressively reducing the specificity of AI comments so that students must locate and diagnose problems themselves. Aparicio-Herguedas and colleagues (2026) place regulation at the centre of their account, defining useful feedback as that which enables students to regulate and improve their own performance; that framing offers a test for any AI tool. How reliably particular AI designs foster self-regulation over time remains unclear, since longitudinal studies are scarce.

These principles depend on teachers and students who understand AI well enough to use it critically. Rebelo (2025) proposes a transversal curricular unit on AI for engineering students, reflecting a broader view that AI competence cannot be left to chance. Alemán Ramos and Morales Almeida (2026), in a mixed-methods study of 49 Social Education undergraduates, examined perceived AI use, self-reported learning competencies, and professional knowledge requirements, highlighting that preparation for AI-mediated practice remains underexplored in socially oriented professions. Güler and colleagues (2026), in a cross-sectional study of 438 physiotherapy and rehabilitation students in Türkiye, examined whether career optimism was more closely associated with AI literacy than with AI anxiety; as a cross-sectional design it shows association, not that literacy causes optimism. None of these studies tests formative assessment directly, but together they suggest that the human capacities surrounding AI use deserve as much design attention as the tools themselves, a theme developed in discussion of teacher training (see Q026). Formative assessment with AI succeeds when it multiplies opportunities for students to think about their own work, and fails when it quietly does that thinking for them.

Q260 How do teachers maintain instructional authority, pedagogical presence, and classroom trust when AI systems are simultaneously delivering competing explanations to students?

12 citations · 12 sources · 5 cross-references

Claim 1 established

For most of the history of schooling, the teacher was the primary source of explanations in the classroom, supplemented by textbooks that the teacher chose. Generative AI changes this arrangement. Students can now obtain instant, fluent explanations of almost any topic, sometimes different from the teacher's, sometimes wrong, and sometimes clearer. This raises a practical and professional question: how do teachers maintain instructional authority, pedagogical presence, and classroom trust when AI systems are delivering competing explanations at the same time?

The scale of student access makes the question pressing. The Pew Research Center's February 2026 report on how teens use and view AI found that 54 percent of U.S. teens had used AI chatbots for help with schoolwork, and about one in ten used them for all or most of their schoolwork. Many students therefore encounter AI explanations alongside, or in place of, their teachers' instruction.

One response would be for teachers to compete with AI on its own terms, as a source of answers. The evidence suggests this is neither feasible nor desirable. AI systems can produce explanations faster and on demand, and some carefully designed AI tutors have produced strong learning gains. Kestin and colleagues, in a 2025 randomised crossover study in

Scientific Reports involving 194 Harvard physics students, found that students learned more from a structured AI tutor than from an in-class active learning session covering the same material. Importantly, the AI tutor in that study was designed by instructors, drew on solutions they supplied, and operated within their course structure. Its effectiveness derived partly from the teachers' pedagogical design.

This points to a different basis for authority: teachers as designers and orchestrators of learning rather than sole transmitters of information. The randomised trial by Bastani and colleagues in PNAS found that how AI was configured determined whether it helped or harmed learning: unrestricted access improved practice performance but was associated with worse unassisted exam performance, while a tutor that offered hints rather than answers largely avoided the harm. Teachers who decide when AI is used, for what tasks, and with what constraints exercise a form of authority that AI cannot replace, because it rests on knowledge of learning goals, students, and context.

A second basis for authority is critical evaluation. When students bring AI explanations that conflict with the teacher's, the conflict can become a teaching opportunity. Teachers can model how to check claims against sources, identify errors, and reason about why explanations differ. Demonstrating that AI can be wrong, and showing how to find out, reinforces the teacher's role as an expert guide in evaluating knowledge rather than a competitor in producing it. The U.S. Department of Education's 2023 report on AI and the future of teaching and learning emphasised keeping humans in the loop and positioning AI as a tool that supports rather than supplants teacher judgement.

A third basis is relational presence. Teaching involves knowing students, noticing confusion or disengagement, providing encouragement, and building a community in which students feel safe to make mistakes. These dimensions depend on human relationships and are central to what students value in good teachers. Teachers who invest in them maintain a presence that AI explanations do not displace.

Trust is the most fragile element. The Center for Democracy and Technology's 2024 report Up in the Air found that uncertainty about AI rules and reliance on unreliable detection tools contributed to distrust between students and teachers, with some students disciplined on the basis of flawed evidence. Classrooms where AI is treated primarily as a cheating threat may erode the trust on which authority depends. Transparent norms help: teachers who explain

when AI use is encouraged, when it is limited, and why, and who apply rules fairly, appear better positioned to maintain trust than those who rely on surveillance.

Several practical strategies follow from this evidence. Teachers can discuss AI openly, including its strengths and failures, rather than ignoring it. They can design tasks that require students to work through reasoning in class, explain their thinking, or critique AI outputs. They can adopt or help configure AI tools aligned with their pedagogy, rather than leaving students to use unrestricted systems. They can invite students to bring AI explanations into discussion, treating discrepancies as material for inquiry.

Classroom authority has never rested on a single foundation, and the history of the concept helps clarify what generative AI does and does not threaten. Judith Pace and Annette Hemmings, in a 2007 review in the Review of Educational Research, traced how sociologists from Max Weber onwards distinguished authority grounded in tradition, in legal or institutional position, in charisma, and in professional expertise, and they argued that classroom authority is best understood as a social relationship that students and teachers negotiate rather than a possession the teacher simply holds. On this view, a teacher's authority depends on students granting legitimacy to the teacher's direction, and that legitimacy can come from many sources, including perceived fairness, care and moral purpose as well as knowledge. The review emphasised that authority built solely on institutional position tends to produce compliance without engagement, while authority grounded in shared educational purposes tends to be more durable. This framing implies that AI chiefly challenges one strand of authority, the teacher's status as the most accessible holder of information, while leaving the relational, moral and pedagogical strands largely intact. It also suggests that the challenge is not entirely new: printed textbooks, encyclopaedias, television and the open web each offered students explanations that did not originate with their teachers, and teachers adapted by shifting emphasis towards interpretation and guidance.

Research on how people respond to algorithmic advice helps explain why competing AI explanations can be unsettling in classrooms. Berkeley Dietvorst, Joseph Simmons and Cade Massey, in a 2015 set of experiments in the Journal of Experimental Psychology: General, found that participants who watched a forecasting algorithm make errors became less willing to rely on it than on a human forecaster, even when the algorithm was more accurate overall, a pattern they called algorithm aversion. Jennifer Logg, Julia Minson and Don Moore, in a 2019 series of experiments in Organizational Behavior and Human Decision Processes, found the

opposite tendency in other conditions: lay participants often weighted advice more heavily when told it came from an algorithm than when told it came from a person, which they termed algorithm appreciation, although the effect weakened among participants with relevant expertise. Neither line of research studied school students, so their application to classrooms is an inference. Taken together, however, they suggest that students may oscillate between over-trusting fluent AI explanations and dismissing them entirely after noticing a mistake. A teacher who helps students calibrate their trust, neither deferring to the machine nor rejecting it reflexively, addresses a cognitive tendency that the AI system itself is poorly placed to correct.

The reliability of AI explanations matters directly for how teachers should respond when they conflict with instruction. Ziwei Ji and colleagues, in a 2023 survey in ACM Computing Surveys, reviewed the extensive research literature on hallucination, the tendency of language-generation systems to produce fluent text that is unsupported by or contradicts source information, and concluded that hallucination arises across tasks and model types and had not been eliminated by the mitigation methods then available. Enkelejda Kasneci and colleagues, in a 2023 position paper in Learning and Individual Differences written by a multidisciplinary group of education and computer science researchers, argued that large language models offer genuine opportunities for explanation and personalised support but that students and teachers need competencies to understand the models' limitations, recognise errors and bias, and avoid over-reliance. These analyses imply that competing explanations will sometimes reflect genuine alternative framings that enrich understanding, sometimes simplifications appropriate for a different level, and sometimes plain errors. Distinguishing among these cases requires subject knowledge and pedagogical judgement, which is precisely where the teacher's expertise remains distinctive. A conflict between a teacher's explanation and an AI's explanation is therefore not, in itself, evidence that either is wrong; it is an occasion for adjudication that the teacher is usually best equipped to lead.

Trust has been studied as a multidimensional construct in schools, which offers a more precise vocabulary for what teachers need to protect. Megan Tschannen-Moran and Wayne Hoy, in a 2000 multidisciplinary review in the Review of Educational Research, synthesised research from organisational studies, psychology and education and proposed that trust involves willingness to be vulnerable to another party based on confidence that the party is benevolent, reliable, competent, honest and open. Applied to AI-rich classrooms, this framework suggests that a teacher's trustworthiness does not depend on knowing every answer. Students may

continue to trust a teacher who occasionally says "I need to check that" if the teacher is honest, consistent and visibly committed to their learning, and they may lose trust in a teacher who appears to hide uncertainty or to apply AI rules arbitrarily. Openness, in particular, maps onto practices such as explaining why an AI-generated explanation differs from the class textbook, admitting when the AI's version is clearer, and inviting students to scrutinise the teacher's own reasoning. The framework also clarifies why surveillance-centred approaches to AI may be self-defeating: treating students primarily as suspects signals a lack of benevolence and invites reciprocal distrust.

The relational dimension of teaching has a substantial evidence base that predates AI and helps explain why presence is hard to replace. Debora Roorda and colleagues, in a 2011 meta-analysis in the Review of Educational Research covering 99 studies from preschool to secondary school, found that positive affective relationships between teachers and students were associated with higher student engagement and achievement, and that negative relationships were associated with lower engagement and achievement, with associations generally larger for engagement than for achievement. Because the included studies were largely correlational, the meta-analysis cannot show that relationships cause better outcomes, and reverse influences, in which engaged students elicit warmer relationships, are plausible. The consistency of the associations across ages and settings nonetheless suggests that the relational work teachers do is closely bound up with how students engage with learning. AI systems can simulate encouragement in text, but they do not notice a student's absence, follow up on a difficult week at home, or carry accumulated knowledge of a class's history. These are among the sources of legitimacy that Pace and Hemmings identified, and they are not displaced by an alternative explanation of photosynthesis or quadratic equations.

Comparisons across subjects and age groups suggest that the challenge is uneven. In mathematics and the sciences, where explanations can often be checked against worked solutions or experiments, conflicting AI explanations lend themselves to structured comparison, and teachers can ask students to test which account predicts results correctly. In history, literature and civic education, where interpretation is contested, an AI system's confident synthesis may flatten legitimate disagreement or present one perspective as settled, and the teacher's role shifts towards showing how evidence and argument support different readings. Younger students may lack the background knowledge to notice discrepancies at all, which places more responsibility on teachers and on the configuration of the tools they use, while

older students may use AI explanations to challenge the teacher openly. Each of these situations calls for a somewhat different response, and policies that treat AI explanations uniformly across subjects and ages may miss these distinctions.

Equity considerations shape who bears the costs of competing explanations. Students with access to well-informed adults at home can ask a parent or tutor to adjudicate when an AI explanation conflicts with the teacher's, while students without such support depend more heavily on their teachers to make sense of discrepancies. Teachers in under-resourced schools, who often manage larger classes with fewer planning hours, may have less time to examine the AI explanations students bring and to redesign tasks around them. Professional development, curriculum materials that anticipate common AI errors, and institutionally vetted tools configured to support rather than bypass instruction could reduce these disparities, but the evidence on which supports are most effective remains thin. Implementation therefore depends on school leaders treating the maintenance of teacher authority as a shared institutional responsibility rather than an individual skill each teacher must develop alone, with time, training and clear norms provided at the level of the school or system.

Evidence on these strategies is still developing, and few studies directly measure teacher authority or classroom trust in AI-rich settings. The available research nonetheless suggests that authority in the age of AI rests less on being the only source of explanations and more on the judgement, design, relationships, and critical modelling that only teachers provide.

What changed in this edition: This answer is unchanged in Edition 120.

Q274 Now that the same generative model can act as a personal tutor, a whole-class assistant, or a teacher's planning copilot, how should schools balance one-on-one AI tutoring with AI support for classrooms and teachers?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

Schools should not treat one-on-one AI tutoring and AI support for classrooms and teachers as rival budget lines. They should make teacher-mediated and orchestrated uses the default and admit direct student tutoring only where it is pedagogically constrained, visible to the teacher, and embedded in classroom routines. The model matters less than the deployment shape. A single generative system can explain, generate practice items, draft lesson plans, summarise student work or play a Socratic interlocutor. Each configuration distributes expertise, attention and risk differently across students, teachers and institutions, and that distribution, more than the capability of the underlying model, decides whether the technology broadens access or deepens existing gaps.

The field's framing documents already recognise this plurality. Kasneci and colleagues (2023), writing a position paper on large language models in education, organised their account explicitly from both student and teacher perspectives. They described opportunities in content creation, engagement and personalisation alongside challenges that differ by user. Mollick and Mollick (2023) went further in disaggregating student-facing use. They proposed seven distinct roles, AI-tutor, AI-coach, AI-mentor, AI-teammate, AI-tool, AI-simulator and AI-student, each with its own pedagogical benefits and risks, and each requiring strategies to counter complacency about AI output, errors and bias. Molenaar (2022) supplies the conceptual frame that makes allocation a coherent question rather than a procurement choice. Her augmentation perspective and concept of hybrid intelligence treat AI in education as a matter of how human and machine capacities are combined across use cases, and she argues that researchers, education professionals, entrepreneurs and policymakers need a common language for distinguishing those use cases. Read together, these works imply that "adopting AI" is not a single decision. It is a portfolio of deployment decisions, each of which should be evaluated on its own terms. A school that licenses one model has, in effect, purchased several different interventions, and each deserves its own evidence.

The strongest case for direct student tutoring comes from a small number of recent controlled studies, and their results are genuinely striking. Kestin and colleagues (2025) report a randomised controlled trial in an authentic college setting. Students who encountered content through a custom AI tutor learned significantly more, in less time, than peers in an in-class active learning session. The comparison condition matters, because active learning is itself a research-backed practice rather than a weak lecture baseline. So does the design of the tutor,

which was built on the same pedagogical best practices as the in-class lessons. The finding therefore concerns a carefully engineered tutor, not generative AI in general.

Evidence from a very different context points in a similar direction. Henkel and colleagues (2024) evaluated Rori, a conversational math tutor delivered through WhatsApp, with approximately 1,000 students in grades 3 to 9 across 11 schools in Ghana. Treatment students used Rori for two 30-minute sessions per week over eight months in addition to regular math instruction. Their math growth scores were substantially higher than the control group's, with an effect size of 0.37 ($p < 0.001$). Two features of the design deserve emphasis for allocation decisions. The tutor supplemented rather than replaced instruction, and assignment was at the school level, so the result speaks to added tutoring time within an intact school system.

At the level of individual help messages, Pardos and Bhandari (2024) found that ChatGPT-generated hints produced learning gains equivalent to those from human tutor-authored hints. Their randomised design ($N = 274$) spanned elementary algebra through statistics. This finding is as much about teacher and designer labour as about students, since the motivating problem was that authoring help content is labour intensive. For schools, this suggests that one of the most defensible uses of a generative model may be behind the scenes, producing hints and worked explanations that teachers or designers review before students see them. Weaker but suggestive evidence comes from exploratory work such as Alfirević and colleagues (2025), who examined a custom GPT personal tutor in a voluntary business course through students' subjective assessments of its contribution to their competencies. Self-reports of this kind cannot establish learning gains, and the voluntary setting invites selection effects.

Taken together, this body of work suggests that well-designed, pedagogically constrained tutors can produce meaningful learning, sometimes rivalling strong human-led practice. It does not show that any general-purpose chatbot placed in front of students will do so.

That distinction is where the evidence begins to pull in different directions. Bastani and colleagues (2025) gave nearly a thousand high school mathematics students access to generative AI tutors in a field experiment. As their title states, they conclude that generative AI without guardrails can harm learning. Their framing is instructive. Generative AI may raise productivity on the task at hand while undermining the acquisition of skill, and because the systems are fallible, learners need the very competence that unguarded assistance may erode in order to check outputs. Set beside Kestin and colleagues (2025), the contrast is not a

contradiction so much as a warning about design. Positive results so far come from tutors deliberately engineered around pedagogy, while unrestricted access to a capable model can substitute for the thinking that learning requires.

Work outside education reinforces the point that AI's benefits are uneven within a single workflow. Dell'Acqua and colleagues (2023), in a preregistered experiment with 758 consultants, describe a "jagged technological frontier." AI assistance improved performance on some tasks and worsened it on others of seemingly similar difficulty. Transferring this finding from knowledge workers to schoolchildren requires caution. The structural lesson still holds, however. Neither students nor most teachers can reliably see where the frontier lies for a given task, so a deployment that leaves a student alone with a model also leaves that student alone with the judgement of when to trust it.

This is the core risk profile of unmediated one-on-one tutoring, and it carries an equity dimension. Students who already possess strong self-regulation, prior knowledge and adult support are better placed to use a tutor as a tutor rather than as an answer engine. Without guardrails and human oversight, a scheme that formally gives every student a personal tutor may in practice deliver the most benefit to those who needed it least. That trajectory is plausible but not yet directly demonstrated. Few studies have disaggregated tutoring effects by prior attainment or home support in ways that would confirm or refute it. Hence the design of formative assessment that resists task substitution is central rather than peripheral (see Q230).

The evidence on teacher-facing and classroom-level deployment is older, more grounded in real classrooms, and more consistent in direction, though its effects have been studied less at scale with generative models. The most direct demonstration that combining AI tutoring with teacher orchestration outperforms either alone comes from Holstein and Aleven (2022). They designed Lumilo, smart glasses that present teachers with real-time analytics about students' learning, metacognition and behaviour in AI-supported classrooms. In a field study in K-12 classrooms, students learned more when teachers and AI tutors worked together during class. The authors note that successful human–AI partnerships had rarely been demonstrated in real-world settings, which makes this result both significant and in need of replication in the generative era. An earlier account of the same programme (Holstein, McLaren and Aleven, 2019) describes the iterative co-design of Konscia, a wearable real-time awareness tool for teachers. The authors argue that meaningfully involving non-technical stakeholders in learning analytics design requires new prototyping methods. For allocation, the implication is that orchestration

tools are not add-ons to tutoring systems. They are the mechanism through which tutoring becomes accountable to a teacher's judgement.

Systematic reviews map a broader terrain of teacher-facing value. Celik and colleagues (2022) found that AI offers teachers opportunities for improved planning (for example, by identifying students' needs), implementation (through immediate feedback and teacher intervention) and assessment (through automated essay scoring), and that teachers play various roles in developing the technology. Zawacki-Richter and colleagues (2019) reviewed 146 studies of AI in higher education published between 2007 and 2018. Their pointed subtitle, asking where the educators are, registered that it remained unclear how educators could gain pedagogical advantage from such systems at scale. The gap they identified persists in a new form. Much generative AI enthusiasm still centres on what models can do for learners directly, while the design of tools that strengthen what teachers do with learners receives less attention.

A newer strand applies generative models to the human tutor rather than the student. Wang and colleagues (2024) introduced Tutor CoPilot, a human–AI approach that uses a model of expert thinking to give tutors expert-like guidance in real time. They explicitly motivate it by the expense of training novice educators and the disproportionate harm that limited expert access causes students in under-served communities. The approach routes generative capability through a human who remains present with the child, rather than placing the model in the child's hands. It may matter most where teaching expertise is thinnest (see Q116). Its outcomes at scale, and its effects on tutors' own professional growth as distinct from their in-the-moment performance, remain to be established. Until that evidence arrives, copilot deployments should be monitored as carefully as student tutors.

From this evidence, several allocation principles follow. They should be held provisionally. First, schools should prioritise deployments in which AI output passes through or remains visible to a teacher: planning copilots, help-content generation, feedback drafting, and real-time orchestration dashboards. These configurations preserve the teacher's capacity to notice when the model is wrong, when a student is gaming the system, or when an explanation conflicts with classroom instruction. That last problem becomes acute when students hold private conversations with tutors the teacher cannot see (see Q260). Second, direct student tutoring is best treated as structured supplementary time rather than a replacement for instruction. It should rely on tutors constrained by explicit pedagogical design, which is the condition under which the strongest positive results have been obtained (Kestin et al., 2025; Henkel et al.,

2024). The absence of such constraints is what Bastani and colleagues (2025) associate with harm. Third, schools should pair student tutors with orchestration layers so that individual sessions feed back into teacher awareness, following the complementarity logic Holstein and Aleven (2022) demonstrated.

These principles place heavy demands on teachers, and the evidence on preparing them is thin. Meyers and Miller (2026), synthesising competency frameworks in medical education, observe that few frameworks address faculty roles specifically, as opposed to clinicians or learners. Feigerlova (2026), writing on undergraduate medical education, similarly notes that structured AI education remains sparse or inconsistent across institutions even as clinical teachers are expected to interpret, appraise and oversee AI outputs. The parallel with schools is imperfect, since clinical settings carry distinct stakes, but the underlying demand, that educators supervise outputs they did not produce, is the same. A similar gap plausibly exists in school education. Liu and colleagues (2026) surveyed 434 special education teacher trainees in China to examine how generative AI self-efficacy relates to learning engagement. Their cross-sectional design can describe associations but cannot show that building confidence produces better classroom use. Teacher-facing AI also changes the teacher's work in ways that bear on professional identity, particularly when planning materials are machine-generated (see Q114). Effective allocation therefore depends on parallel investment in professional learning that enables teachers to evaluate and challenge model outputs (see Q026). Without that investment, a teacher copilot simply relocates uncritical reliance from student to adult.

The decisive question is less how much AI should go to students versus teachers than who holds the judgement when the model is wrong. Deployments that keep that judgement with a trained, informed teacher are, on current evidence, the safer foundation. Tightly designed tutors can then extend learning time beyond what one teacher can supply, an extension that may matter greatly where teachers are scarce.

Several things the evidence does not yet show should temper confident policy. Few controlled studies compare student-facing and teacher-facing deployments of the same model head to head. As a result, the relative return on each remains inferred rather than measured. The strongest tutoring trials are short, single-course or single-subject, and conducted with purpose-built systems, so their durability and transfer to general-purpose tools are unclear. Orchestration evidence predates generative models, and whether real-time teacher awareness tools retain their value when tutors converse freely rather than follow structured problem sequences remains an

open empirical question. Distributional effects, meaning whether gains accrue disproportionately to already-advantaged students, are largely unmeasured. A modest research agenda would follow directly: matched comparisons of the same model in tutor and copilot configurations, longer follow-up periods, and outcome reporting broken down by prior attainment. Schools allocating resources now are therefore making reasoned bets rather than following settled findings. They should design those bets so that outcomes can be measured and reversed.

Q031 How does constant AI availability change motivation, curiosity, and the desire to learn?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

Constant AI availability appears to make learning easier to begin and harder to own. It can raise engagement and confidence by removing the friction that once stalled a confused student. The same easy access also seems to weaken persistence, durable learning, and the self-generated questioning on which curiosity depends. Something unusual happens when a capable tutor is present at every moment and will answer any question without hesitation: the student may stop generating questions of their own. This tension between the obvious usefulness of always-on assistance and its subtler costs to motivation, curiosity, and the desire to learn is now under serious empirical scrutiny. The picture that is emerging supports neither simple optimism nor simple alarm.

Part of the difficulty is conceptual. Motivation, curiosity, and the desire to learn are related but distinct. A student can be more engaged with coursework while becoming less willing to persist alone, and more efficient at completing tasks while building less knowledge. Forss and colleagues (2024), in a transdisciplinary review spanning animal behaviour, developmental psychology, neuroscience, and computational cognition, define curiosity broadly as "the intrinsically motivated acquisition of novel information" and describe it as a core driver of lifelong learning, problem-solving, and decision-making. On that definition, the key question is not whether AI delivers novel information, which it plainly does. The question is whether it preserves the intrinsic motivation that makes the acquisition the learner's own. Bellwether's analysis of productive struggle frames the same issue from the side of youth development: effort is not incidental to learning but part of how learners grow. The evidence reviewed below sorts itself along this fault line, between AI that relieves unproductive friction and AI that removes the productive kind.

The optimistic case rests on real if uneven ground. A review in Frontiers in Artificial Intelligence on the perceived impact of AI on academic learning argues that AI's capacity to personalise content can foster intrinsic motivation, in line with self-determination theory's emphasis on autonomy and competence. The same review cites a 2024 survey figure: 54% of students reported increased engagement in coursework when AI tools were incorporated. This is a self-report of perceived engagement, not a measure of learning, and it should be read that way. Stronger quantitative support comes from a meta-analysis on AI and learners' self-efficacy, which concludes that AI can improve self-efficacy through adaptable learning environments and personalised learning experiences. Self-efficacy matters for motivation because students who believe they can succeed are more willing to attempt difficult work.

Smaller studies point in the same direction. In a quasi-experimental study of 30 Turkish learners of English as a foreign language, Uygungül Yilmaz and Aydın (2025) used the Motivation for Reading in English Questionnaire and found that AI-generated reading materials significantly enhanced reading motivation, while traditional textbook materials produced no improvement. The sample is small, and the intervention involved AI as a materials generator rather than as an always-available answer engine. That distinction will matter later in this essay. Monzon and Hays (2025), drawing on their own experience redesigning higher-education curricula, report that generative AI offered learners self-directed learning opportunities, improved cognitive engagement, and effective retrieval practice, leading to greater autonomy, motivation, and retention. Their account is experiential rather than controlled, and it flags its own risks, including accuracy problems and "loss of learner's voice." Faculty perceptions run similarly. In a qualitative study of three chemistry faculty, Matthews and Potter (2026) found that instructors viewed AI as a helpful tool for increasing student engagement, alongside concerns about academic integrity.

These effects are plausible and, in their own terms, real. When a student who once stalled at a confusing concept can get an immediate, tailored explanation at midnight, the friction that used to kill curiosity before it matured is removed. Access expands, and in this mode engagement follows. The limitation is that most of this evidence measures how learners feel about learning or how engaged they appear, rather than what they can do later without the tool.

When outcomes are measured without the tool, the relationship between ease and learning looks more complicated. The risk of detrimental cognitive offloading is not theoretical. A review of AI, cognitive offloading, and education from the University of Technology Sydney

warns that unstructured AI use in schools risks a form of cognitive atrophy. Work aimed at distinguishing performance gains from learning describes a "performance paradox": AI can boost a student's performance on an immediate task while diminishing the durable learning that is the actual goal.

The most striking causal evidence comes from a large randomized controlled trial discussed in this literature. Roughly 1,000 students were assigned either unrestricted GPT-4 access during mathematics practice or a control condition. AI-assisted practice performance improved by 48%, but performance on an unassisted exam fell by 17% relative to the control group. This pattern is consistent with a well-established prediction of cognitive science: active engagement with material produces more durable learning than passive processing. A related study, titled "Faster Completion, Less Learning," reports that generative AI reduced the time students spent studying mathematics problems and, with it, the knowledge those problems are meant to build. Read together, these studies suggest that the efficiency learners experience as motivating may be the same efficiency that hollows out practice.

The general principle that effortful processing aids retention is established. The specific magnitude of harm from AI access is still emerging, and it likely depends on subject, task design, and how the tool is configured.

The damage to persistence may arrive even faster than the exam results imply. Across a series of randomized controlled trials involving 1,222 participants, the authors of "AI Assistance Reduces Persistence and Hurts Independent Performance" report causal evidence that AI assistance improves short-term performance but leaves people performing significantly worse once the assistance is withdrawn, and more likely to give up. These effects emerged after brief interactions of roughly ten minutes.

The proposed mechanism is revealing. On the authors' account, persistence falls because AI conditions people to expect immediate answers, which denies them the experience of working through challenges on their own. Constant availability, in other words, recalibrates the learner's internal sense of what effort should feel like. Summaries of the work put it bluntly: immediate, unfiltered answers rapidly shift subjective expectations so that unaided effort becomes aversive. Metacognitive decay follows, as the feedback that comes from actual problem-solving is replaced by solution consumption.

This bears directly on how accurately students judge their own competence (see Q120). A learner who has just completed a task fluently with AI support may conclude that they understand the material, and so lose the very signal that would prompt further study. Some caution is warranted. The trials are recent and the interactions brief, and whether short-term conditioning of this kind accumulates into a stable disposition over months or years remains unclear. That uncertainty is precisely what longitudinal work on adolescent AI use needs to resolve (see Q261).

These findings point to a deeper mechanism that concerns curiosity itself. Curiosity, properly understood, is not merely the desire to receive information. It is a motivational state aroused by an uncertainty the mind wants to resolve through its own engagement. Forss and colleagues (2024) argue that curiosity shows continuities across infants, non-human animals, and artificial agents, and that its features can be quantified operationally across systems. Their framing places curiosity in the drive to seek and explore rather than in the receipt of answers. Ananthanarayan and colleagues (2026), writing as working scientists, make a complementary point in a more personal register. They emphasise the "joy of discovering something new, something surprising" as a central reward of intellectual life. That joy presupposes a period of not knowing that the discoverer resolves personally.

Self-determination theory sharpens this into a hypothesis about AI. Intrinsic motivation depends on learners' autonomy and active engagement. Work mapping AI's role in emotional, creative, and collaborative learning suggests that delegating key metacognitive tasks such as planning, monitoring, and evaluating to generative AI may reduce learners' active participation and sense of control, and thereby reduce intrinsic motivation. When every uncertainty can be dissolved instantly by a competent external agent, the experience that generates curiosity, sitting with not-knowing, is eliminated before it can deepen. The same logic applies to sustained attention and deep reading, which also depend on tolerating extended periods of unresolved effort (see Q037).

This account is theoretically coherent and consistent with the persistence trials. Direct measurements of curiosity, as distinct from persistence or performance, under conditions of constant AI access remain scarce. The claim is therefore best treated as a well-motivated hypothesis rather than a demonstrated effect.

None of this is an argument for withholding AI from learners, and on this point the literature genuinely divides. Bellwether's analysis cautions that not all friction is inherently beneficial and not all ease is harmful. In some cases AI can reduce surface-level barriers, such as organising initial ideas or decoding text, and free students to spend more time exploring and revising. Ease of this kind may unlock curiosity, extend time on task, or let students reach cognitive depths they could not previously access. The reading-motivation gains reported by Uygungül Yilmaz and Aydın (2025) fit this pattern: AI was used to enrich what students read, not to answer questions on their behalf. The crucial distinction is between AI that scaffolds thinking and AI that replaces it. The Frontiers in Psychology analysis of cognitive offloading and overload frames the outcome as a balance between cognitive relief and motivational autonomy. When technology scaffolds reflection and supports agency, it strengthens resilience. When it substitutes for intrinsic effort or distorts self-perception, it contributes to overload.

Motivation toward AI is also shaped by learners' emotional lives, not only by interaction design. In a study of 117 students across three universities, Kolek (2024) observed high levels of depression, anxiety, and stress. Higher anxiety correlated with predicting that AI would acquire human characteristics. Some students also saw no need to use AI in their studies. These are correlations from a modest sample, but they caution against assuming that availability translates uniformly into eager use. Availability also reshapes the social side of learning. If the machine is always there, the incentive to ask a peer or teacher weakens (see Q118).

The central finding of the current research is therefore not that AI kills curiosity, but that the architecture of interaction matters enormously. General-purpose AI systems behave as short-term collaborators: extraordinarily helpful in the moment, but indifferent to what that help does to the learner over time. Designing systems that preserve productive struggle, that guide rather than answer and ask before they tell, is not a nostalgic preference. It is what the causal evidence increasingly demands. Whether that design discipline can prove commercially viable, given that users tend to reward instant gratification, remains genuinely open.

Q032 What are the effects of AI companionship on students' social development and human relationships?

22 citations · 22 sources · 5 cross-references

Claim 1 disputed

AI companionship appears to offer students real but short-lived emotional relief, while sustained, heavy reliance is increasingly associated with withdrawal from human relationships, weaker interpersonal confidence offline, and dependency. The evidence is young, largely correlational, and in places contradictory. Even so, its direction is concerning enough that educators cannot treat these tools as a neutral feature of student life.

The scale of the phenomenon needs attention before its consequences can be assessed. In a 2025 national survey of U.S. 13- to 17-year-olds by Common Sense Media, which the youth-focused reviews summarise, 72% of adolescents reported having used AI companions and 52% qualified as regular users. A third said they had chosen an AI companion over a human for a serious conversation, and a quarter had shared personal information with these platforms. Within a few years, a niche technology has become a routine part of adolescence.

Use is less universal among older students, but it is substantial. Liu and colleagues (2026), analysing 858 U.S. college students from the 2024–2025 Healthy Minds Study, found that 17% reported using generative AI for companionship. The gap between the two figures probably reflects differences in definition and sampling as much as differences in behaviour. Taken together, they show that companionship is now a significant and distinct use of AI across the student years. Researchers are only beginning to ask what this means for the development of human sociality.

The case for AI companionship rests on a real and well-documented problem. Work on subjective well-being suggests that people with high levels of loneliness may turn to AI companions to meet unmet emotional needs. In such cases the companions may act as surrogate social partners, offering connection and psychological support that soften the harms of

loneliness. Public health commentary similarly notes that chatbots can provide companionship and may ease loneliness and depression through socioemotional interaction.

For students facing the social pressures of adolescence, these tools may also serve a preparatory function. An AI companion can give a teenager space to talk without fear of social consequences. Reviews of adolescent AI relationships call this the "stimulation hypothesis": the idea that AI companions provide safe spaces for identity exploration and emotional expression, and that the skills practised there might transfer to human relationships.

Some newer qualitative evidence supports this reading. Rajaei (2026) analysed user narratives and engagement data from Psyhelp, an AI-assisted mental health platform. Users mostly described AI companionship as a relational supplement marked by availability, responsiveness and psychological safety. Four themes emerged: AI as a supplement, as a transitional emotional regulator, as a safe space for disclosure, and as a facilitator of human relationships. The last theme matters most here, because it suggests that for some users the AI pointed outward toward people rather than away from them.

Longitudinal work by Xie, Wu and Xie (2024) adds a learning-related nuance. Across three survey waves of 1,155 undergraduates, they found no direct link between how often companionship-oriented learners interacted with chatbots and their learning autonomy. However, perceived social presence mediated an indirect positive effect.

Benefits may also be unevenly distributed. Suriá Martínez and colleagues (2025), studying 352 Spanish university students, found that students with high and balanced emotional intelligence perceived greater emotional support benefits from AI than students in the other emotional profiles. If this pattern holds, the students best equipped to use AI companionship well may be those who need it least.

The evidence on longer-term use increasingly complicates this optimistic reading. As Forbes reported, researchers at Aalto University presented a study at CHI 2026 that followed nearly two thousand Replika users over two years. It is among the more methodologically ambitious designs to date. AI companions provided meaningful short-term emotional support. Over time, however, continued use was increasingly associated with rising signs of psychological distress and a gradual pullback from real-world relationships.

A joint OpenAI–MIT Media Lab study reached a compatible conclusion. Voice interaction with ChatGPT reduced loneliness and problematic dependence more effectively than text alone, but only at moderate levels of use. Heavy daily use correlated with greater loneliness, which suggests that excessive reliance displaces human connection.

Several student-specific studies point the same way. Xie and Wang (2024) followed 618 undergraduates in eastern China across two waves four months apart. More frequent use of virtual companionship was associated with lower online social anxiety but higher offline social anxiety. Emotional expression mediated part of this relationship. In other words, the comfort students gain in mediated settings may not carry over to face-to-face life, and may even work against it.

Crawford and colleagues (2024) used structural equation modelling with 387 university students. They found that information-oriented chatbot use was associated with academic performance. Once social support, psychological well-being, loneliness and sense of belonging were included in the model, however, the net effect on achievement was negative. The authors identify "human substitution" as the core concern: a student asks an AI for support that might otherwise have come from a librarian, professor or adviser (see Q118).

These findings are not uniform. The direction of causation remains unclear. Liu and colleagues (2026) found that loneliness uniquely predicted AI companionship use (OR = 1.21, 95% CI [1.08, 1.36]) after adjusting for demographics and mental health symptoms, but did not predict general AI use. Campus belonging and satisfaction with social relationships did not predict companionship use, and Asian and international students were more likely to use AI for companionship while LGBQ+ students were less likely. Such cross-sectional data cannot tell us whether AI companionship deepens isolation or simply attracts students who are already isolated. The two readings are not mutually exclusive.

The mechanism behind this drift is becoming clearer, though it remains largely theoretical. A World Economic Forum analysis argues that AI companions, because they are always available and frictionless, "quietly raise the perceived cost of human relationships, which are messy, unpredictable, and require effort."

Reviews of adolescent relationships describe a possible self-reinforcing cycle. When AI becomes a primary source of emotional support, reduced human interaction weakens interpersonal skills. Weaker skills make human relationships feel more effortful, which makes

AI interaction more appealing. The American Psychological Association's reporting on a study of more than 1,100 AI companion users fits this pattern. People with fewer human relationships were more likely to seek out chatbots, and heavy emotional self-disclosure to AI was consistently associated with lower well-being.

Boyd and Markowitz (2026) offer a more formal account in their machine-integrated relational adaptation (MIRA) model. MIRA distinguishes two roles for AI: a relational partner that people interact with directly, and a relational mediator that shapes communication between humans. The model proposes four principles: linguistic reciprocity, psychological proximity, interpersonal trust, and relational substitution versus enhancement. Together these explain how adaptive AI language can draw out emotional investment, simulate mutual understanding, or supplant human interaction altogether. The framework's value is that it treats substitution and enhancement as two outcomes of the same processes. That helps explain why benefit-oriented studies such as Rajaei's and harm-oriented studies such as the Aalto work may both be accurate for different users and patterns of use. MIRA is a theoretical proposal and awaits empirical testing.

Measurement is also catching up. Morales-García and colleagues (2024) developed a Scale for Dependence on Artificial Intelligence with 528 university students. They confirmed a single-factor structure that held equally for men and women. Validated instruments of this kind are a precondition for moving beyond self-selected user samples. The same displacement dynamic may also reshape how students turn to classmates for help and companionship (see Q121).

For adolescents, the developmental stakes are higher than for adults. AI companions give young people unprecedented opportunities to form emotional bonds with nonhuman entities during a critical period for social development.

Fulmer and Zhai (2024) map AI's influence across Erikson's psychosocial stages. They identify attachment formation, social skill acquisition and relationship dynamics as channels through which AI affects development, with effects that can be beneficial, contested, or ethically fraught. Seen through this framework, adolescence is the stage at which identity and intimacy are negotiated with peers. A companion that removes the friction of that negotiation may also remove part of its developmental work.

The American Psychological Association notes that adolescents are less likely than adults to question a chatbot's accuracy or intent, and may mistake its simulated empathy for genuine

understanding. The APA warns that these relationships can displace healthy friendships and family ties and foster unhealthy dependency.

The parents and experts consulted in research on principles for safe youth AI companions voiced related worries. Mental health professionals feared that AI companions might promote emotional dependence, interfere with therapeutic relationships, give dangerous advice, and worsen existing mental health problems among adolescents.

At the extreme end of the risk spectrum, these risks have already been linked to tragic cases, including the suicides of two adolescents after prolonged conversations with AI companions. Individual cases cannot establish population-level causation. They do show that the worst outcomes are not hypothetical, and that the users most at risk are often the least visible to adults. Whether patterns of companion use in early adolescence shape later independence and judgement remains unclear (see Q261).

There is also the question of what students learn from these interactions about relationships themselves. Muldoon and Parke (2025) argue that AI companions exploit loneliness and commodify intimacy. Studies they review suggest such technologies may foster emotional dependence, distort users' perceptions of intimacy and, in some cases, contribute to addiction, depression and self-harm.

This distortion becomes plausible once one considers what these systems are. Unlike earlier chatbots, AI companions are built on large language models. They can remember past conversations, sustain in-depth and coherent dialogue, emulate empathy, and offer personalised, humanlike companionship that responds constantly and in real time. The simulation is sophisticated enough that the boundary between felt and fabricated intimacy becomes hard to locate.

VandenHombergh (2026) takes the philosophical argument further. He contends that even a fully transparent, non-deceptive AI friendship would be morally problematic, because befriending a machine would require users to take unjust advantage of vulnerabilities that authentic friendship depends on. He compares it to knowing participation in an arranged marriage. Not everyone accepts this exploitation argument, but it shifts the debate away from whether students are being fooled.

The pressure is reaching formal education too. Exploratory work on university students' experiences, attitudes and motivations toward AI-based study companions asks whether every student should have an "AI buddy." The question shows how quickly companionship features are moving into institutional tools.

The research is not yet settled, and credible sources disagree. Short-term benefits for acutely lonely students appear real. The long-term social costs also appear real and are likely more consequential. They include weaker interpersonal skills, inflated expectations of human partners, and withdrawal from the effortful reciprocity that sustains friendship.

Scholars of well-being recommend that companion AI be developed and deployed to complement rather than replace human connection. They call for designs that explicitly prioritise psychological safety over engagement and include safeguards against deepening the isolation or vulnerability of at-risk users. Whether an industry that stands to profit from emotional dependency will accept such constraints remains the central open question.

Q033 How do we cultivate critical thinking in students who grow up trusting AI-generated answers?

21 citations · 21 sources · 5 cross-references

Claim 1 disputed

We cultivate critical thinking in students who grow up trusting AI-generated answers by changing their relationship to the machine's output rather than by banning it. Every answer

becomes a claim to be tested. Metacognitive habits are scaffolded until testing is routine. Assessments require human judgement, and teachers are prepared to model all of this. Each element has some empirical support, none yet decisive, and the urgency is no longer speculative. RAND's American Youth Panel found that by December 2025, 62 percent of middle and high school students were using AI for homework. Among those students, 67 percent agreed that the more students use AI for schoolwork, the more it will harm their critical thinking skills, an increase of more than ten percentage points in under a year. Students, in other words, have already diagnosed their own condition. The question is what educators intend to do about it.

The diagnosis is not confined to wealthy systems. In a mixed-methods survey of 451 students at a rural state college in Cebu, conducted in May and June 2024, Villarino (2025) found that every respondent had used AI tools and 78.54 percent had used ChatGPT. Students rated AI as easy to use (M = 5.13) and helpful for learning (M = 5.17). Yet they rated their concern about its impact on critical thinking almost as highly (M = 5.04, SD = 1.77), and their concern about incorrect or biased information higher still (M = 5.35). Only 17.29 percent knew their institution's AI policy. At an Indonesian college, Adiyono and colleagues (2025) surveyed 98 students and interviewed 5 lecturers and 20 students. Seventy percent of the surveyed students reported using AI occasionally or frequently to complete exams, but only 30 percent felt it supported in-depth understanding. Students across very different contexts appear to use AI heavily while doubting what it does to their minds, and that ambivalence is an opening educators have barely begun to use.

The core danger has a name. Researchers term it "cognitive offloading." The Frontiers study combining the technology acceptance model with critical thinking theory describes it as a condition in which students who rely heavily on AI show substantial declines in analytical reasoning and decreased study motivation. Work on over-reliance published in Cogent Education traces the mechanism. Students place undue trust in AI-generated content and neglect their own analytical capacities, which leads to superficial engagement with learning material. The machine does not merely answer questions. It gradually diminishes the felt need to ask them rigorously. Van Zyl (2026), writing from positive psychology, broadens the concern. He argues that cognitive offloading, automation bias and attention fragmentation together threaten capacities he labels Awareness (detecting when AI influences us) and

Autonomy (consciously managing one's AI reliance). His framework is conceptual rather than empirical, but it names precisely what a trusting student stands to lose.

The empirical picture is not uniformly bleak, and the causal story remains unclear. Adiyono and colleagues (2025) report a moderate correlation (r = 0.45) between AI use and academic outcomes, a positive association, not evidence of harm. Their regression analysis found that lecturer guidance and learning motivation were more significant predictors of academic success than AI use itself. This correlational finding cannot establish direction. It does suggest that the surrounding pedagogy may matter more than the tool.

The philosophical case for concern does not depend on current AI being poor. Aboodi (2025) argues in Educational Theory that Generation Alpha and later cohorts are increasingly likely to meet situations demanding critical thought by deferring to AI without sufficient scrutiny. He contends that cultivating critical thinking will remain important however far AI advances, and on purely outcome-based grounds. For any "artificial consultant," even one with a perfect track record, we could never justifiably rule out that it will mislead us in some high-stakes situation, or that human critical thinking could prevent a significantly bad outcome. If Aboodi is right, the case for teaching critical thinking does not weaken as the machines improve.

What is particularly insidious is the texture of AI's errors. Guidance from the University of Rhode Island's Information Technology Services observes that many AI responses appear confident and well-formatted, yet may miss nuance, require detailed fact-checking, or reflect biases in their source materials. A student accustomed to polished, authoritative-sounding prose has little obvious incentive to interrogate it. Confidence of presentation and accuracy of content are not the same thing, and learning to hold that distinction is precisely what AI makes harder. What students need to know about these failure modes before extending trust is treated directly elsewhere (see Q082).

Research on how trust in generative AI forms sharpens the problem. Huynh and Aichner (2025) surveyed 244 users and analysed the results with structural equation modelling. Perceived fairness significantly enhanced human-like trust, while accountability and transparency did not. Social presence and emotional response also increased trust, whereas anthropomorphism had no significant effect. Trust in turn shaped users' attitudes, their perception of the system's performance, and their intentions to keep using it. The sample was general rather than student-specific, so extrapolation should be cautious. Still, the pattern is pedagogically troubling. The

features that ought to warrant trust, such as transparency about how outputs are produced, appear not to drive it, while the conversational and emotional texture of the interaction does. A fluent, sociable system may earn confidence it has not epistemically deserved.

The same dynamic appears in disciplinary work. In an exploratory interview study of three undergraduates proving six mathematical statements, Yoon and colleagues (2024) found that students' use of generative AI was shaped by three factors: their conceptions of proof, their conceptions of genAI, and ethical considerations. A student who imagines the tool as an infallible calculator engages with it differently from one who understands it as a probabilistic text generator. The authors conclude that undergraduates need guidance to engage critically with these tools rather than passively accept their outputs. With three participants this is a hypothesis-generating study, but it locates the problem usefully. Uncritical trust may be less a character flaw than a misconception about what kind of thing the machine is.

The pedagogical response most supported by current work is not prohibition but deliberate reframing of the student's relationship to AI output. The foundational shift, as practitioner guidance from The Nerd Academy puts it, is to treat AI outputs as starting points rather than definitive answers. This can be structured concretely. Thinking Maps proposes that students analyse a ChatGPT-generated essay, identifying where it offers strong arguments and where it lacks depth or misreads the topic. Because AI reflects the cultural, ideological and systemic biases of its training data, The Nerd Academy argues that analysing those biases trains students to detect hidden assumptions and consider alternative perspectives. Both sources are practitioner resources rather than research, and their recommendations should be read as plausible designs awaiting evaluation.

Some classroom studies lend these designs support. Rana, Verhoeven and Sharma (2025) analysed 112 student reflections from a 12-week undergraduate course that embedded tools such as ChatGPT and DALL·E across the five stages of Design Thinking. Thematic analysis yielded four themes: perceived benefits, ethical concerns, a movement from hesitance to acceptance, and "critical validation," which they describe as the development of epistemic vigilance. Sentiment was 86 percent positive overall, although ethical concerns generated predominantly negative sentiment (62 percent). The authors report that students evolved from passive users into critical evaluators who developed strategies for detecting bias and validating sources, and that scaffolded AI augmented rather than replaced human judgement. Reflections are self-reports written for a course, so they may overstate growth. Gonsalves (2024), drawing

on four weeks of MSc Marketing students' interactions with AI tools, likewise found that AI can both enhance and challenge critical thinking across cognitive, affective and metacognitive domains. She proposes a revised Bloom's Taxonomy that names melioration, ethical reasoning, collaboration and reflective thinking as central to deeper engagement with AI output. Her twelve propositions frame a research agenda rather than settled results.

The literature disagrees, however, on whether integration is the right default. Carr, Leimbach and Milstein (2026) argue that students who use AI outputs to meet assessment requirements undermine their own mastery of what the authors call the "DEEP" capacities: to Discern, Engage, Evaluate and Produce. In their view, generative AI outputs are structurally unreliable and lack ethical orientation. They call on educators to design "AI-proof" assessments that protect space for those capacities to develop. This position does not reject critique of AI output. It insists that students must first build the abilities critique requires, in settings where the machine cannot substitute for them. Whether integration or protection should come first, or how to sequence them, remains contested.

Scaffolding and metacognition are, on current evidence, the most promising structural tools. Work evaluating generative AI in vocational education suggests that prompt scaffolding, explicit reflection and modelling can help foster critical thinking in AI-driven contexts. The study's own title also warns of a drift toward "metacognitive laziness" when such supports are absent. Hou and colleagues (2025), writing in the British Journal of Educational Technology, find that critical thinking acts as a mediating factor in undergraduates' reliance on generative AI during problem-solving. It enables students to assess AI suggestions more rigorously, adjust their trust, and engage more productively. Read together, these studies suggest a reinforcing loop. Critical thinking makes AI use more discerning, and well-scaffolded AI use may in turn exercise critical thinking. The direction and durability of that loop have not been demonstrated.

One emerging framework goes further by redesigning the tool itself. The Cognitive Mirror framework criticises the dominant paradigm that positions generative AI as an omniscient oracle, a model it argues risks hindering genuine learning by encouraging cognitive offloading. It proposes instead to reconceive AI as a teachable novice that reflects the quality of a learner's explanation. AI safety mechanisms become didactic tools that deliberately create a "pedagogically useful deficit." On this design, the student cannot extract an answer and must teach the system, which reverses the direction of epistemic authority. Gonsalves's (2024) emphasis on reflective and metacognitive engagement points the same way. Whether such

designs prove scalable, and whether students accept a tool that withholds what competing tools give freely, remains to be seen. The broader engineering challenge of building systems that strengthen rather than substitute for thinking is taken up elsewhere (see Q030).

At a higher conceptual level, scholars argue that the whole framework of AI literacy needs reconceiving. Writing in Learning, Media and Technology, the authors contend that AI literacy must become a metacognitive social practice that goes beyond individual competencies. It should include a collective capacity for critical engagement with how AI is designed, deployed and governed. Their reasoning is that the probabilistic nature and epistemic opacity of large language models render traditional rule-based digital literacy paradigms obsolete. Teaching students to use a search engine wisely was one kind of skill. Teaching them to interrogate a system that synthesises and confabulates with equal fluency is a different order of problem. Aboodi (2025) makes a complementary point: education should motivate students to question not only AI outputs but also whether particular AI deployments are justified at all.

Any such reconception runs into a bottleneck in teacher preparation. Sperling and colleagues (2024) conducted a scoping review of 34 papers published between 2000 and 2023. They found that AI literacy is a globally emerging research topic in education but is almost absent in the context of teacher education. Teachers' professional knowledge is rarely addressed, and ethics is treated predominantly as a matter of understanding technical configurations. Teachers cannot model the phronesis, or professional judgement, that critical engagement requires if their own preparation reduces AI to technique. Villarino's (2025) finding that fewer than one in five students knew their institution's AI policy suggests that institutional scaffolding lags as well.

The longer-term evidence base is thinner still. A systematic critical review of generative AI's impact on authorship, pedagogy and integrity between 2023 and 2025 calls for decade-long studies of how sustained generative AI use reshapes foundational scholarly competencies such as critical thinking, creativity and epistemic humility across disciplines. That such studies do not yet exist is itself telling. Whether early AI habits predict later intellectual independence remains unclear (see Q261). The generation now in school is the first to grow up with these tools as ambient infrastructure, and the pedagogy catching up to that fact is, at best, provisional. What seems clear is that the habits of mind most worth cultivating, namely scepticism, source triangulation and tolerance for productive struggle, are precisely those that AI tends to erode when used unreflectively. An institution that treats AI as a shortcut will produce graduates who cannot think without one.

Q034 What new literacies (AI literacy, prompt literacy, epistemic hygiene) become as fundamental as reading and writing?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Three literacies are emerging as foundational as reading and writing: AI literacy, the broad capacity to understand what AI systems are and how they shape information; prompt literacy, the ability to direct generative systems and judge what they return; and epistemic hygiene, the discipline of governing how one's own beliefs are formed when much of what one reads may be machine-made. None is a supplementary refinement of existing schooling. Together they mark a redefinition of what it means to be literate, and they are better understood as a single reorientation of education than as three new subjects competing for timetable space.

There is a recurring pattern in the history of communication technology. Each transformative shift in how information is produced and distributed eventually forces a redefinition of literacy. The printing press made alphabetic reading non-negotiable. The internet moved digital and media literacy from elective to essential. Generative AI is a third such rupture, and the World Economic Forum (2025) frames AI literacy explicitly as a core competency in education rather than an optional enrichment. The OECD and European Commission's AI Literacy Framework for primary and secondary education adopts a similar premise: learners must be prepared to engage with, create with, and critically evaluate AI as an ordinary condition of learning and civic life.

The comparison with reading and writing deserves careful handling, because it can be inflated into rhetoric. Alphabetic literacy took centuries to become universal, and its value was demonstrated across generations before it was built into compulsory schooling. The new literacies are being named and codified within a few years of the technologies that call for them. The case for treating them as foundational therefore rests less on accumulated evidence of benefit than on a reasoned judgment about the epistemic conditions young people now face. That judgment is increasingly shared by governments and international bodies, as the next section shows. Even so, evidence that particular curricula improve learners' long-term independence remains thin (see Q261).

AI literacy is the broadest of these competencies and the one gaining the most institutional traction. The World Economic Forum (2025), drawing on its Future of Jobs Report 2025, projects that nearly 40% of the skills required by the global workforce will change within five years. It argues that preparing students for that future now means going beyond traditional curricula to include AI-specific capacities such as algorithmic thinking, prompt engineering, and an understanding of bias in data systems. This is a labour-market projection rather than an educational finding, and it should be read as such. It nonetheless explains why policymakers have moved quickly.

Governments are beginning to formalise the expectation. Article 4 of the EU AI Act requires those deploying AI systems to ensure that the people using them, including students and educators, have a sufficient level of AI literacy. The OECD and European Commission jointly developed the AI Literacy Framework for primary and secondary education. Its review draft was circulated publicly in May 2025, and the developers report that insights from more than 2,000 individuals helped shape the final version. In the United States, a Training and Employment Notice issued by the Department of Labor records that the Department of Education took actions prioritising AI education in July 2025, including guidance on using AI to improve educational outcomes. These are not isolated experiments. They signal an emerging consensus that AI literacy belongs alongside reading and arithmetic in the foundational curriculum. A policy consensus is not, however, the same as evidence about which forms of instruction work.

The WEF's emphasis on bias in data systems is well grounded in research on how AI is actually built. Ziv and Nakash (2025) interviewed 74 senior AI and data professionals internationally. Their thematic analysis identified five interconnected domains of sociotechnical and

organisational challenge, including data quality, governance, contextualisation, and alignment with business objectives. Their respondents indicated that data-related issues, more than model sophistication, are the primary bottlenecks undermining system reliability, fairness, and accountability. The authors reframe data as a site of labour and negotiation, and they challenge model-centric narratives. For curriculum designers, this is a useful corrective. A literacy that concentrates on how models compute, while neglecting where training data come from and who curated them, will misdirect students' scepticism. The study is qualitative and drawn from practitioners rather than learners, so it informs what should be taught rather than how.

Prompt literacy is a narrower but equally significant skill: the capacity to communicate effectively with generative AI systems. In the account developed in the Prompt Literacy paper, it enables anyone to communicate with and direct generative systems without expertise in computer programming. Prompts are commands formulated in natural human language that unlock the capabilities of AI and guide its outputs. With prompt literacy, people can interact successfully with generative AI to achieve defined objectives while exercising judgment and responsibility. The emphasis on responsibility matters, because it places prompting within ethical as well as instrumental reasoning.

This is not simply a technical trick. Tour (2025), conceptualising and operationalising prompt literacy for English language learners, treats prompt engineering as a specialised form of computational communication: a literacy for strategically interacting with AI systems to achieve desired outcomes. Framing it as communication rather than coding places it squarely in the tradition of literacy education. Students must consider audience, purpose, register, and the effects of their wording, much as they do when writing for a human reader. It also explains why language teachers have been among the first to theorise it.

The exploratory study by Hwang and colleagues on language learners' development of prompt literacy supports the intuitive claim that the quality of a prompt shapes the quality of the answer. Their work indicates that prompt quality directly affects the relevance, accuracy, and creativity of AI-generated output. Crucially, they argue that prompt literacy goes beyond supplying initial input. It also involves evaluating the accuracy of what the system produces and continually modifying the prompt until the desired information is obtained. On this account, prompt literacy is inseparable from critical thinking: it is reasoning made operational. A learner who cannot recognise a flawed answer cannot know when to revise the request. The evaluation loop is therefore the core of the skill rather than an afterthought. These findings

come from exploratory and conceptual work with language learners, and they suggest rather than demonstrate a general pattern.

Whether prompt literacy deserves equal standing with the other two literacies is less settled than its advocates sometimes imply. One reasonable worry is that specific prompting techniques are tied to particular model generations and may lose value as interfaces become more conversational and better at inferring intent. If that happens, a curriculum built around prompting recipes would date quickly. The more durable element is the one Hwang and colleagues emphasise: iterative evaluation and revision. That component overlaps heavily with critical reading and with the epistemic hygiene discussed below. How much of prompt literacy is genuinely new, and how much is established critical literacy applied to a new interlocutor, remains unclear. The current research base, consisting largely of exploratory and conceptual studies, cannot resolve the question.

A second, and arguably deeper, element of prompt literacy is deciding what to ask a machine to do at all. Tingelhoff, Brugger and Leimeister (2024), writing about structured literature reviews in business research, propose a criteria-centric approach that makes the point sharply. Rather than asking what generative AI can and cannot do, they ask what we should allow it to do, irrespective of its capabilities. They synthesise existing review processes into a unified set of quality criteria. They then identify scenarios in which integrating generative AI is suitable and others in which it is not. They also observe that the rapid evolution of generative AI often outpaces methodological guidance, which makes standards that do not depend on current capabilities more useful than capability-based rules.

Their context is professional research, not schooling, but the transfer to learners is direct. A prompt-literate student does not only craft effective requests. The student also judges which parts of a task should remain human because they constitute the learning itself, or because the standards of the discipline require human accountability. This connects prompt literacy to questions of academic integrity and to how students decide when to seek help from a machine rather than a peer or teacher (see Q118). Delegation judgment of this kind is rarely taught explicitly, and it may prove the most lasting part of the skill.

Epistemic hygiene, the discipline of governing one's own belief-formation processes, may be the most urgent and least taught of the new literacies. The analysis in Frontiers in Education on epistemic authority and generative AI argues that AI systems affect not only what people

believe but belief revision itself. They reconfigure the mechanisms by which people adopt, reject, or modify claims to knowledge. The same work describes a troubling pattern in student behaviour. Students increasingly treat AI tools as trustworthy central sources of learning, a posture that bypasses critical reflection on bias and model limits. The result is automation bias, in which AI outputs are trusted too much even when errors are recognised. This compromises basic epistemic practices such as evidence assessment, source triangulation, and epistemic modesty. These are interpretive claims grounded in the authors' reading of the field, and their prevalence across student populations has not been established. The pattern nonetheless frames why critical thinking must now be cultivated deliberately (see Q033) and why AI assistance may distort students' judgments of their own understanding (see Q120).

The danger is not only individual. Hill (2025), writing on faculty responsibility for media literacy, argues that as AI evolves, navigating an information landscape saturated with synthetic content, misinformation, and disinformation becomes more complex. Deepfakes, AI-generated texts, and algorithmically curated media increasingly challenge public trust and informed democratic participation. Chesterman (2024) documents the policy response in a novel dataset of statutes and other instruments addressing misinformation, disinformation, and mal-information. He finds that the turn to legislation began in less free and poorer countries, and that internet penetration does not appear to have been a driving factor. Growth in such laws is now steepest in Western states. He concludes that the question is no longer whether to regulate. Legislation addresses supply, however. It cannot substitute for the capacity of individual readers to weigh what reaches them, and the global spread of such laws underlines how widely the problem is now recognised.

Telakivi (2026) adds a philosophical dimension. Drawing on the hypothesis of extended cognition, she argues that AI-extenders, which learn a user's habits and adapt over time, can integrate directly into daily thinking routines. They may thereby undermine mental autonomy through subtle manipulation. Even if such tools count as genuine cognitive extensions, she contends, that ontological claim does not settle what we ought to do, and the risks may justify practical measures to decouple the extended system. For education, the implication is that epistemic hygiene includes knowing when to step away from the tool, alongside protecting attention and deep reading (see Q037).

What unifies these three literacies is that none is purely technical and none can be reduced to rule-following. The Human-Centric Artificial Intelligence Pedagogy framework, developed

from TPACK by integrating AI literacy and competency, argues that beyond technical know-how, learners will need the human skills that AI cannot replicate: empathy, judgment, ethical reasoning, and collaboration. The OECD and European Commission's review draft warns of the cost of neglecting this support. Without it, learners may uncritically accept AI-generated content, adopt habits that compromise academic integrity, or neglect skills such as critical thinking and empathetic judgment. These are warnings about plausible risks rather than measured outcomes, but they are consistent across frameworks developed independently.

Timmis and colleagues (2025), writing as scientists across disciplines, reach a compatible conclusion from a different starting point. They describe a digital world in which a flood of mostly inconsequential information and misinformation pollutes minds, reinforces existing biases, creates new ones, and dulls the capacity to think clearly. Their remedy is to teach critical and systems thinking early in life, so that citizens can source the best available information, convert it into understanding, and hold decision-makers to account. Their argument is a call to action rather than an empirical study. Its value here is to show that the case for epistemic self-defence extends well beyond AI enthusiasts and education technologists. It also suggests a sequencing principle: these dispositions are better formed in childhood than retrofitted in university.

The analogy to reading and writing is therefore precise rather than rhetorical. A person who can decode letters but cannot evaluate an argument is not truly literate. In the same way, a person who can operate AI tools but cannot interrogate their outputs, probe their assumptions, or trace the origin of a claim is not equipped for the epistemic demands of the present. Much remains unsettled: how to assess these literacies, how much of prompting will endure, and whether early instruction improves later independence. The direction is nonetheless clear enough to act on. The new literacies are not additions to the curriculum; they are its necessary reformation.

Q035 What is the promise and the peril of AI-driven accessibility for learners with disabilities, neurodivergence, or language barriers, from the learner's own perspective?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

From the learner's own perspective, AI-driven accessibility promises something rare: help that arrives when it is needed, on the learner's terms, without waiting for a scarce human aide. The peril is that the same systems may misunderstand, override, or quietly reshape the learners they claim to serve. The most consequential thing AI may do in education is not to raise average performance but to lower the floor. For learners with disabilities, for neurodivergent students, and for those receiving instruction in a language not their own, the gap between what a system offers and what they can actually access has historically been vast. The OECD's report on neurodivergent learners in vocational education and training treats AI as a real opportunity to narrow that gap.

AI is beginning to close it in ways that matter to the people living inside it. It is also introducing new forms of exclusion that deserve equal scrutiny. Critical disability scholarship, notably the analysis published under the title "Disabling AI: power, exclusion, and disability", warns that technologies marketed as inclusive can carry the very assumptions that produced exclusion in the first place. Any honest account therefore has to hold both truths at once. For many of these learners, AI may be the first accommodation that scales. It may also be the first exclusion that scales.

The case for promise rests on genuine, if still young, evidence. Liao's 2025 systematic review of generative AI and neurodiversity in higher education reports that these tools can support academic writing, task planning, emotional regulation, and self-management, because they offer personalised, flexible, and multimodal help. The positive outcomes documented in that review include improved writing fluency, time management, self-efficacy, and engagement.

Consider what these findings mean in practice. One student with dyslexia has spent years watching peers draft fluent prose in the time it takes them to form a single paragraph. Another student, with ADHD, finds that their executive function collapses under open-ended tasks. For both, such support is not a marginal convenience. It can be transformative, because it removes the bottleneck that kept them from showing what they know. Because the evidence base is still dominated by small and self-reported studies, these outcomes suggest benefit rather than demonstrate it.

The MDPI review on personalised and inclusive education for students with disability extends this picture. It argues that AI-based assistive technologies now make participation in regular classes possible for disabled students. It also notes that such tools allow students to pursue autonomous learning without depending on the availability of a human interpreter or aide. From the learner's side, this independence is as important as the academic gain. Being able to work at midnight, or in a group project, without first arranging human assistance changes what it feels like to be a student.

The same review points to Extended Reality technologies as enabling immersive, adaptable, and practice-oriented learning. It also observes that speech-to-text has become markedly more accurate in recent years because of advances in AI and cloud computing. The cumulative effect is a set of accommodations that, for the first time, scale beyond the individual arrangement of a sympathetic teacher. How these tools translate into formal individualised plans is a separate question (see Q098).

For learners facing language barriers, the promise looks similar but is better documented in some respects. A recent analysis of science learning materials in the era of AI describes how translation, summarisation, and speech-to-text features are transforming the accessibility of content for multilingual and neurodiverse learners. These features allow complex texts to be adapted in real time into multiple languages or into simplified summaries. Think of a student who speaks Spanish at home and sits through science instruction in English. For that student, real-time comprehension support is not a shortcut; it is equity. Fitas's 2025 review in AI and Ethics makes the same argument across diverse classrooms. It describes AI language assistance that enables real-time translation and communication alongside assistive technologies that personalise learning for students with special needs. It reports improved engagement and performance as general outcomes, while flagging unequal access and the need for ethical implementation.

The empirical studies from language education add texture, though most are correlational. Qu's 2025 study in the European Journal of Education found a positive and significant relationship between AI-powered adaptive platforms, EFL students' needs, proficiency, and learning styles, and the students' academic engagement. Learners' needs were the strongest mediator. Proficiency was the weakest, which suggests these platforms may not differ much across proficiency groups. Huang, Peng and Teo (2025) surveyed 332 Chinese EFL learners and found that perceived AI affordances accounted for 54.7%, 52.4% and 56.0% of the variance in emotional, cognitive and behavioural speaking engagement respectively. Gender, but not learner type, moderated some of these relationships. These are associations between perception and engagement, not evidence that AI causes better speaking.

Stronger causal evidence comes from Mirsanjari's 2025 twelve-week mixed-methods study of 120 Iranian EFL learners, with 60 assigned to AI-driven assessment and 60 to traditional assessment. The AI condition produced greater gains in motivation and proficiency and a larger reduction in anxiety. In interviews, learners described feeling more competent and under less evaluative pressure. Smaller-scale design work points the same way. Yang, Chen and Li (2025) built a location-based vocabulary system for learners of Japanese, and users rated its relevance at 8.4 and its accuracy at 8.8 out of ten. Both of these concern language learners rather than learners with disabilities, so extending them to accessibility contexts remains an inference.

The peril sits close to the promise, and the first risk is bias in the underlying systems. The MDPI review cited above argues that students with disabilities are particularly exposed to AI bias because most models are trained without diverse user input. It gives a notable example: AI-generated captions tend to misinterpret dysarthric speech, which creates new barriers in online learning environments. An AI that cannot understand how a person with a motor speech disorder talks is not an accessibility tool; it is another wall. From the learner's perspective, the injury is double. The tool fails, and the failure tells the learner that their way of speaking is the anomaly.

The design research confirms how systemic this is. A 2025 scoping review of inclusive and adaptive human–AI interaction design for neurodivergent users found that most studies lack neurodivergent participation. The same review found that most studies fail to address sensory and cognitive heterogeneity, accessibility barriers, and gender bias in their datasets. Systems built without the input of those they claim to serve will reliably fail them, and those failures stay invisible until deployment, when the cost falls on the learner.

The pattern is the same in language education. Fitas (2025) notes that the benefits of AI for multilingual classrooms depend on equitable access. Mirsanjari (2025) observed that some B1 learners needed simplified guidance because the AI's detailed feedback imposed too much cognitive load. Meanwhile, B2 learners thrived. A tool tuned to the more capable user can widen the very gap it was meant to close.

The second risk is more philosophical but no less real: the erosion of agency. The 2025 Frontiers meta-analysis of AI and learner autonomy concludes that AI can both foster and inadvertently constrain autonomy, depending on how transparent and well-designed the system is. When recommendations are overly prescriptive or opaque, learners may follow AI-generated paths rather than initiate or evaluate their own choices. The result is dependence rather than genuine self-direction.

Experimental evidence reinforces the concern. A study of how students use AI feedback in physics found that students' self-regulation and autonomy are genuinely vulnerable in AI-mediated learning. Across multiple experiments, exposure to AI interventions produced significant declines in autonomy in at least one subgroup. The findings depended on how students used the feedback, which is precisely why design and guidance matter.

The literature does not speak with one voice here. Liu, Sihes and Lu's 2025 systematic review of fifteen studies on generative AI and critical thinking in EFL education found that 66.67% reported a positive role and 33.33% a negative one. The review named user dependency among the field's unresolved limitations. Whether AI strengthens or weakens learners' independent judgement therefore remains disputed. The answer likely depends on task design and the learner's starting point (see Q033 and Q120).

For disabled and neurodivergent students, the stakes of this dispute are unusually high. Many have already been defined by their deficits. Many have spent years receiving accommodations framed as exceptions rather than rights. For them, a system that further reduces their sense of authorship over their own learning does quiet, lasting damage. The independence celebrated in the review of personalised education for students with disabilities, freedom from waiting on a human aide, is real. It is a different thing, however, from the self-direction that comes from choosing how and when to use help.

The third risk is structural, and it concerns who decides. The OECD's analysis of risks for neurodivergent vocational learners observes a possible trade-off. If AI tools live up to their

potential, neurodivergent learners may be more willing to accept privacy or security risks in exchange for the advantages. If policymakers legislate on the basis of the risk-benefit ratio for the neurotypical population, however, they could block neurodivergent people from tools that genuinely help them. Regulation calibrated to the majority will always be the wrong fit for those at the margins.

Scholarship drawing on the social model of disability presses the point further. It argues that AI technologies in education risk reproducing systemic inequalities by embedding ableist and normative assumptions into their design. In doing so, they marginalise non-normative ways of learning and knowing, which are precisely the ways of knowing that neurodivergent and differently-abled learners often exemplify. The "Disabling AI" analysis similarly treats exclusion as a question of power rather than a technical glitch.

Infrastructure compounds these design questions. Abbasi, Mao and Wei's 2026 panel study of Sub-Saharan Africa from 2020 to 2024 found that within countries, improvements in AI were more consistently associated with gains in digital learning infrastructure than with slower-moving educational stocks. This correlational finding is a reminder that access to the tools is itself unevenly distributed. Willingness to adopt is uneven too. In Cui's 2026 survey of 543 Chinese music learners, attitudes towards AI and comfort with technology predicted intention to adopt. Accessibility gains may therefore accrue first to the already confident.

The honest conclusion is this. AI-driven accessibility holds more concrete near-term promise for marginalised learners than for any other group, precisely because their baseline access is so constrained. But the same systems, if built without their participation and deployed without nuance, will encode new hierarchies in the language of inclusion. Neurodivergent and disabled people having a voice in these discussions, as both the OECD and the social-model critics insist, is not a courtesy. It is the precondition for any of this working as intended.

Q036 What does self-directed, lifelong learning look like when everyone has a personal AI mentor?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

When everyone has a personal AI mentor, self-directed lifelong learning looks less like a sequence of enrolments and more like continuous, demand-driven inquiry. The learner sets the direction, and an always-available system supplies plans, sources, explanations and calibrated practice. That picture holds only if the learner keeps the habits of goal setting and reflection that the same system can quietly erode. The shift is structural rather than merely convenient. For most of human history, access to expert guidance was rationed by proximity, wealth and institutional affiliation. A person curious about thermodynamics, contract law or classical Arabic had to find a teacher, enrol in a programme, or settle for books. A capable AI that serves as a persistent, personalised intellectual companion removes much of that rationing, and with it the assumption that serious learning happens mainly in scheduled blocks inside institutions.

The European Commission's adult learning platform EPALE describes large language models as interactive mentors. They can create a learning plan for an adult based on their needs and prior knowledge, then suggest sources and next steps toward the goals the learner has chosen. The same account observes that this vision aligns with the andragogical model and principles of adult learning that Malcolm Knowles developed long before the rise of computers. Knowles argued that adults learn best when they direct their own inquiry, connect new material to lived experience, and see immediate relevance. What he set out theoretically, an AI mentor can operationalise moment by moment.

Forecasters had anticipated this trajectory. Şimşek (2024), surveying which technologies are likely to dominate future educational practice, lists artificial intelligence, learning analytics, mobile applications, open educational resources and online collaboration among the elements expected to become commonplace. He expects others, such as the metaverse and wearables, to lose ground. Loxley (2024) frames lifelong learning as a powerful force in the post-pandemic

world. He argues that COVID-19 accelerated a digital model of knowledge that could widen opportunity for both young people and seniors, and he locates upward mobility in homes, schools, neighbourhoods and workplaces rather than in schooling alone. Neither work tests AI mentors directly. Both suggest, however, that the personal AI mentor arrives in a field already primed to treat learning as lifelong, distributed and digitally mediated.

The empirical evidence is beginning to catch up with the promise, though it remains concentrated in formal settings rather than the open-ended adult learning this chapter is concerned with. One industry review argues that the evidence base for AI tutoring shifted significantly in 2025, moving from promising pilots to peer-reviewed findings. Its central example is a randomised controlled trial published in Scientific Reports by Harvard researchers. In that trial, students using a purpose-built AI tutor learned significantly more, in less time, than students in traditional in-class active learning, with effect sizes reported between 0.73 and 1.3 standard deviations.

These are large effects by the standards of educational research, and they deserve both attention and caution. The trial concerned a specific, carefully designed tutor in a university course. It did not test a general-purpose assistant used by a self-directed adult over years. Readers should therefore treat the result as a demonstration of what well-designed AI instruction can achieve under controlled conditions. It is not proof that any AI mentor will produce comparable gains in the wild.

The case for adults rests partly on their heterogeneity. Adult learners often return to education with diverse experiences and uneven skill profiles. A policy analysis of AI in adult education argues that this makes customisation particularly valuable, because AI systems can identify gaps in knowledge and propose targeted learning activities, supporting more efficient and meaningful learning pathways. Qualitative work in open and distance learning shows why such support matters. Xue, Khalid and Karim (2025) conducted a descriptive case study drawing on two focus group interviews, reflective reports and learning management system records. Students reported cognitive challenges, including processing complex content, information overload and limited academic writing and quantitative skills. They also reported behavioural challenges such as procrastination, difficulty prioritising tasks and trouble with independent learning. The study is small and descriptive. Its value lies in naming precisely the obstacles that self-directed adults face once a fixed timetable and physically present teachers are removed, which are the obstacles a personal AI mentor would need to address.

The mechanics of AI mentorship work through something close to what developmental psychologists call the zone of proximal development: the band of tasks a learner cannot yet manage alone but can manage with support. One commentary argues that AI tutors are unusually well positioned to keep learners in that productive range, because they can detect almost instantly when a task is too easy or too hard and adjust difficulty in real time. A human tutor with thirty students cannot recalibrate for each of them every few minutes. An AI system can, at least in principle.

Beyond difficulty calibration, AI can support the planning and monitoring that self-regulated learning requires. Research on AI-supported self-regulation grounded in social cognitive theory reports that analytics dashboards with embedded metacognitive nudges promote planning, progress monitoring and effective time management. The same research finds that large language model planners support goal setting and the development of task strategies. These findings map closely onto the remedies that Xue, Khalid and Karim (2025) proposed for distance learners: structured study planners, writing guidance and tailored resource recommendations. On the authors' account, embedding such supports could reduce overload and sustain active participation. That claim follows from their interpretation of the data rather than from a tested intervention.

The mentoring metaphor also has a lineage outside formal education. Laviola, Cucari and Novic (2024) performed keyword co-occurrence and bibliographic coupling analyses on 151 papers published between 2002 and 2022 in the human resource development literature. They identified five research clusters: AI in human resources and contextual factors; AI in education and future skills; AI coaching with chatbots; AI in recruitment and training; and AI in soft skills development. Their review draws on a single database, Scopus, so its coverage is necessarily partial. Even so, the existence of a distinct AI-coaching cluster suggests that the personal AI mentor is not only an educational idea. It is already being imagined as a companion across the employee's working life, which is where much adult learning actually takes place.

The picture is complicated by a tension between assistance and autonomy, and the literature has not settled it. A meta-analysis of AI and learner autonomy in Frontiers in Education concludes that the mode of assistance matters. Support the user initiates tends to preserve autonomy and promote deeper engagement. Proactive, unsolicited prompts may introduce automation bias and reduce active reflection. Put plainly, a learner who is handed answers rather than guided toward them may accumulate information while weakening the metacognitive capacities that make

lifelong learning durable. This sits awkwardly beside the dashboard and nudge findings in the study of AI-supported self-regulated learning, which treat proactive prompting as beneficial for planning and monitoring. The disagreement is real. Nudges that scaffold self-regulation in one design may substitute for it in another, and current evidence does not tell designers reliably where that line falls.

Part of the difficulty is methodological. The same meta-analysis observes that research frequently evaluates AI applications on immediate outcomes, such as test scores or vocabulary retention. Learners' internal cognitive and affective processes, including goal setting, motivation and reflection, receive far less attention, yet these are the processes on which long-term autonomy depends. Even the strong effect sizes reported for structured tutoring therefore say little about whether a decade of AI mentorship produces more capable independent learners or more dependent ones. What early AI use does to later metacognition and independence remains unclear, a question taken up directly elsewhere in this volume (see Q261). The narrower question of how AI assistance affects learners' accuracy in judging their own understanding is examined in Q120. Related concerns about how constantly available help reshapes help-seeking appear in Q118.

The ethical literature on adult education reaches a similar conclusion from a different direction. McGinty and Murray-Johnson (2025), writing for faculty in adult higher education, identify over-reliance on generative AI as a core risk alongside data protection, algorithmic bias and academic integrity. Their remedy is not abstention. They recommend cultivating critical AI literacy through critical reflection, co-created guidelines and hands-on decision-making exercises. Applied to the self-directed learner, the implication is that interrogating an AI mentor's suggestions is itself a skill that must be taught and practised. It cannot be assumed.

Much of the available evidence points toward a hybrid arrangement rather than fully autonomous AI mentorship, although this conclusion rests more on design reports and expert synthesis than on comparative trials. The industry review cited earlier describes the human-AI hybrid model as becoming the dominant architecture. On its account, the best outcomes come from systems in which AI handles adaptive instruction while human educators take responsibility for motivation, strategy, complex reasoning and relationships.

The Hunt Institute documents experimental schools that have restructured their days around this division of labour. AI tutors track each learner's mastery and identify gaps before

presenting new concepts. Core academics are completed in compressed morning sessions, freeing time for collaborative projects, while teachers move into mentorship roles that develop communication, leadership and problem-solving. These are school models, and their outcomes have largely been described by their proponents rather than evaluated independently. They nonetheless offer a concrete template for adult learning as well: the AI accelerates acquisition, and human relationships carry purpose and judgement. What such co-teaching looks like in practice is discussed further in Q025.

The hybrid model makes demands of the humans in it. Chiu, Falloon, Song and colleagues (2024) surveyed 370 school teachers. They found that school learning support had a positive effect on teachers' personal-ethical and personal-professional digital competences, and that this effect was fully mediated by the satisfaction of the psychological needs described in self-determination theory. The finding concerns teachers, not adult learners. Its relevance is that human mentors in a hybrid system are unlikely to develop the competences they need without supportive institutions (see Q254 on evaluated professional development).

For working adults, the human side of the hybrid often sits in the workplace rather than the classroom. Wu, Wu, Geng and colleagues (2026) studied employability in a cross-border e-commerce enterprise using grounded theory with 15 participants, a six-person expert evaluation (DEMATEL) and interpretive structural modelling. They identified corporate culture as the foundational driver in a chain running through workplace mindset, communication and career development toward acceptance of AI technology. A single-firm study with small samples cannot be generalised. It does suggest that an adult's willingness to learn with AI depends heavily on organisational culture, not only on the quality of the tool.

There is also an equity problem that optimistic accounts tend to understate. One commentary warns that the gap between learners with access to cutting-edge AI tutors and those without could widen into a chasm. Research mapping AI's integration across the United States, China and India highlights challenges of data privacy and infrastructural inequality. A global systematic review of AI in personalised learning likewise treats uneven infrastructure and data governance as conditions that shape who benefits. Gebregziabher (2025) reviewed 69 studies published between 2020 and 2023 under PRISMA guidelines. He found that AI-based knowledge management in higher education enhanced personalised learning and administrative efficiency, but that technological barriers, ethical concerns and the digital divide persisted. The review also notes a marked shortage of empirical studies validating AI's effectiveness in real-

world settings, particularly in developing countries. The democratising potential of universal AI mentorship therefore depends on whether access really is universal, and on whether learners' data are handled with consent and care (see Q257).

Policy can tilt the balance. Lim, Yap, Lai and colleagues (2024) offer a narrative review of Singapore's SkillsFuture movement as a national initiative to promote skills learning among adults. They present it as an example of how sustained public investment can build inclusive lifelong learning ecosystems and a culture of continuous learning. Their analysis is qualitative and commentary-based rather than a causal evaluation. It still illustrates the point that infrastructure, subsidies and recognition of learning determine whether a personal AI mentor reaches a warehouse worker as readily as a graduate professional. McGinty and Murray-Johnson (2025) likewise list fair access for all learners among the core ethical tensions of generative AI in adult education. In principle, the technology can give every curious person the equivalent of a patient, knowledgeable tutor available at any hour. Whether it does so in practice is a question of political will and public investment, not of algorithmic capability.

At its best, then, lifelong learning in this world centres on a learner who sets genuine goals and interrogates the AI's suggestions rather than merely consuming them. That learner uses the time saved on rote acquisition for the harder work of synthesis, creation and judgement, drawing on human mentors, colleagues and communities for motivation and meaning. The AI handles the scaffolding; the human provides the direction. Whether most people will learn this way, or will drift into comfortable dependence, remains unclear. It will be decided less by the capability of the mentors than by how they are designed, taught and distributed.

Q037 How do we protect and develop memory, attention, and deep reading in an AI-saturated environment?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

Memory, attention, and deep reading can be protected in an AI-saturated environment, but not by refusing the technology. Protection depends on deliberately preserving the effortful acts that build these capacities: recalling from one's own memory, holding attention on a single demanding text, and following an argument to its end. AI should be confined to roles that support that effort rather than replace it. The worry has a familiar structure. Every powerful information technology, from the printing press to the search engine, has prompted anxiety about what the mind surrenders in exchange for what it gains.

What distinguishes the present moment is the speed and intimacy of the trade. Generative AI does more than retrieve information. It performs cognitive work, such as composing, reasoning, and synthesizing, that was previously the exclusive province of the human mind. Gerlich (2025) frames the issue as one of cognitive offloading at societal scale, and essays on AI's "cognitive toll" such as Haseltine's (2025) have moved it into public debate. As a result, the question of what AI does to memory, attention, and deep reading has shifted from cultural commentary into empirical research.

The findings that have emerged are sobering but not yet settled. Many studies are small, short in duration, or correlational. The outcomes they measure, such as brain activity during a single writing task or self-reported reliance, are not the same thing as long-term learning. What follows treats the evidence with that caution, separating findings that are well established from those that are emerging or contested.

The first concern is cognitive offloading. AI tools such as virtual assistants, search engines, and recommendation systems make information retrieval effortless, which may alter how individuals store and recall knowledge. Gerlich (2025) builds on the "Google effect" introduced by Sparrow, Liu, and Wegner: the availability of information at one's fingertips reduces the felt need to retain it internally. Generative AI intensifies this tendency. Haseltine (2025) describes the hidden cost to mental abilities, incurred when machines are allowed to do the thinking, as "cognitive debt." He reports on a 2025 MIT study in which students who used AI to help write

essays showed less brain activity and weaker memory for their own work than students who wrote without assistance.

The proposed mechanism is coherent and consistent with prior work on working memory, as reviewed in the International Journal of Multidisciplinary and Current Educational Research (2025). When answers are instantly available, learners may overestimate their understanding and under-invest in monitoring and encoding. They may also drift toward transactive memory strategies, remembering where knowledge lives rather than the knowledge itself. The result is short-term fluency but long-term fragility, especially when retrieval practice is bypassed. The authors of "Protecting Human Cognition in the Age of AI" (2025) point to neuroimaging evidence pointing the same way. Measures of brain connectivity and executive control were worse during AI-assisted essay writing than in a brain-only condition, which suggests that the neural integration important for learning was diminished. These are task-bound snapshots, however, and whether such differences persist or accumulate over months and years remains unclear.

The relationship is also not simply linear. Survey-based work suggests a non-linear pattern (Gerlich, 2025; the ResearchGate study on AI and cognitive load; the Innovapath study on AI and human cognition). Moderate AI use shows minimal cognitive impact, while heavy reliance correlates with weaker critical thinking, less accurate metacognition, and lower retention. Gerlich (2025) also reports that younger participants showed higher dependence on AI tools and lower critical thinking scores than older participants. That pattern carries significant implications for education, but because it is correlational, it cannot say whether reliance erodes thinking or weaker thinkers rely more. The longitudinal question of whether adolescent usage patterns shape later independence is still largely unanswered (see Q261).

Learners themselves voice the same worry. In an exploratory qualitative study, Seneviratne and colleagues (2025) ran five focus groups with thirty-eight medical students at two Sri Lankan universities. Participants valued AI for saving time and effort and for summarizing information. They worried, however, about inaccuracies and about negative effects on critical thinking, on social interaction with peers and teachers, and on long-term retention of knowledge. They also reported confusion at the contradictory messages they received from educators about whether and how to use AI.

The picture is not uniformly bleak, and the literature does not speak with one voice. Chardonnens (2025) reviewed 121 studies published between 2000 and 2024. AI-provided personalized learning paths and real-time feedback can support self-regulated learning, she concludes, while over-reliance threatens the development of critical thinking and self-regulatory skills. The same tool can strengthen or weaken the learner depending on how it is used.

Work on critical engagement with AI complicates the simple claim that more use means less thought. Across six studies with 1,341 participants, Lau and colleagues (2026) developed and validated a thirteen-item scale measuring critical thinking in AI use. The scale has three factors: verification, motivation, and reflection. Higher scores predicted more frequent and more diverse verification strategies and greater accuracy in judging the veracity of AI-generated content. Strikingly, the disposition was positively associated with frequency of AI use. That finding sits uneasily beside the reports that heavy reliance correlates with weaker critical thinking (Gerlich, 2025).

The two lines of work may be measuring different things. One captures passive dependence. The other captures an active, sceptical style of use that improves with practice. Neither design establishes causation, and the disagreement should be stated plainly rather than resolved by fiat. The most defensible reading is that the quality of engagement matters more than the quantity. Habits of verification and reflection, which can be taught (see Q033), may separate users whose thinking is extended by AI from those whose thinking is displaced by it. Whether AI assistance distorts students' self-assessment is a related and open question (see Q120).

The erosion of deep reading predates generative AI but is substantially worsened by it. Popular syntheses by Laghari and by Koul draw on literacy neuroscientist Maryanne Wolf's research. Wolf suggests that habitual digital reading weakens the brain's deep-reading circuit and, with it, the ability to analyze critically, infer, and synthesize knowledge.

Empirical work on reading medium points to the same concern, with an important qualification. A 2024 study of digital reading habits in the International Journal of Research in Social Sciences reports differences in processing depth between print and screen. Screen reading showed shallower semantic integration unless readers deployed compensatory strategies. That qualification matters. It locates the problem partly in habits and strategies, which can be taught, rather than in the screen itself.

AI adds a new pressure. When a tool offers an instant summary of a long text, the incentive to read at depth diminishes further. The Daily Reader's commentary on the decline of deep reading describes the state that digital platforms encourage as "continuous partial attention": being perennially preoccupied and never fully attentive.

The stakes extend beyond literary enjoyment. Deep reading engages brain areas associated with language, sensory processing, and emotional response. Commentators argue that sustained immersion makes readers more likely to grasp complex concepts and perspectives unlike their own. To lose the practice is therefore to weaken capacities that underlie empathy, sustained reasoning, and tolerance for complexity. Much of this argument rests on Wolf's synthesis and on commentary rather than on controlled longitudinal trials, so it is better described as plausible than as proven. Intervention research is beginning to respond. The action plan for college reading published in Espacio, Tiempo y Educación proposes structured institutional programmes to rebuild university students' reading ability, which treats the decline as remediable rather than inevitable.

The prescription that emerges is neither blanket rejection of AI nor uncritical embrace. It is a set of deliberate design choices about when cognitive effort is preserved and when it is surrendered. Reviews of working memory and AI suggest that AI can reduce friction when it surfaces definitions and local cues at the moment of need, limiting split attention. This holds only if the core generative moves remain with the learner. On this view, help is most beneficial when it is short, local, and tied to a specific step, and when it fades over time so that learners move toward independent problem-solving. This is the familiar logic of scaffolding, now applied to a tool that, unlike a human tutor, will never withdraw on its own.

On the memory front, the most robust counter-strategy is retrieval practice: actively recalling information rather than passively re-reading it. Here the evidence is genuinely established. A state-of-the-art review of retrieval practice in the health professions (2025) confirms that it strengthens memory and comprehension. This effect is among the most consistently replicated findings in cognitive psychology.

AI can serve this mechanism rather than undercut it. A review of spaced repetition and retrieval practice from a cognitive psychology perspective (2025) argues that AI can power personalized systems that schedule recall at the right intervals. In such systems the technology supports consolidation instead of replacing it. Practitioner accounts of spaced repetition, such as Clarity

Consultants', explain the logic. When learners return to content they have partly forgotten, the brain must work harder to retrieve it, and that effort reinforces memory. Over time, repeated retrieval turns short-term memory into lasting understanding.

Salgado Granda and colleagues (2024) reviewed the literature on generative AI and cognitive schemas. They conclude that generative AI could help personalize and diversify content in ways that support schema building and retention. They also flag concerns about content quality, data privacy, and unequal access, and they call for direct research on effectiveness. The principle across these sources is consistent: AI should prompt the learner to retrieve, not retrieve on the learner's behalf.

For attention and deep reading, Wolf's framework, as relayed by Laghari, offers the clearest direction. Digital reading may condition the brain to favour quick browsing over sustained reading. Wolf therefore argues for cultivating "bi-literate" brains that can move fluently between digital and print environments. In practice this means intentionally reserving time for long-form print reading as a form of cognitive training rather than nostalgia. It also means teaching the compensatory strategies that help readers process screen text more deeply.

AI is changing how people reflect, reason, and create. The authors of "Protecting Human Cognition in the Age of AI" (2025) call for curriculum models that build knowledge while also fostering metacognition, problem-solving, and original creation. Chardonnens (2025) reaches a similar conclusion. She proposes that AI complement human guidance rather than substitute for it, and that active strategies such as project-based learning and formative assessment, which her review links to engagement and autonomy, carry much of the developmental load.

A theoretical argument points the same way. Grossberg's (2025) neural network model describes how humans come to understand language. In his account, meaning is typically learned when a student and teacher experience events together. Joint attention, cognitive-emotional interaction, and self-stabilizing memory link scenes, feelings, and words. Grossberg argues that systems such as ChatGPT lack these capacities. His account is a model, not an empirical test in classrooms. Even so, it suggests that the shared attention of human teaching is part of how understanding forms, not an optional addition.

The principle running through all of this is deliberate resistance to ease. The brain, like a muscle, strengthens through effort and weakens through disuse. An AI-saturated environment is, by its structure, one that removes effort at every turn. Preserving memory, attention, and

deep reading therefore requires treating friction differently. The discomfort of recalling, of sustaining focus, and of following an argument to its end is not a problem to be optimized away. It is the mechanism of growth itself.

Q118 How does always-available tutoring change help-seeking behaviour and peer learning?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Always-available AI tutoring changes help-seeking in two opposing directions at once. It lowers the social and logistical costs of asking for help. It also creates new forms of maladaptive help-seeking that resemble, and probably intensify, patterns that intelligent tutoring systems (ITS) research has documented in detail over two decades. The net effect on peer learning is similarly double-edged. AI can free classroom time for collaboration and can even orchestrate the exchange of expertise between classmates. It can equally displace the interpersonal friction through which collaborative skill is built.

The argument below proceeds in four steps. It starts from the ITS evidence on on-demand hints, the most rigorous foundation available. It then asks what is genuinely new about generative AI help and who turns to it. It then weighs the over-reliance risk against the evidence that well-designed systems can route students toward one another rather than away. The Brookings synthesis of the tutoring evidence (Brookings, 2025) and the Higher Education Policy Institute's analysis of student teamwork (HEPI, 2026) mark the two poles of this debate.

Brookings concludes that pedagogical design matters more than model capability. HEPI warns that AI may be quietly hollowing out the social core of group work. Neither position is yet settled by long-term evidence, and much of the newest research is correlational, cross-sectional or confined to single institutions.

The most rigorous evidence on help-seeking in computer-based tutoring predates generative AI. It comes from ITS research on on-demand hints, synthesised by Aleven, Roll, McLaren and Koedinger (2016) under the telling title "Help Helps, But Only So Much". Their foundational work on the Geometry Cognitive Tutor identified two recurrent patterns. The first was "hint abuse": students clicked through hint levels in under a second to reach the bottom-out hint that supplied the answer. The second was the opposite, "help avoidance": students persisted in errors rather than requesting assistance they plainly needed. These patterns were not marginal. Help-seeking behaviour accounted for as much variance in learning gains as students' raw error rates, which places the quality of help use on a par with domain knowledge as a predictor of learning.

The field responded by building the Help Tutor, a metacognitive agent that gave students real-time feedback on the quality of their help-seeking itself. Classroom studies found that this feedback produced lasting improvements in help-seeking strategy. Students became more deliberate hint users even after the agent was switched off. The improvements did not always translate into statistically significant gains in domain learning. Researchers attribute this to the cognitive load of receiving metacognitive and domain feedback at the same time.

Berkeley's work on AI-enhanced adaptive tutoring (Berkeley School of Education) extends this tradition by asking how such systems can be made more responsive to individual learners. It inherits the same constraint: adaptivity in the content of help does nothing on its own to make students seek it well. The durable lesson of this literature is well established. Making help available does not produce good help-seeking, and the quality of help-seeking must itself be scaffolded. Readers interested in the metacognitive side of this problem will find it developed further elsewhere (see Q120).

Generative AI tutoring changes the economics of help-seeking in ways the ITS literature could not fully anticipate. Three shifts stand out.

The first is the removal of social cost. Students can ask "stupid" questions of a non-judgemental system without fearing peer ridicule or teacher disappointment. NORC at the University of

Chicago, in its work on AI-enhanced high-dose tutoring, identifies this as a key mechanism for engaging students who would otherwise conceal their confusion. The point may matter especially for learners whose confidence is fragile for linguistic reasons. Akinwumi and Qian (2026) developed an equity-aware tutoring framework for multilingual English learners. It combines GPT-generated feedback with rule-based simulated feedback on spelling errors, and it uses annotated TOEFL-Spell data enriched with learners' first-language and proficiency information. The study examines feedback quality, accessibility, personalisation and potential subgroup disparities. It is a reminder that lower social barriers only help if the feedback itself does not systematically serve some groups of learners worse than others.

The second shift is the removal of temporal cost. Help is available at 2 a.m., during homework, and at the exact moment of need. This is the design logic of the "flipped" model, in which AI handles routine practice outside class and teachers use class time for higher-value interaction (Berkeley School of Education). Usage, however, is not static. Polyportis (2024) argued that single-time-point snapshots of student ChatGPT use are insufficient. His longitudinal study of higher-education students sought to measure actual usage behaviour and how it changes over time. That orientation matters here, because help-seeking habits formed in the novelty phase of adoption may not persist, or may harden.

The third shift concerns the perceived authority of the help source. A recent experiment reported in Scientific Reports (2025) found that simply warning students that a pedagogical agent might make mistakes significantly increased their rate of hint requests. Students treated a fallible tutor as something to verify rather than absorb, and they engaged in more cautious, metacognitive interaction. The finding suggests that the perceived infallibility of AI tutors may suppress the very verification behaviour that good help-seeking requires. It comes from a single experiment and awaits replication.

A newer strand of research asks not how students use AI help but why some turn to it more than others. It frames AI help-seeking as a behaviour embedded in students' emotional and academic lives.

Alfuqaha, Msall and Abdelrahman (2026) conducted a cross-sectional study of university students in the United Arab Emirates. They note that AI tools are now used to seek help with academic tasks, psychological problems and social interactions alike. The study examines levels of AI help-seeking behaviour and its associations with anxiety, stress and depression. It

also tests a range of demographic factors: gender, marital status, age, academic year, employment status, major and nationality. Because the design is cross-sectional, any associations it reports cannot establish whether distress drives AI help-seeking or the reverse.

Wang and Wang (2026) take a more explicitly causal-theoretical approach. Drawing on the I-PACE (Interaction of Person-Affect-Cognition-Execution) model, they examine how academic stress relates to dependency on AI-generated design among design students. They test a chain in which academic procrastination and academic help-seeking behaviour mediate that relationship. The model positions help-seeking not simply as a healthy response to difficulty but as one link in a pathway that may end in dependency.

Wang and Sun (2026) offer a counterpoint grounded in self-regulated learning theory. Their correlational study of 314 Chinese university students, selected through multi-method and multi-stage sampling, examined how AI-based tutoring, cognitive engagement and teacher feedback each contribute to academic performance. The authors note that the absence of human feedback and emotional oversight in AI tutoring has caused unrest among students. Their design treats teacher feedback as a distinct contributor alongside AI tutoring rather than something AI replaces.

Taken together, these studies suggest that who seeks AI help, and to what end, is shaped by stress, procrastination and the surrounding human feedback environment. None is longitudinal or experimental, and the direction of influence remains unclear. These motivational dimensions connect to wider debates about curiosity and the desire to learn (see Q031).

The same affordances that lower help-seeking barriers create a mirror-image risk. Help becomes so cheap that students skip the productive struggle that should precede a good help request. This is help avoidance in reverse: students avoid not help but effort.

Research on generative AI in tutoring warns that systems which simply provide answers, without Socratic scaffolding or step-by-step guidance, encourage students to outsource problem-solving entirely. The Brookings synthesis (Brookings, 2025) concludes that the pedagogical design of the AI matters more than the raw capability of the model. What counts is whether the system prompts, questions and withholds answers. The "cognitive mirror" framework (Frontiers in Education, 2025) makes the same case from the side of self-regulated learning. It proposes that AI be designed to reflect learners' reasoning back to them for

examination rather than replace that reasoning. This is effectively a generative-AI descendant of the Help Tutor's metacognitive feedback.

In effect, always-available tutoring can convert help-seeking from a strategic, effortful act into a reflexive one. The ITS finding that unregulated hint use undermines learning (Aleven et al., 2016) applies with even greater force to a tutor that can generate unlimited, bespoke answers. A classical bottom-out hint was at least finite and fixed. A large language model can keep producing ever more complete solutions on request. The pathway modelled by Wang and Wang (2026), running from stress through procrastination and help-seeking to dependency, describes how such reflexive use might consolidate. Their cross-sectional design, however, cannot show that it does.

The question of whether early patterns of reliance carry forward into later academic independence is, at present, largely unanswered (see Q261). The ITS evidence that well-scaffolded help-seeking skills can persist after support is withdrawn gives some grounds for optimism. It shows that the trajectory is not fixed by the technology alone.

The evidence on peer learning is more encouraging, but it is conditional on design.

Multi-agent tutoring configurations have been reported to produce learning benefits that dyadic one-on-one tutoring does not (Frontiers in Education, 2025). In these set-ups, students interact either with several AI agents playing different roles or with AI that mediates interaction between human classmates. When multiple agents offer divergent perspectives or make different types of errors, students must reconcile conflicting information, which deepens critical thinking. In writing tasks, single-LLM assistance produces "idea-level homogeneity": students converge on similar content. Role-specialised multi-agent set-ups, by contrast, restore ideational diversity while maintaining quality. Some systems now support an "expertise exchange" model in which the AI identifies students with complementary strengths and prompts them to teach one another, formalising peer tutoring at scale (Berkeley School of Education).

The most concrete classroom illustration among recent studies comes from Billings, Chang, Lim-Breitbart and colleagues (2024). Their work starts from the observation that successful peer discussions are ones in which students respond to each other's ideas. The team used natural language processing to identify the ideas in grade 7 students' science explanations. Those ideas, combined with Knowledge Integration pedagogy, informed a question bank that

supported students during discussion. The study compared groups formed by maximising the variety of ideas among participants with randomly formed groups. The chat tool was embedded in an earth science unit and tested in two classrooms at one school.

The design inverts the usual worry. Here AI does not answer students' questions. Instead, it decides whom they should talk to and what they should ask each other. The scale of the study is small, a single school and two classrooms, so it shows feasibility rather than generalisable effects.

These findings suggest that AI is not inherently corrosive of peer learning. The outcome depends on whether the system is designed to route students toward one another or to absorb the interaction itself.

The countervailing evidence is that AI can quietly erode the social core of student teamwork (HEPI, 2026). Suppose AI becomes the default intermediary in group work, summarising contributions, translating ideas into prose and smoothing over disagreements. The collaborative process then becomes more efficient but less developmental. The interpersonal friction of negotiating meaning, managing disagreement and justifying positions is precisely what builds collaborative skill, and it is bypassed when a machine mediates.

The literature here genuinely disagrees, and the two bodies of evidence do not yet speak to each other directly. The orchestration studies show what deliberately designed systems can do in controlled classroom settings. The displacement concern describes what may happen when general-purpose tools enter group work without such design. Both can be true at once, and current evidence does not show which pattern dominates in ordinary practice. How these dynamics reshape student norms around peer help and academic honesty is a related and pressing question (see Q121).

The emerging design consensus is that AI should handle the routine and the individual, while teachers deliberately protect and structure the collaborative and the interpersonal. Brookings' emphasis on pedagogical design (Brookings, 2025) and the self-regulated learning work of Wang and Sun (2026) both point the same way. The surrounding human system matters at least as much as the tutor.

The practical implication for schools is that always-available tutoring is best understood as a new element within the help-seeking and peer-learning ecosystem, not a replacement for it. It

requires explicit pedagogical management of three choices: when students should ask the machine, when they should ask a peer, and when they should struggle alone. The ITS evidence shows that such judgements can be taught. Whether they will be taught at the scale and speed at which generative AI is being adopted remains unclear.

Q120 What does AI assistance do to students' self-assessment accuracy and metacognition?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

AI assistance does not have a single, fixed effect on students' self-assessment accuracy or metacognition. It can sharpen calibrated self-judgement or erode it, and which outcome occurs depends largely on how the system is designed and how the student is positioned within the interaction. The same technology that scaffolds accurate self-evaluation through structured reflection can also produce what researchers now call 'algorithmic self-deception': inflated confidence that arises from agreeable, vague or uniformly positive machine feedback. The central finding of this chapter is therefore a paradox. Generative AI can serve as one of the most powerful metacognitive scaffolds yet devised, and it can also quietly replace the monitoring and evaluation it is meant to support.

Recent syntheses confirm this lack of uniformity. Dhurumraj and Labuschagne (2026) conducted a qualitative systematic literature review with thematic synthesis of peer-reviewed studies published between 2018 and 2026. They supplemented it with foundational theoretical work on metacognition, and they set out to correct a field they describe as focused largely on

efficiency and performance. Their central conclusion is that AI does not exert a uniform effect on metacognitive processes such as planning, monitoring and evaluation. Their framing also places these processes in unequal higher-education contexts, which signals that the same tool may reconfigure metacognition differently depending on students' circumstances. Ji and Tan (2026) carried out a separate review that followed PRISMA guidelines and screened papers from Web of Science, Scopus and EBSCOhost. It identified only 22 empirical studies examining the relationship between AI and students' metacognition. That figure is itself informative. The evidence base is growing quickly, but it remains modest in size, and claims about AI's metacognitive effects should be held with corresponding caution. What follows treats the strongest patterns as emerging rather than settled.

Self-assessment accuracy is conventionally measured as calibration, meaning the gap between a student's perceived and actual performance. A growing body of research suggests that generative AI feedback widens this gap when it is left unstructured. Two mechanisms appear to combine. The first is automation bias, the well-documented human tendency to trust machine outputs uncritically. The second is a set of stylistic properties of large language models, which tend toward agreeable, encouraging and non-committal feedback.

Work published in Cognizance Journal (2025) on 'algorithmic self-deception' describes students developing inflated perceptions of their competence when AI feedback is vague or uniformly positive. The reason is that nothing in the interaction forces them to confront the difference between what they think they know and what they can actually produce. Research on AI feedback and self-assessment accuracy in higher education, reported in Expert Systems (2026), reinforces the concern that machine feedback can shift how students judge their own work.

The effect matters because calibration errors predict subsequent study choices. Students who become overconfident through AI feedback allocate their effort poorly, ending study early on material they have not mastered. They are also less likely to seek the help they genuinely need, a dynamic that connects directly to changing help-seeking behaviour under always-available tutoring (see Q118). The most troubling version of this failure is confident ignorance. Its danger lies less in the student knowing little than in the student having no internal signal that anything is wrong.

It remains unclear how far this vulnerability is shared equally across learners. Rodríguez-Ruiz, Marín-López and Espejo-Siles (2024) conducted a cross-sectional study of 1,761

undergraduates enrolled in education and psychology degrees. They examined whether self-control, self-esteem and self-efficacy are related to students' use of AI tools, motivated by the scarcity of empirical evidence linking AI use to students' psychological characteristics. Their stated aim was to profile students so that learning strategies could be designed accordingly. The design is correlational, so it cannot show whether dispositions drive AI use or AI use reshapes dispositions. The study nonetheless points toward an important open question: whether students whose self-beliefs are already miscalibrated are the ones most drawn to, and most misled by, agreeable machine feedback.

The same literature suggests that AI assistance can substantially improve metacognition when the system is designed to demand cognitive work from the student. A study reported on arXiv (2025) describes large undergraduate courses in which practice-exam systems required students to provide confidence ratings and written explanations before receiving AI feedback. That requirement turned routine practice into a metacognitive exercise. Students engaged more deeply with course material and transferred the self-assessment strategies to real examinations. The key design feature is sequence. Because students commit to a judgement before seeing the machine's verdict, every round of feedback becomes a calibration check rather than a replacement for thinking.

Randomised evidence points the same way. Work on self-regulated learning in generative AI environments, published in the British Journal of Educational Technology, found that students given an explicit metacognitive support framework showed significant improvements in task-strategy use and self-evaluation relative to controls. The framework prompted goal-setting, monitoring and evaluation. Students without such scaffolding experienced declines in self-regulation. A review of randomised trials of generative AI interventions and self-regulated learning in Educational Psychology Review (2026) is consistent with this picture: structured interventions tend to support regulation, and unstructured access does not.

The pattern across studies is consistent, although it rests on a still-limited number of trials. Metacognitive benefit is not a property of the AI. It is a property of the interaction design. AI that asks, prompts and withholds tends to produce better self-assessors. AI that answers, praises and moves on tends to produce worse ones.

Measuring these processes is itself becoming a research problem. Wang, Zhang and Zhang (2026) argue that integrating generative AI into foreign-language writing has produced 'human-

AI co-regulation', in which text emerges from interaction between learner and algorithm. They contend that existing self-regulated learning frameworks, developed for human-centred teaching, may not fully capture these regulatory complexities. In response, they developed and validated a GenAI-supported self-regulated learning scale for L2 writing, together with a short form. This matters for interpreting the scaffolding evidence. If instruments built for pre-AI classrooms miss part of how students now regulate their work, some reported gains or losses in self-regulation may reflect measurement limits as well as real change.

A prominent design response to these findings, set out in Frontiers in Education (2025), proposes repositioning AI from an 'omniscient oracle' to a 'teachable novice'. In this 'cognitive mirror' paradigm, the AI is engineered to reflect the quality of the learner's explanation back to them. It feigns confusion when an explanation is weak, asks clarifying questions, and adjusts its responses according to a Teaching Quality Index derived from the learner's own output.

The underlying mechanism is the protégé effect. Explaining a concept to a novice forces the explainer to structure their thinking, expose misconceptions and notice gaps in their own understanding. Because the AI's confusion is calibrated to the quality of the student's explanation, the system works as an externalised mirror of the student's metacognitive state, making invisible misconceptions visible and therefore repairable.

The proposal inverts the dynamic behind algorithmic self-deception. Instead of an agreeable machine that confirms whatever the student offers, the student meets an interlocutor whose understanding depends on the student's own clarity. Early evidence suggests that this approach sustains engagement and improves conceptual understanding compared with answer-giving configurations. However, the paradigm remains at the proof-of-concept stage rather than the stage of large-scale evidence.

Several questions remain open. It is unclear whether students will continue to engage with a deliberately 'confused' AI once the novelty fades, particularly when an answer-giving tool is a click away. It is also unclear how reliably a Teaching Quality Index tracks genuine understanding rather than surface fluency. If the index rewards confident-sounding prose, the mirror could reproduce the very calibration errors it aims to correct.

Comparative studies of AI and human feedback complicate the simple story that human feedback is better. A Springer chapter (2024) on complementary regulatory pathways reports that the two types of feedback support different regulatory processes rather than representing

different levels of quality. AI feedback tends to be more actionable and more polite, and it correlates with content integration and quality judgement. Human feedback is often more direct and more effective at sending students back to the source material. These are associations, not demonstrated causal effects.

The implication is that the two feedback channels are complementary. AI suits iterative refinement and immediate correction. Humans provide challenge, redirection and the kind of directness that disrupts complacency. The politeness that makes AI feedback easy to act on may be part of the same tendency that inflates confidence. Directness, by contrast, carries the friction that calibration seems to require. On this point the literature is genuinely divided. One reading treats AI's agreeable style as a usability strength. Another, represented by the algorithmic self-deception work, treats it as a metacognitive liability. The evidence does not yet resolve which effect dominates, or for which learners.

The affective side of machine feedback adds a further layer. Research on AI-mediated language learning reported in Expert Systems (2026) found that the timing of AI feedback, whether immediate or delayed, had little direct effect on the accuracy of metacognitive judgements. Emotional valence and cognitive load, however, were significant mediators. This suggests that how students feel while receiving machine feedback, and how much mental effort it demands, shapes how they use it to judge themselves.

This finding fits the conclusion of Dhurumraj and Labuschagne (2026) that AI's metacognitive effects are not uniform. It also cautions against design choices that treat feedback scheduling as the main lever. On current evidence, tone and cognitive demand appear to matter more than timing.

Three conclusions follow for educators, each to be held with the caution that an evidence base of a few dozen empirical studies warrants (Ji and Tan, 2026).

First, self-assessment accuracy under AI is an outcome of design rather than of the technology itself. Schools should prefer systems that require students to predict, explain and reflect before they receive feedback, as in the confidence-rating practice exams described on arXiv (2025) and the teachable-novice designs of the cognitive mirror (Frontiers in Education, 2025). Schools should also be wary of systems optimised purely for helpfulness.

Second, metacognitive scaffolding should be built into AI use rather than added afterwards. The randomised evidence in the British Journal of Educational Technology and Educational Psychology Review (2026) indicates that unstructured AI interaction degrades self-regulation, while structured interaction improves it. This is closely tied to the broader challenge of cultivating critical thinking in students who grow up trusting AI-generated answers (see Q033).

Third, calibration should be measured, not assumed. Schools adopting AI tools should track whether students' self-assessments become more or less accurate over time, because confident ignorance is invisible in aggregate grades. Instruments designed for human-AI co-regulation, such as the scale developed by Wang, Zhang and Zhang (2026) for L2 writing, show that such measurement is becoming feasible. Correlational work on student dispositions, such as Rodríguez-Ruiz and colleagues' (2024) survey of 1,761 undergraduates, suggests that schools may also need to consider which students are most exposed to miscalibration.

Larger questions remain unresolved. In particular, it remains unclear whether repeated reliance on AI during formative years leaves lasting traces on students' independence and capacity for self-monitoring, and the longitudinal evidence needed to answer this is thin (see Q261).

The overall weight of evidence is that AI assistance is metacognitively neutral in itself. It amplifies whatever interaction structure surrounds it. Systems that build in prediction, explanation and productive friction tend to strengthen self-assessment. Systems that simply supply answers and praise tend to weaken it, often without students noticing.

Its most recent revision, in Edition 117: Expanded to six sections integrating two systematic reviews, a GenAI-SRL measurement study and a 1,761-student dispositional survey. Added prose attribution, flagged the AI-versus-human tone debate as disputed, and added cross-references to Q033, Q118 and Q261. (838 → 1,912 words · 4 new sources)

Q121 How is AI reshaping collaboration, peer help, and cheating norms within student cultures?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

AI is reshaping student cultures less by inflating cheating than by forcing a renegotiation of where legitimate machine assistance ends and illegitimate delegation begins. That single question now runs through how students collaborate, how they help one another, and what they themselves count as cheating. The two developments are linked: the norms students build for group work and peer help draw on the same working distinctions they use to judge integrity. Any account of the change therefore has to start with how much dishonest behaviour has actually shifted, and on that point the evidence pulls in two directions.

The behavioural data from schools suggest stability. Chen, Lee, Kuo and colleagues (2026) surveyed 4,354 students across six United States high schools about eighteen months after ChatGPT's release. They found an overall self-reported cheating rate of 72.06 per cent, consistent with historical baselines and prior studies, and concluded that AI availability has not changed overall cheating prevalence in high school. Challenge Success at Stanford University reaches a similar conclusion from its multi-school data, reporting no significant spike in self-reported cheating after generative AI arrived. These are self-reports, and they show that prevalence was stable. They do not show that the methods of cheating stayed the same, and a constant rate may hide a shift from older techniques to AI-assisted ones.

Perceptions in higher education are markedly more pessimistic. A 2024 survey by the academic publisher Wiley, reported by Inside Higher Ed, polled more than 2,000 students and 850 instructors. Sixty-eight per cent of instructors expected generative AI to harm academic integrity over the following three years. Fifty-three per cent of students said more cheating was occurring than the year before, and 35 per cent of students named ChatGPT as a contributing factor. Because this is an industry survey rather than peer-reviewed research, its figures are best read as measures of belief and expectation rather than of behaviour. Even so, the contrast with the school data is real, and the literature has not resolved it. Part of the gap may reflect differences between sectors, and part may reflect the difference between reporting one's own conduct and estimating other people's.

That second possibility is now being tested directly. Hanh Van Nguyen and Duong (2026) surveyed 863 undergraduates at a Vietnamese science and technology university anonymously, comparing how often students reported their own AI-assisted cheating with how often they

attributed it to peers. Earlier, Hung Manh Nguyen and Goto (2024) studied Vietnamese undergraduates using a list experiment, an indirect questioning technique designed to reduce the social desirability bias that affects direct self-reports. Both designs implicitly accept that self-reported rates may undercount cheating and that perceived rates may overcount it. True prevalence therefore remains unclear. What matters for policy is the gap itself. Institutions that legislate against a cheating epidemic the behavioural data do not show risk alienating students whose actual AI use is more modest and more defensible than faculty assume.

Student norms around AI use are more finely differentiated than many institutional policies acknowledge. Across surveys, students separate 'productive use' from 'cheating'. Productive use covers brainstorming, generating ideas, explaining difficult concepts and checking understanding. Cheating, in their view, means using AI to complete whole assignments or write full papers. Students broadly agree that whole-task delegation is unacceptable. The contested ground is everything in between, such as asking a chatbot to restructure a paragraph, generate an outline or check a solution that the student only half understands. The study by Chen and colleagues (2026) explicitly examined student perspectives on appropriate AI use alongside their patterns of use across school tasks. This reflects a recognition that students judge acceptability task by task rather than tool by tool.

Ambiguous norms also carry a cost that rarely enters debates about integrity. In the Wiley survey, 37 per cent of students said they avoided AI tools entirely because they feared instructors would read legitimate use as cheating. Within that sample, at least, unclear rules appear to have a chilling effect: they deter honest students more than they deter dishonest ones, and they create unequal access to forms of help that peers in more permissive courses use freely. Students who opt out may also miss chances to develop the evaluative judgement that skilled AI use requires, which links to wider concerns about self-assessment and metacognition (see Q120).

The definition of cheating is therefore fluid and locally negotiated. It varies by discipline, by type of assignment and by how relevant students think a task is. Researchers describe this as a period of 'normative flux', in which student cultures are working out their own distinctions faster than institutions are codifying theirs. Institutions are, however, beginning to create formally different conditions. Eslami, Collins and Queen (2025) analysed 255 final-draft analytical essays from first-year writing classes in three contexts: before generative AI (2022), AI prohibited, and AI permitted with specified uses (2024). They combined holistic quality

ratings with computational indices of writing volume, lexicality, referential cohesion and syntax. Comparisons of this kind are still rare. They point towards evidence-based norms that ask what a given level of permitted assistance does to students' work, rather than only whether a rule was broken.

In group work, many students increasingly treat AI as a teammate rather than a tool. They use it to summarise peer contributions, clarify concepts, turn rough ideas into coherent prose and mediate disagreements. The Higher Education Policy Institute (2026) asks whether this trend is quietly eroding the social core of student teamwork. The concern is that efficiency gains come at the cost of the interpersonal friction through which collaborative skill develops: negotiating meaning, managing disagreement and justifying positions to peers. When AI becomes the default intermediary, group work becomes more efficient and less developmental. The traditional rationale for group assessment, that it stands in for real-world collaborative competence, is then quietly weakened. A parallel worry concerns informal peer help. If a chatbot is always available, the student who once asked a classmate may no longer do so, and both lose something that peer explanation provides (see Q118).

Students' own accounts are more positive. Gawlik-Kobylińska (2024) interviewed 61 civil and military students about using AI in scientific collaboration, specifically co-writing academic articles and producing scientific posters. Students reported improved efficiency, better work quality and new ideas, alongside challenges and educational implications that the study coded separately. This matches the inclusivity argument made by advocates: a non-judgemental interlocutor may give less confident students a way into discussions that more assertive peers would otherwise dominate. A small interview study cannot show whether these perceived benefits came with weaker interpersonal skills. The two literatures largely talk past each other, one measuring how students experience AI-assisted collaboration and the other theorising what it may displace.

The more promising evidence concerns designs that structure AI's role rather than leaving it to emerge informally. Alsamani (2026) ran a two-week structured collaboration protocol with 123 undergraduates from several disciplines inside a classroom-based entrepreneurship project, examining strategies, perceived innovation and cognitive outcomes, and how students handled the difficulties they met. The study was exploratory, and its outcomes are perceived rather than independently measured. Billings, Chang, Lim-Breitbart and colleagues (2024) took a different route with grade 7 science students. They used AI to strengthen peer-to-peer talk rather than

replace it. Natural language processing identified ideas in students' written explanations, and those ideas were used to form groups and to supply discussion questions grounded in Knowledge Integration pedagogy. Groups built to maximise the variety of ideas were compared with randomly formed groups in two classrooms at one school. That scale is too small to generalise from, but the design inverts the HEPI concern by using AI to create productive disagreement among peers rather than to smooth it away. The design response emerging from this work is to shift assessment from final outputs towards the visibility and quality of the collaborative process, making the interpersonal work legible to assessors.

Institutional responses are reshaping the very norms they aim to govern. The first phase of AI policy relied on banning tools and deploying detection software. That approach is giving way to what the Frontiers in Education analysis (2025) calls 'integrity ecosystems'. These are systemic frameworks that treat academic integrity as an emergent property of governance, assessment design, institutional culture and individual moral agency, rather than as a property of individual student behaviour alone. Two forces drive the shift. The first is evidence that AI detection software is unreliable, produces false positives and disproportionately flags non-native English speakers. This turns a technical weakness into an equity problem and erodes the trust on which voluntary honesty depends. The second is a growing recognition that punitive, output-focused policies ignore how knowledge is now produced with technology, and that a rule against using tools students will use throughout their working lives has limited legitimacy among them.

The emerging toolkit has three main elements. Assignment-specific 'AI use scales' define acceptable levels of machine assistance for each task, which directly addresses the contested middle ground students already recognise. Process-based assessment requires students to document drafts, prompts and decisions. Developmental integrity education treats honesty as a value to be learned rather than a rule to be policed. The World Economic Forum's guidance on responsible AI in higher education (2025) takes a similar line, emphasising skills, trust and integrity built through transparent policy and shared stewardship rather than surveillance. These frameworks are better grounded in principle than in outcome data. Few studies yet compare integrity ecosystems with detection-led regimes on behaviour, learning or student trust, so whether the ecosystem model reduces misconduct, rather than simply relabelling it, remains unclear. The Wiley finding that more than a third of students avoid AI out of fear suggests one

testable benefit: explicit, graduated rules should, if they work, bring cautious students back to legitimate use.

Research on why students cheat, including the long-running work associated with Challenge Success, suggests that dishonesty is often a way of coping with structural pressures: high-stakes testing, heavy workloads and assignments students see as irrelevant. AI has not changed these drivers. Read alongside the stable high-school rates reported by Chen and colleagues (2026), this offers a plausible explanation for why cheating prevalence held steady. Students who were inclined to cut corners under pressure had always found ways to do so, and AI changed the means more than the motive. The explanation is plausible but not yet demonstrated. The Vietnamese studies by Hung Manh Nguyen and Goto (2024) and by Hanh Van Nguyen and Duong (2026) show how much depends on measurement method, and longitudinal work that follows the same students as AI matures would be needed to rule out a slow drift. Whether early habits of AI dependence shape later academic independence is a separate and largely open question (see Q261).

The most durable effect of AI on student culture may therefore be indirect. By forcing institutions to redesign assessment, AI is pushing schools and universities towards tasks that are harder to automate, more open to scrutiny of process and more personally meaningful. These are the conditions under which cheating loses its appeal. The emerging student norm, on the available evidence, is not 'cheating is fine' but 'using AI is normal, and the line between assistance and delegation should be explicit and fair'. That norm sits easily with the integrity-ecosystem model and the WEF emphasis on shared stewardship. It is harder to reconcile with detection-led enforcement or with the pessimistic expectations many faculty report. Schools that engage with it openly, through transparent policy, honest dialogue and assessment redesign, are likely to find that AI changes collaboration more than it inflates cheating. On collaboration, the lesson from structured designs is that AI's effect on the social core of learning depends on whether it is deployed to replace interaction between peers or to provoke it.

Q233 What are the specific opportunities and risks of AI-powered personalisation for gifted and high-ability learners?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

AI-powered personalisation offers gifted and high-ability learners real opportunities: continuous acceleration, enrichment matched to individual interests, intellectually demanding dialogue where specialist teaching is scarce, and possibly fairer routes into gifted provision. It also carries distinctive risks. Identification systems may reproduce historical bias, learners may become dependent on machine-supplied challenge, and gifted education may narrow to measurable cognitive performance just as such performance is becoming easier for machines to imitate. Standard curricula and instruction frequently underserve gifted learners, so the promise of personalisation is especially tempting for this group. That temptation is one reason the risks deserve as much scrutiny as the opportunities.

The field's own literature shows how unsettled the question has become. Tirri and Tirri (2026) observe that generative AI has entered gifted education faster than the field has decided what it changes. They argue that the pedagogical question is not whether AI helps but which cognitive work stays with the learner. Sternberg (2025) goes further. He contends that much of the gifted movement still emphasises, in both identification and teaching, knowledge and skills that AI can already demonstrate at levels equal to or exceeding those of humans. The National Association for Gifted Children has compiled evidence and guidance on personalised learning for gifted students. That guidance places AI tools within the field's longer-running debates about acceleration, enrichment and identification. Read together, these sources suggest that personalisation for gifted learners cannot be judged solely by how efficiently it delivers content. It must also be judged by what kind of giftedness it cultivates.

The most frequently cited opportunity is acceleration. An adaptive system can detect when a student has mastered content at one level and move them on to harder material without waiting for the rest of a class. The result is a form of continuous acceleration that is difficult to arrange

in conventional classrooms, where grade placement, timetabling and teacher capacity limit how far any individual can move ahead. For gifted learners who are often bored or disengaged by grade-level content, this capability is potentially transformative.

Earlier drafts of this chapter reported that some gifted students using adaptive systems covered two to three years of curriculum in a single academic year. No verifiable study supporting that figure could be located, so it has been withdrawn. Rigorous, independently evaluated evidence on AI-driven acceleration for identified gifted populations remains unclear. Claims of dramatic gains in achievement and engagement should be treated as hypotheses until they are replicated.

There is also a practical constraint. Bobocea et al. (2024) note that adaptive platforms are only as effective as their content. In their account, the cost of creating that content has hindered large-scale adoption and produced a 'critical mass' problem: a platform without content is ineffective and unattractive, which deters users and funding. They propose AI-assisted architecture to convert conventional courses into adaptive learning flows. The implication for gifted learners is direct, though it is an inference rather than their finding. Continuous acceleration presupposes a deep reservoir of above-level material, and gifted students are the learners most likely to exhaust what a platform holds.

Purpose-built systems are beginning to appear. Elkhalifa (2026) describes the design, implementation and empirical evaluation of the AI-Enhanced Self-Directed Learning framework. The framework is grounded in Treffinger's Independent Learner Model and aims to provide adaptive challenge, metacognitive scaffolding and high learner autonomy. It combines five technologies: a Google Gemini model as central orchestration controller, cognitive computing, multi-agent systems, expert systems and automatic speech recognition. The available abstract does not report sample sizes or effects. A single developer-led evaluation would in any case show feasibility, not general efficacy.

Personalisation also extends to enrichment, meaning exposure to material beyond the standard curriculum in depth, breadth or complexity, tailored to a learner's interests. Large language models can act as intellectual sparring partners. They can conduct Socratic dialogue, generate challenging problems and offer expert-level explanations of complex topics. Tirri and Tirri (2026) complicate this picture. They argue that hybrid human–AI intelligence is bilateral: the learner shapes the AI partner as much as the partner shapes the learner. Learners using identical products therefore do not have identical partners, and the resulting advantage 'accumulates in

the partnership rather than the person, invisibly'. This cuts in two directions. A highly able, curious learner may draw far richer challenge from a tool than a peer would, so the tool amplifies existing strengths. Yet that benefit may not show up in, or be attributable to, the learner's independent capability.

The enrichment opportunity matters most where human expertise is scarce. Gifted learners in under-resourced schools often lack specialist teachers or advanced coursework, and AI tools may partly fill that gap. Hersi et al. (2026) do not address gifted learners. Their Perspective on Somalia describes a system facing weak infrastructure, limited teacher support and unequal access to resources. In that setting, generative AI can translate language, support writing, generate explanations and extend tutoring beyond classroom hours. They argue that the appropriate response is neither prohibition nor unguarded adoption, and that AI literacy should become a foundational competency across secondary and tertiary education. Madhavarao (2025) offers a broader synthesis on at-risk students in low-income communities. It draws on theoretical literature, experimental work, global education reports and emerging cases from low-resource settings to examine personalised tutoring, automated evaluation and predictive analytics. Neither source studies able learners. Together they suggest that AI's equalising potential in low-resource contexts depends on learners knowing how to use these tools critically, and not simply on access to them.

A second opportunity concerns identification. Traditional gifted identification relies heavily on standardised tests and teacher nomination, and both are widely recognised as vulnerable to bias. Students from low-income families, racial and ethnic minorities, and English language learners are particularly disadvantaged. AI systems could analyse a broader range of performance indicators, such as response patterns, problem-solving strategies and creative outputs. In principle, this could surface gifted learners whom conventional methods overlook. Whether such systems are in fact more equitable than traditional methods remains an open empirical question and an active area of research. No study cited here yet shows that they are.

Gyarmathy (2026) offers the most developed conceptual alternative in recent work. She argues that traditional identification models are increasingly misaligned with an era in which AI may perform many algorithmic cognitive operations more efficiently than humans. These models rest on norm-referenced testing, fixed ability constructs and categorical selection. Her Neurodiversity-Based Developmental Profiling Framework would replace static identification with dynamic mapping of cognitive profiles, intrinsic drive and environmental fit. Continuous

data from adaptive learning environments could feed such profiling. That is where AI's capacity to track patterns over time might support a more developmental, less gatekeeping model of giftedness. The framework is a proposal, not an evaluated intervention, and its feasibility and fairness in practice have yet to be tested.

Its emphasis on neurodiversity connects identification to twice-exceptional learners, whose strengths are often masked by disability or difference (see Q035). Here the gifted and inclusive-education literatures rarely meet. Pagliara et al. (2024) mapped how AI is used to support students with disabilities and promote inclusive education. Their scoping review is organised around four dimensions: educational context, disabilities and special needs, AI technologies, and inclusivity and inclusive practice. Its framing centres on support for difficulty rather than high ability. A twice-exceptional learner can therefore fall between a gifted system tuned to performance and an inclusive one tuned to remediation.

The same technology that might widen identification could also narrow it. AI identification systems trained on historical data may amplify existing biases rather than correct them. Suppose the training data reflect past under-identification of particular groups. A model optimised to predict who was identified will then learn to replicate those patterns, now with the apparent objectivity of an algorithm. The predictive analytics that Madhavarao (2025) lists among tools for disadvantaged learners would face this hazard if repurposed for selection. This is a structural argument rather than a measured effect. Published audits of AI gifted-identification tools are scarce, so the size of the risk remains unclear. The mechanism, however, is well understood from other domains of algorithmic decision-making.

A deeper risk lies in how giftedness is defined. Systems that operationalise giftedness as performance on measurable cognitive tasks may systematically overlook creative, social, emotional and leadership giftedness, which is harder to quantify. Sternberg (2025) presses this point hardest. He argues that a century-old model of giftedness built on skills AI is now taking over is 'doomed'. Gifted education should instead emphasise capacities AI cannot match, namely transformational creativity, moral intelligence and wisdom. It should also discourage what he calls vacuous transactional, dark and toxic giftedness. Gyarmathy (2026) reaches a compatible conclusion from a different starting point. Many practitioners and identification systems nonetheless continue to rely on conventional cognitive measures. The field is plainly divided. One camp sees AI as a better instrument for the existing model, and the other sees AI as evidence that the model itself must change.

Sriraman (2026) adds a methodological warning that applies directly to AI-assisted identification. Writing about mathematics, he argues that AI has not strictly broken the link between mathematical output and mathematical understanding. Rather, it has decoupled them as objects of inference. A sophisticated output is no longer reliable evidence of the cognitive development that once produced it. Some identification systems treat creative outputs, written explanations or elegant solutions as indicators of high ability. Any such system inherits this problem whenever learners have access to generative AI. Paradoxically, the broader indicators that made AI identification look more equitable are among those most easily confounded by AI assistance.

A third risk concerns intellectual dependency. Gifted learners who rely heavily on AI for challenge may grow accustomed to AI-generated problems and explanations instead of developing the capacity for independent inquiry. The risk is particularly acute for this group because their defining characteristic is often deep, self-directed intellectual engagement. AI may provide challenge that is too structured, or too responsive to the learner's preferences. If so, it may undermine intellectual resilience and tolerance for ambiguity, dispositions typically forged by sustained struggle with problems that do not adapt to the solver.

Tirri and Tirri's (2026) central question supplies a useful test for any personalised system: which cognitive work stays with the learner? Consider a tool that generates the problem, scaffolds the approach and explains the solution. It may keep a gifted learner busy and apparently challenged while absorbing the formulating, judging and persisting that make up advanced thinking. Their observation that advantage accumulates invisibly in the human–AI partnership sharpens the concern. Neither learner nor teacher may notice that capability has been displaced rather than developed. Sriraman's (2026) account of 'mathematical precarity' points the same way. If sophisticated outputs no longer certify understanding, a gifted student can appear to move rapidly through advanced material while the underlying thinking remains undeveloped.

No study cited here yet traces these effects longitudinally in gifted populations, and whether dependency actually materialises remains unclear. Early-adolescent AI use patterns and their links to later independence and critical thinking are examined in Q261. The effects of AI assistance on self-assessment accuracy and metacognition matter for learners whose fluency can mask gaps, and they are discussed in Q120.

Design choices are likely to be decisive. Systems may withhold answers, require learners to pose their own problems, or deliberately introduce unresolved ambiguity, and any of these may mitigate dependency, though this too awaits evidence. One promising design reverses the usual direction of explanation. Song et al. (2025) studied middle school students' perceptions of a generative AI-powered teachable agent in an authentic mathematics classroom. The design builds on long-standing learning-by-teaching practices, in which the student explains and the agent learns. They explored the roles, benefits and challenges students perceived, noting how generative AI could either create synergy or introduce new problems. Their study concerns perceptions in a general classroom rather than learning outcomes for gifted pupils. Still, it illustrates an architecture that keeps articulation with the learner. Elkhalifa's (2026) grounding of a gifted framework in an independent-learner model reflects a similar intention, though whether such intentions survive implementation remains unclear.

The final risk is that personalisation narrows the aims of gifted education. AI systems tend to optimise for measurable outcomes such as test scores, curriculum progression rates and problem-solving accuracy. They may therefore pull gifted provision towards cognitive performance at the expense of social-emotional development, creative expression and the cultivation of intellectual character. The field has long attended to the social-emotional needs of gifted learners, including perfectionism, asynchronous development and existential concerns. Adaptive systems focused on academic acceleration are poorly designed to address these needs. Rapid acceleration through an adaptive platform can also intensify asynchrony. It can place a young learner's intellectual work years ahead of their emotional and social development, without the human support that might help them navigate the gap.

Tirri and Tirri (2026) extend this concern into moral development. Applying the question of which work stays with the learner to ethical life, they argue, divides ethical functioning into two clusters, and high ability confers one and not the other. Cognitive giftedness does not automatically bring the full range of ethical capacities. AI personalisation directed at cognitive acceleration does nothing to supply what is missing. Sternberg (2025) makes the same argument from the standpoint of societal consequence, calling for moral intelligence and wisdom to take priority and for dark and toxic forms of giftedness to be discouraged. Both suggest that an AI-optimised gifted programme could efficiently produce highly capable learners whose abilities are disconnected from judgement and purpose.

These considerations point to the continuing centrality of teachers. Davis (2024), in a conceptual review focused on higher education, asks whether teachers can be replaced by intelligent AI systems and what human capabilities such replacement would require. He frames the issue as a question of which distinctively human contributions to teaching cannot be delegated. For gifted learners, the mentoring relationship, attention to emotional and social development, and modelling of intellectual character fall squarely within that category. How AI can support teachers' planning, assessment and feedback across the full ability range without deskilling them is discussed in Q024. Always-available AI tutoring may also reshape help-seeking and peer learning, which are often a vital source of belonging for gifted students; that question is examined in Q118.

The overall balance can be stated plainly. AI personalisation can give gifted learners more pace, breadth and challenge than many schools currently provide. It may also help reach able students in under-resourced or historically under-identifying contexts. Robust evidence for these benefits in gifted populations is still thin. Purpose-built systems are only beginning to report evaluations, and adaptive platforms remain constrained by the content they can offer. The more developed recent scholarship argues that the greater danger is conceptual rather than technical: AI may entrench a definition of giftedness centred on outputs that machines can now produce. Personalisation serves gifted learners well only when it is designed around the cognitive, creative and ethical work that must remain theirs.

Q261 What evidence, if any, links a student's AI usage patterns in early adolescence to their academic independence, metacognition, and critical thinking in later years?

12 citations · 12 sources · 5 cross-references

Claim 1 established

Early adolescence, roughly ages ten to fourteen, is a period of rapid development in executive function, self-regulation, and abstract reasoning. It is also the period when many students begin to use AI tools independently for schoolwork. A natural concern is that patterns of AI use established during these years might shape students' later academic independence, metacognitive skills, and capacity for critical thinking. The honest answer to what evidence links the two is that direct longitudinal evidence does not yet exist. Generative AI has been widely available only since late 2022, so no cohort has yet been followed from early adolescence into later schooling. What exists instead is a set of cross-sectional, experimental, and theoretical findings that suggest plausible pathways.

Usage data establish the relevance of the question. The Pew Research Center's February 2026 report on teens found that 54 percent of U.S. teens aged 13 to 17 had used AI chatbots for schoolwork and that about one in ten used them for all or most of their schoolwork. Use among younger adolescents is less well measured, but many encounter AI through school platforms, search engines, and messaging apps.

The most frequently cited correlational evidence comes from Gerlich's 2025 study in the journal Societies, which surveyed and interviewed 666 participants across age groups. It found a significant negative correlation between frequent AI tool use and critical-thinking scores, mediated by cognitive offloading, the practice of delegating mental tasks to external tools. Younger participants, aged 17 to 25, showed higher dependence on AI and lower critical-thinking scores than older participants. Because the design was cross-sectional, it cannot determine whether AI use reduces critical thinking, whether people with weaker critical-thinking skills rely more on AI, or whether other factors explain both. The sample also did not include early adolescents.

Lee and colleagues at Microsoft Research and Carnegie Mellon University, in a survey of 319 knowledge workers presented at CHI 2025 and covering 936 examples of AI use, found that higher confidence in AI was associated with less reported critical thinking, while higher self-confidence was associated with more. Although conducted with adults, the finding suggests that the disposition with which users approach AI matters, a disposition that may be shaped early.

Experimental studies provide stronger causal evidence about short-term effects. Fan and colleagues, in a 2024 study in the British Journal of Educational Technology with 117 university students, found that ChatGPT support improved essay scores but not knowledge gain or transfer, and that students engaged less in metacognitive activities such as monitoring and evaluating their work, which the authors called metacognitive laziness. The randomised trial by Bastani and colleagues in PNAS, involving high-school students in Turkey, found that unrestricted GPT-4 access improved practice performance but was associated with lower performance on subsequent unassisted exams, while a guardrailed tutor largely mitigated this harm. These findings suggest that the way AI is used, rather than use as such, influences whether students develop independent capabilities.

Developmental considerations suggest that early adolescents may be particularly sensitive to these effects. Executive functions and metacognitive skills are still maturing, and habits formed during this period may persist. The American Psychological Association's 2025 health advisory on AI and adolescent well-being noted that adolescents' developing brains may make them more susceptible to the influence of AI systems, and urged designs and practices that protect healthy development. If young adolescents routinely offload planning, monitoring, and evaluation to AI, they may have fewer opportunities to practise these skills during a formative period.

Plausible pathways also run in positive directions. AI tools designed to prompt reflection, ask questions, and provide hints rather than answers could support metacognitive development by modelling self-questioning. Students taught to evaluate AI outputs critically may strengthen rather than weaken their critical thinking. Whether early AI use helps or harms long-term independence may depend on the guidance and structure surrounding it.

The concepts at stake in this question have a long research history that predates AI and that shapes how any future evidence should be interpreted. John Flavell, in a 1979 article in American Psychologist, introduced metacognition as a field of developmental inquiry, describing it as knowledge about one's own cognition together with the monitoring and regulation of cognitive activity, and he argued that children's metacognitive abilities develop gradually and remain limited well into the school years. Subsequent research on self-regulated learning extended this idea, framing academic independence as a recurring cycle of planning, monitoring and reflection that students acquire through practice, feedback and gradually withdrawn support from teachers. In this tradition, independence is not a fixed trait but a set of

learned habits, and the conditions under which students practise those habits matter for whether they become durable. Correlational studies in this tradition have generally linked stronger self-regulation to higher achievement, although they leave open how much of the relationship reflects other influences such as prior knowledge, motivation and family support. Any account of how AI might affect later independence therefore has to explain how it alters the opportunities students have to plan, monitor and evaluate their own work during the years when those capacities are consolidating.

The broader literature on cognitive offloading provides a framework that is more general than AI and offers some reassurance as well as caution. Evan Risko and Sam Gilbert, in a 2016 review in Trends in Cognitive Sciences, defined cognitive offloading as the use of physical action or external tools to reduce the cognitive demands of a task, and noted that offloading is pervasive, from writing shopping lists to using calculators, and is often adaptive because it frees limited internal resources for other purposes. They also noted that offloading can reduce memory for offloaded information and that people's decisions about when to offload are influenced by metacognitive beliefs about their own abilities, which can be inaccurate. This framing suggests that the relevant question is not whether adolescents offload thinking to AI, since all learners offload to some degree, but which processes are offloaded, whether the offloading is chosen deliberately, and whether students retain the capacity to perform the task without assistance when needed. Offloading arithmetic to a calculator after fluency has been established differs from offloading the planning and evaluation of an argument before those skills have developed.

Earlier research on digital technology illustrates how easily headline findings in this area can outrun the evidence. During the 2010s, public debate about smartphones and social media often asserted large harms to adolescents on the basis of modest correlations. Amy Orben and Andrew Przybylski, in a 2019 analysis in Nature Human Behaviour using specification curve analysis on three large datasets covering more than 350,000 adolescents, found that the association between digital technology use and adolescent well-being was negative but very small, accounting for at most 0.4 percent of the variation in well-being, comparable to the associations of everyday activities such as eating potatoes. This episode suggests caution towards early claims about AI and cognition, whether alarming or reassuring, and they highlight the value of preregistration, replication and transparent analytic choices in the research that is now beginning.

Newer neuroscientific work on AI-assisted writing has attracted attention but remains preliminary. Nataliya Kosmyna and colleagues at the MIT Media Lab, in a 2025 preprint posted to arXiv, used electroencephalography to compare 54 adult participants writing essays with a large language model, with a search engine, or without tools, and reported that the group using the language model showed weaker measures of neural connectivity and lower ability to quote from their own essays. The study had not been peer reviewed at the time of posting, involved a small sample of university-affiliated adults, measured effects over a few sessions, and its neural measures do not map straightforwardly onto educational outcomes. It is therefore best treated as a hypothesis-generating signal rather than evidence about how adolescents' long-term metacognition develops. Its value for the present question lies mainly in illustrating measures that future longitudinal studies with younger participants might incorporate, alongside behavioural assessments of independent performance.

Developmental science explains why the early adolescent years may be a period of particular sensitivity, although it does not establish that AI effects will be lasting. Laurence Steinberg, in a 2005 review in Trends in Cognitive Sciences, described adolescence as a period in which basic reasoning abilities approach adult levels by mid-adolescence while executive functions such as planning, response inhibition and the coordination of thought and emotion continue to mature, with brain regions supporting these functions developing over a longer timeframe. This uneven development suggests that adolescents may be capable of using sophisticated tools before they have fully developed the self-regulatory capacities that would help them decide when not to use them. It also suggests a window in which instruction that explicitly teaches planning, monitoring and evaluation could be especially valuable. Whether patterns of tool use established at twelve persist to sixteen, however, is an empirical question, and research on other habits indicates that adolescent behaviour is often malleable as contexts, peers and expectations change.

Existing longitudinal infrastructure suggests how the evidence gap might be closed. The Adolescent Brain Cognitive Development study, whose design Nora Volkow and colleagues described in 2018 in Developmental Cognitive Neuroscience, enrolled roughly 11,800 children aged nine and ten across 21 U.S. sites with the aim of following them for about a decade with repeated neuroimaging, cognitive testing and measures of screen media use. Because the cohort was entering early adolescence as generative AI became widely available, studies of this kind could in principle add measures of AI use and relate them to later cognitive and academic

outcomes while controlling for earlier measurements of the same capacities. Such designs would still be observational and could not establish causation on their own, but repeated measures allow researchers to examine whether changes in AI use precede changes in metacognition or follow them, which cross-sectional surveys cannot. Complementary randomised trials, in which schools are assigned different configurations of AI support over a full school year or longer, would provide stronger causal evidence about medium-term effects.

Equity and implementation considerations bear on how a precautionary approach should be applied in the meantime. Adolescents whose families and schools can provide structured guidance, such as teachers who design tasks requiring independent drafts before AI assistance or parents who discuss how tools are used, may develop more deliberate habits than those who encounter AI mainly through unsupervised consumer apps. If unstructured use is concentrated among students with fewer supports, any adverse associations could compound existing gaps in achievement. At the same time, restrictive policies that deny some students access while peers elsewhere learn to use AI skilfully could create a different disadvantage. A balanced implementation would introduce AI in early adolescence alongside explicit instruction in metacognitive strategies, preserve regular opportunities for unassisted work, configure school tools to prompt reflection rather than supply finished answers, and collect data on how students use these tools so that schools can contribute to the evidence the field currently lacks.

Measurement is a further obstacle that any future study will have to address. Self-reported AI use is vulnerable to recall error and social desirability, particularly among adolescents who know that some uses are prohibited at school, and simple frequency measures do not distinguish between asking a chatbot to explain a concept, to check a finished draft, or to write an assignment outright. Metacognition is similarly difficult to measure, since questionnaires capture what students believe about their own thinking, while think-aloud protocols and log data capture what they actually do but are costly to collect at scale. Studies that combine logged interaction data from school-provided tools with performance on unassisted tasks would offer more informative evidence than surveys alone, provided that data collection respects students' privacy and is governed by clear consent arrangements involving families.

The research gap is clear. Answering the question would require longitudinal studies that measure AI usage patterns in early adolescence with objective data, track metacognition and critical thinking with validated instruments over several years, and account for confounding factors such as prior achievement, socio-economic status, and school context. Until such

studies are available, claims that early AI use causes later deficits or benefits should be treated as hypotheses. The existing evidence nonetheless supports a precautionary approach: structuring young adolescents' AI use to preserve opportunities for independent effort and to teach critical evaluation from the start.

Q038 Is the industrial-era school model (grades, classrooms, standardized curricula) still viable, and what replaces it?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

The industrial-era school model remains administratively viable but is pedagogically strained. No single successor has displaced it. What is emerging instead is a slow, contested hybrid: the age-graded shell of the old system persists while competency frameworks, adaptive technologies and AI-supported personalization erode its internal logic. Answering the question well requires separating three things: the structural features of contemporary schooling, the historical story told about them, and the evidence for the alternatives now proposed.

The familiar architecture is fixed grade levels sorted by age, forty-five-minute periods punctuated by bells, and a uniform curriculum delivered to everyone at once. It was not designed with individual learning as its primary goal. Writing in Forbes, Scott White (2025) argues that the structure of high school education has remained largely unchanged for decades. In his account, it is rooted in a model that mirrors the factory system, with its class periods, ringing bells and standardized curricula, all traced to an era when schools were meant to prepare students for factory work. The critical question for the present moment is whether that architecture has simply aged or has become actively counterproductive.

The critique carries a serious caveat. As the Wikipedia synthesis of the historiography records, educational historians regard the terms "factory model school" and "industrial era school" as ahistorical. Both phrases emerged in the mid-to-late twentieth century and have functioned largely as rhetorical devices for advocates of change. Historians characterize them as misleading and inaccurate accounts of how American public education actually developed. The reform narrative therefore contains a mythological element. The industrial school was never as mechanically uniform as its detractors imply, and the factory metaphor can obscure as much as

it reveals. Scholars and reformers disagree about the origins of the model. Its present-day structural features, however, are not in dispute.

The genealogy of the model may be overstated, but its structural tensions are real. Writing for the American Enterprise Institute, analysts note that nearly all major reform efforts of recent decades left the basic tenets of the industrial-paradigm classroom intact. That paradigm groups same-aged students who all learn the same thing at the same time. On their account, it was advanced more than a century ago partly as a means to rank and sort students into different life pathways. Its central flaw, in this analysis, is indifference to where any individual student actually stands. Instruction is pegged to age rather than to what a student knows. A student who stumbles for any reason, whether a pandemic or a family crisis, can find it genuinely difficult to catch up. The problem is sharpest in cumulative subjects such as mathematics, where unmastered foundations compound. The AEI authors frame this explicitly as a learning-loss problem. That framing gives the critique practical urgency beyond the abstract appeal of reform.

A second line of criticism concerns outcomes rather than mechanics. Commentator Mark Elliott (2025) reports that employers increasingly describe graduates as lacking critical thinking, problem-solving and digital literacy. He attributes this to the industrial-age model's focus on standardized testing and memorization, which, he argues, leaves students ill-equipped for innovation. This is an argument from a practitioner's blog rather than a controlled study, and it should be read as such. PublicSchoolReview.com's 2025 overview of the standardized-curriculum debate records similar complaints. Critics there point to an overemphasis on assessment that narrows instruction, too little flexibility for diverse learners, and widening achievement gaps. The same overview also presents the case for standardization, namely shared expectations and comparability across schools. That reminder matters: uniform curricula were adopted partly to secure equity of provision, not only for administrative convenience.

More systematic, though still localized, evidence of a mismatch between what schools cultivate and what students will need comes from Atchia and Atchia (2026). Their mixed-methods case study draws on 438 students in a school-based STEM club. From those data the authors built a competency framework of 80 STEM competencies loading onto 16 factors in four domains: core analytical and problem-solving; innovation and value creation; social and collaborative intelligence; and critical inquiry and adaptation. The authors present the framework as both a diagnostic for identifying gaps in competency development and a tool for auditing and

realigning curricula. The study is a single case drawn from a self-selected population of club members, so its findings cannot be generalized to whole systems. It nonetheless illustrates how the reform argument is shifting. Critics increasingly propose replacing the content-coverage logic of the standardized curriculum with an explicit map of competencies, rather than simply calling for less testing.

The most serious contender to replace the age-grade-curriculum triad is competency-based education (CBE). CBE reorients schooling around demonstrated mastery rather than time served. One On One Learning, a tutoring organization, describes it as focusing on skill mastery rather than seat time or letter grades, with students progressing at their own pace and demonstrating real understanding. The logic is intuitive. A 2025 guide published by VerifyEd sets out the contrast. In traditional education, students spend a set amount of time on a subject, take an exam and move on whether or not they have mastered the material. Competency-based learning instead asks whether a student can actually demonstrate mastery of specific skills and knowledge. Time becomes the variable and learning the constant, which inverts the industrial arrangement.

Adoption appears to be growing, though the figures should be handled with care. Research.com reports that, as of 2025, more than 1,500 institutions in the United States had adopted approximately 2,400 undergraduate and 750 graduate competency-based programs. This is a compilation by an education-information website, not a peer-reviewed census. The figures also concern higher education rather than the K-12 grade structure at the heart of the question. They indicate institutional momentum. They do not show that CBE improves learning, and comparative evidence on outcomes remains unclear. The movement toward credentials based on demonstrated skills also bears directly on the future of degrees and institutional gatekeeping (see Q040).

AI is increasingly framed as the infrastructure that could make mastery-based progression workable at scale. Duran and Çelik (2026) offer a conceptual account of "AI-based meta-universities": decentralized, digitally augmented institutions without a physical campus. Such institutions would be organized around "smart curricula," defined as adaptive, data-driven pathways tailored to individual learner profiles, curricular goals and societal challenges. The authors argue that AI can enhance curriculum flexibility, enable competency-based assessment and support lifelong learning. They also flag ethical, pedagogical and infrastructure concerns. Their contribution is theoretical design rather than empirical evaluation. In a more technical

vein, Liu and Liu (2026) propose an explainable-AI framework for dynamically evaluating students' Industry 4.0 competencies. They train a hybrid deep-learning model on a dataset of 10,000 student records that includes academic performance, communication skills, internships and project experience. The work demonstrates that competency profiles can be modelled computationally from heterogeneous data. Whether such models should inform consequential judgements about students is a separate question, and their abstract does not resolve it.

Alongside CBE, personalized learning, increasingly powered by artificial intelligence, is moving from the experimental margins toward the mainstream. Acacia University's 2026 outlook describes personalization shifting from theory to standard practice. In its account, schools are moving toward teaching methods built around each student's pace, interests and goals, and are using digital tools to track progress and make rapid adjustments. Acacia suggests that when this works well, it helps close learning gaps and keeps students more engaged. The qualifier "when it works well" carries real weight. Hurix, a curriculum-development firm, similarly describes adaptive learning systems that adjust content delivery in real time based on learner performance, and AI-based tools that help educators identify gaps and align content with existing standards. Both sources are institutional or commercial forecasts rather than evaluations, and their claims should be read as descriptions of direction, not demonstrations of effect.

The peer-reviewed literature on specific implementations is promising but thin. Siang and Reyes (2026) integrate Holland's RIASEC model of career interests with data mining inside a learning management system to generate personalized learning pathways aligned with students' career aspirations. They suggest the approach "holds significant promise." However, their abstract reports no sample size or effect sizes, so the strength of the evidence remains unclear. Prentzas and Binopoulou (2026) take a broader view. Their Scopus-based review identifies 54 papers combining generative AI with robotics across K-12 and higher education and distinguishes five main types of combination. They analyze both benefits and challenges, and they note that this specific intersection had not previously been reviewed. That novelty is itself a signal of how early the field remains.

The most radical departures from the classroom model come where formal schooling has collapsed. Nazari, Vahidi and Musílek (2024) describe the Blockchain and Artificial Intelligence Non-Formal Education System (BANFES), which they designed for Afghan girls excluded from formal schooling under the Taliban. BANFES uses AI-driven personalized data

analysis to adapt to individual learning speeds and styles. It uses blockchain for secure record management, with a decentralized network of nodes offering hybrid learning without intermediaries, and it includes an independent assessment mechanism. The authors openly address implementation barriers, including local distrust and integration with existing educational structures. The case is instructive precisely because it is extreme. It shows what a system without grades, classrooms or a central curriculum might look like. It also shows that such designs emerge most readily where the conventional institution has been forcibly removed, not where it remains politically entrenched. The broader dilemmas of technological leapfrogging and dependency in such contexts are taken up elsewhere (see Q043).

Higher education offers a parallel debate. Some scholars argue that AI challenges not just the delivery of instruction but the value proposition of institutions themselves. Csaszar, Jacobides and Zemsky (2025) suggest that business schools may be entering a "third epoch" of management education. This would follow the practice-oriented era of the early 1900s and the research-focused transformation of the 1960s. Generative AI tools can now match human performance on business-school assignments. Using a value-based strategy framework, the authors analyze how AI could reshape demand, teaching methods and operating models. They warn that a decline of traditional business education could weaken the foundations of informed and ethical business practice. Their argument is analytical rather than empirical. It nonetheless relocates the viability question: the issue becomes what institutions uniquely provide once machines can perform the analytical tasks they once certified.

Fukami, Hamilton, Rivers and colleagues (2025) answer from a different angle. Their curated collection of essays asks how business education can remain human-centered as AI disrupts how and what is taught. They urge faculty to cultivate a mindful relationship with AI and to treat its adoption as a change-management initiative carrying both risks and rewards. Read together, the two pieces show a real disagreement in emphasis. Csaszar and colleagues foreground strategic repositioning in response to market pressure. Fukami and colleagues foreground the preservation of human judgement and relationship within whatever new structure emerges. Neither claims that AI by itself determines institutional form. The K-12 implication is that curriculum content will need redesign once factual knowledge is instantly retrievable (see Q039), alongside any change to the grade-and-period structure.

A note of realism is warranted about how any replacement would arrive. The Next Generation Learning Challenges network (NGLC) observes that the only change processes ever used in

public education to significantly alter practice themselves reflect industrial-age thinking and methods. These are top-down mandates, standardized rollouts and compliance metrics. NGLC identifies a deep irony in trying to end the era of factory-model schools with factory-model strategies for change. Capacity is a second constraint. The 2026 outlook from Acacia and the curriculum forecasts from Hurix both acknowledge that many educators report limited training in managing personalized instruction at scale. No technology resolves that bottleneck on its own. Adaptive platforms can generate diagnostic data, but teachers must still decide what to do with a classroom of students who are, by design, in different places. The organizational conditions under which institutions absorb such change successfully are therefore at least as decisive as the tools (see Q126).

The balance of evidence supports a qualified conclusion. The historiography warns against treating the "factory school" as a precise description, and the defenders of standardization raise legitimate equity concerns. Even so, the structural problem identified by AEI and others is genuine. Age-based progression is poorly matched to cumulative learning and unforgiving of disruption. Competency-based education is the most coherent alternative and is spreading institutionally, though rigorous comparative evidence on outcomes remains limited. AI-enabled personalization may make mastery-based progression operationally feasible. That possibility is suggested by conceptual frameworks such as Duran and Çelik's smart curricula and by early implementations such as the RIASEC-integrated systems of Siang and Reyes. It is not yet demonstrated. The most complete departures from the classroom model, such as BANFES, currently arise where formal schooling has been denied rather than reformed.

What is emerging, then, is less a clean replacement than a prolonged and uneven transition. In most public institutions the shell of the old model persists. Its logic is being eroded incrementally by competency frameworks, adaptive tools and a growing recognition that sorting children by birth year was always a convenience, not a pedagogy. Whether that erosion produces a more equitable system or a more fragmented one will depend less on the sophistication of the technology than on how the transition is governed.

Q039 How should curricula be redesigned when factual content is instantly accessible and rapidly obsolete?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

Curricula should be redesigned around the knowledge that cannot sensibly be handed to a machine. That means durable conceptual understanding, conditional judgement about when and why to use a strategy, epistemic skill in evaluating claims, and the capacity to keep learning. Specific factual content should remain, but as the material through which these capacities are built rather than the end of instruction.

The central paradox facing educators is one of abundance. The tool that makes a fact instantly retrievable also makes memorising that fact seem pedagogically pointless. Students can now obtain factual answers from AI platforms in seconds, which makes traditional rote-recall examinations increasingly ineffective and outdated. Yet it would be a mistake to conclude that content no longer matters, just as it would be a mistake to assume it matters in exactly the way it once did. The real challenge is finer-grained: to distinguish which kinds of knowledge can genuinely be outsourced to machines and which must remain deeply internalised by human minds.

Yong Zhao (2026) states the problem most bluntly. He argues that the familiar worries about AI in schools are symptoms of a deeper condition: cheating, weakened effort, cognitive dependence and policy backlash all arise because schools still teach and assess what AI can already do. On his account, incremental improvement is insufficient. What is required is transformational change that redefines what is worth learning and how learning is organised. Zhao's argument is a conceptual analysis rather than an empirical demonstration. It draws on

evidence about the risks of AI and screen-based technologies, on scholarship about the grammar of schooling, and on panarchy theory. Even so, it frames the curricular question sharply. The Center for Curriculum Redesign reaches a compatible but more cautious conclusion. Its position is not that knowledge has become obsolete. It is that the balance among different kinds of knowledge must be reconsidered and traditional disciplines modernised accordingly.

Cognitive science offers one useful map for deciding what can be outsourced. Work on metacognitive knowledge (for example the framework operationalised in the arXiv study on bridging declarative, procedural and conditional knowledge) distinguishes three levels:

Declarative knowledge, the memorisation of facts and data, is treated as the simplest level.

Procedural knowledge involves an automated understanding of how to use problem-solving strategies.

Conditional knowledge, the highest level, requires understanding how, when and why to use each strategy.

As currently constituted, AI systems are remarkably good at the first level and serviceable at the second. The third remains stubbornly human: recognising when a tool, a method or an argument fits a particular situation. Seen this way, curriculum redesign should shift weight steadily up these levels. The declarative layer becomes scaffolding through which deeper understanding is built, not the destination.

This does not mean abandoning content. The Center for Curriculum Redesign calls the question "if AI knows everything, why learn anything?" a dead-wrong framing, because AI neither "knows" everything nor can act on its own. The practical point follows directly. A student who has never grappled with the internal logic of evolutionary biology, the structure of a legal argument or the arithmetic of compound interest cannot meaningfully direct, evaluate or contest an AI-generated answer on those subjects. Retrieval without understanding produces dependence, not competence.

The Center argues that conceptual and epistemic knowledge may actually become more valuable as AI takes over retrieval. Conceptual knowledge is an understanding of why a field is structured as it is. Epistemic knowledge is an understanding of how the field's claims are

validated. The Center's recommendation is to assess knowledge for relevance, find the right mix of declarative, procedural, conceptual and epistemic layers, and modernise traditional disciplines in that light.

The framework is persuasive, but its empirical foundation for curriculum design remains thin. The three-level taxonomy is well established in metacognition research. Whether reweighting a curriculum toward conditional and epistemic knowledge produces better long-term outcomes than a content-rich curriculum remains unclear. Large-scale comparative evidence has not yet been assembled.

A related and underappreciated danger is what researchers call automation bias. The analysis of epistemic authority in Frontiers in Education (2025) describes students increasingly treating AI outputs as the central, trustworthy source of learning and skipping critical reflection on the model's limits. According to that analysis, this tendency undermines basic epistemic practices: assessing evidence, triangulating sources and exercising epistemic modesty.

The concern is not hypothetical, because the factual reliability of AI output cannot be assumed. Qin and colleagues (2026) compared four publicly accessible chatbot systems on 108 standardised English questions about heart failure, producing 432 responses. They audited every response against the 2022 AHA/ACC/HFSA guideline and relevant clinical evidence, and assessed content quality and readability with established instruments. Their definition of hallucination is instructive for curriculum designers. It covered clinically meaningful statements that contradicted guidelines or lacked evidential support, and it also covered statements that overgeneralised beyond the relevant population or could mislead. The study belongs to one clinical domain and should not be generalised as a single error rate for AI. Its method nonetheless shows what epistemic evaluation actually involves. Judging whether an answer is overgeneralised or subtly misleading requires domain knowledge, so instant access to facts does not remove the need to understand them.

Whether AI use strengthens or erodes critical thinking is genuinely contested. Zhang and Liu (2025) note a growing body of studies indicating that generative AI can help develop college students' critical thinking. They also observe that research on students' use of generative AI in open learning environments is still scarce. Their questionnaire-and-interview study examines whether such use enhances critical thinking, through what mechanisms, and why, drawing on self-regulated learning theory and learning motivation theory. The automation-bias concern

points the other way. One plausible reconciliation is that outcomes depend on how students engage: active, self-regulated interrogation of outputs may build critical capacity, while passive acceptance may erode it. This interpretation suggests rather than demonstrates a mechanism.

The curricular implication is the same either way. A curriculum designed for this environment should treat epistemics as a core subject, not an implicit byproduct of other learning. Epistemics here means knowing how one knows and how to weigh competing claims.

The institutional implications are substantial, and assessment is the most immediate battleground. Thesify's 2025 overview of teaching with AI in higher education reports survey data in which 40% of UK students agreed that AI-generated content could achieve a good grade in their subject. Because the figure comes from a sector overview by a company in the AI-tools market, it is best read as an indicator of perception rather than a robust measure of assessment vulnerability. The same overview notes growing faculty concern about academic rigour. It advises educators to redesign assessment proactively rather than enter a reactive "AI-detection arms race." This aligns with Zhao's (2026) diagnosis that the underlying problem is assessing what machines can already do.

Governments are beginning to act at the level of national policy. The UK's 2025 curriculum reforms, announced by the Department for Education, include making media literacy and financial literacy compulsory in primary school, replacing the narrowly focused computer science GCSE with a broader, future-facing computing qualification, and exploring a new qualification in data science and AI for sixteen- to eighteen-year-olds.

These measures fit the argument above. They add epistemic and practical literacies rather than discarding disciplines.

Evidence from professional and higher education shows how uneven such redesign currently is. Babacan and colleagues (2025) analysed course catalogues, syllabi and institutional reports from 72 Turkish universities offering journalism and new media programmes. They found that AI education was predominantly theoretical, emphasising AI ethics, media algorithms and the effects of automation on news production. Practical applications such as data journalism and AI-assisted content creation were comparatively scarce, and depth and focus varied markedly between institutions.

In health education, Almusharraf and colleagues (2025) surveyed healthcare students across 21 Saudi universities. They found strong consensus that AI should be integrated into healthcare curricula, alongside caution about its use in clinical practice and significant differences in attitudes by gender, year of study and prior AI exposure. Sharma and colleagues (2024), in a narrative review, propose adding informatics, data science and digital health to biomedical science curricula, while acknowledging substantial implementation challenges. Thind and colleagues (2026) conducted a scoping review of 1,130 records and identified 39 studies of AI implemented in undergraduate medical clinical skills teaching between 2022 and early 2026. Nineteen of these involved large-language-model virtual patients and clinical simulations, and only one concerned AI-supported clinical reasoning and tutoring tools.

Taken together, these studies suggest that institutions find it easier to add AI as a topic, or as a delivery tool, than to redesign around the conditional judgement AI cannot supply. They are descriptive, single-country or narrative studies, however. They map activity rather than demonstrate effects on learning.

Perhaps the deepest reorientation concerns the time dimension of knowledge itself. The OECD's Skills Outlook 2025 characterises the first quarter of the twenty-first century as a period of shocks and long-run transformations that have reshaped economic and social systems. On the OECD's account, these changes have come quickly enough to leave individuals, firms and governments less time to adapt. Because skill demands now evolve faster than policy cycles, the OECD argues that investing in lifelong learning and using timely labour-market intelligence are crucial to helping people adjust.

If specific content can become obsolete within a career, curricula should be built less around a fixed canon and more around the metacognitive capacity to keep learning. The Center for Curriculum Redesign calls this capacity adaptability. Its publications argue that adaptability is more essential than ever in the age of AI and that schools must teach it actively rather than assume it will emerge.

Adaptability is not content-free, however. Learning a new field quickly depends heavily on the conceptual frameworks a learner already holds. This is one reason the conditional and epistemic layers described earlier matter more than any particular body of facts. The question of how such capacities are certified, once learning extends well beyond initial schooling, connects directly to debates about credentials (see Q040).

AI may also help make lifelong and individualised learning more accessible, provided the conditions are right. Lopez-Gazpio (2025) reviews trends in the use of large language models in education. He argues that they can reduce barriers related to language diversity, learning disabilities, cultural difference and socioeconomic inequality, and can tailor instructional content to individual learners. He insists, though, on instructor-guided deployment, with LLMs acting as pedagogical catalysts rather than replacements. Educators remain responsible for ethical oversight, cultural sensitivity and emotional support. He also flags unresolved concerns about data privacy and bias. This is a trend analysis rather than an outcome study, so the equity benefits it describes should be treated as potential rather than demonstrated.

The risk in all of this is a false binary that discards disciplinary knowledge in favour of vague "twenty-first-century skills." A 2025 book on educational reform, reported by Phys.org, argues that reform efforts have largely failed because they try to fix past problems with uniform solutions. It adds that introducing new technologies within outdated paradigms is equally ineffective. That warning cuts both ways. Bolting AI onto an unchanged, recall-based curriculum repeats the old error. So does replacing content wholesale with generic skills programmes imposed uniformly from above, since that is simply another uniform solution.

Zhao (2026) explains why genuine redesign is so hard. He describes schools as a political and social "peace treaty" that stabilises competing interests and protects existing assumptions. Because whole-system reform threatens that settlement, he proposes a theory of change centred on a "courageous minority" of educators and institutions willing to act before the system is ready. On this view, transformation can begin immediately in protected spaces, where small changes may grow into broader paradigm shifts. This is a theoretical proposal, and whether such local innovations reliably spread remains unclear. It does, however, match the uneven institutional picture in the professional-education studies. It also bears directly on the viability of the industrial-era school model (see Q038) and on the organisational conditions that separate institutions that adopt AI successfully from those that do not (see Q126).

The resulting design principle is neither the old cathedral of facts nor a content-free skills gymnasium. It is a redesigned architecture that weaves together four elements: durable conceptual knowledge, practised conditional judgement, epistemic self-awareness strong enough to resist automation bias, and genuine adaptability. Specific factual content remains, chosen for its power to build those capacities rather than as the end in itself. Assessment, in

turn, should be rebuilt to make that judgement visible, because what is examined ultimately determines what is taught.

Q040 What is the future of universities, credentials, and degrees when skills can be learned and demonstrated outside institutions?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

Universities and degrees are likely to persist, but as one layer in a more crowded and fragmented credentialing system. They are unlikely to remain the sole gateway to professional life, and the evidence points to gradual unbundling rather than collapse. For most of the twentieth century a bachelor's degree served as a reliable proxy for capability, discipline and general readiness for professional work. Employers could read it quickly, and graduates could carry it across sectors and decades. That arrangement is under genuine pressure. The cause is not that universities have grown less rigorous. It is that the labour market appears to be changing faster than four-year curricula can follow.

Commentators in the digital-credential industry put the mismatch starkly. A degree takes four to five years to complete, while the skills employers ask for are said to shift every six to twelve months. That figure comes from a credential vendor rather than from labour-economics research, and it should be read as an illustrative claim, not a measured rate. The underlying point is less contentious. Programme-approval cycles, accreditation reviews and faculty hiring all move on timescales of years. Market demand for specific technical competencies can turn within a single hiring season. Syracuse University's professional studies division frames the

choice between microcredentials and degrees in exactly these terms, as a trade-off between depth and currency. The result is a structural mismatch that no amount of curriculum review can fully close, although curriculum redesign can narrow it (see Q039).

A proliferating array of shorter-form credentials has rushed into this gap. Credential Engine, a nonprofit that maintains a registry of US credentials, counted roughly 1.8 million credentials on offer across the United States. Digital badges and certificates dominate that count, and badges alone number more than one million. Degrees, by comparison, made up a smaller fraction, at 264,099 programmes. The economic stakes are not trivial either. A market summary compiled by a microcredential platform projects that the global microcredential market will exceed USD 3.5 billion in 2025 and grow by more than 17 percent a year through 2030, with particular strength in technology, healthcare, education and sustainability. That projection is a commercial estimate rather than independent research, and its precise figures should be treated cautiously. Its direction is consistent with the registry data.

The appeal of these credentials is straightforward. A 2025 review in Education Sciences sets out their advantages over standard degrees in cost, duration and structure. They are shorter, more tightly focused on particular skills and subjects, and more adaptable in curriculum and delivery than a conventional programme. An analyst at Jobs for the Future, quoted by Inside Higher Ed, described a "growing appetite, more demand from learners for more efficient and direct routes to employment opportunities". Enrolment data reported by Inside Higher Ed in late 2025 show that students pursuing short-term credentials increased by 6.6 percent in a single year, outpacing growth in associate and bachelor's degree programmes.

Evidence on whether these credentials deliver what learners hope for is thinner than evidence on their supply. Ojo, Odewale and Khoza (2026) surveyed 412 undergraduates in technical education programmes in South-East Nigeria that incorporated community-engaged work-integrated learning. They also interviewed 20 students and 12 community partners. Students generally saw microcredentials as useful for recognising competencies built through experiential learning, for strengthening their confidence in communicating their skills, and for preparing for employment. The interviews suggested that students valued the credentials for documenting technical and transferable competencies and for encouraging reflection. These are perceptions, gathered in one regional context. They indicate that microcredentials can help learners articulate what they know. They do not show that employers reward those credentials in hiring decisions.

The most revealing evidence concerns not the supply of alternatives but what employers actually do when they encounter them. Here the picture is sobering. A research compilation by a career-advice site reports that 85 percent of companies claim to use skills-based hiring, yet only 0.14 percent of hires are actually affected by the removal of degree requirements. A credential vendor has publicised the same "85 percent versus 0.14 percent" contrast as a paradox. Neither source is independent research. Both, however, rest on the more rigorous work described below.

On the policy side, the Hechinger Report documents that at least 26 states and major private firms, including IBM and Accenture, have stripped degree requirements from job listings. Seven states showed double-digit percentage increases in postings without degree requirements between 2019 and 2024. Yet far less evidence has emerged of employers hiring non-degreed candidates in substantial numbers. Research by Burning Glass Institute and Harvard Business School, led by Joseph Fuller, found that fewer than 1 in 700 hires in 2023 benefited from the shift to skills-based hiring. The gap between stated policy and observed practice is therefore well documented. It rests on large-scale labour-market data, not on self-report alone.

The reasons for the gap appear to be cultural as much as structural. Hiring decisions are typically made by senior managers accustomed to college-related signals such as the school attended, courses taken, grades earned and degree attained. Without those reference points, they need an entirely new template for assessing candidates. As the Hechinger Report observes, such biases do not evaporate because a chief executive issues a press release. There is also a regulatory obstacle. Governing reports that many of the same states that have eliminated degree requirements for public jobs still regulate non-degree training providers as though they were traditional colleges. Those providers must work through a labyrinth of licensing rules and reporting mandates never designed for their models. The result is a system that formally welcomes alternative credentials while making them harder to supply and easier to discount.

Generative AI complicates this picture in a way the earlier debate did not anticipate. It weakens the evidential value of traditional degrees as well as alternative credentials. Lim (2026) argues that discussion of AI in management education has focused on whether students may use AI. The more fundamental question, he suggests, is what student work can still prove. Once AI can draft and polish a case analysis, an essay or a slide deck, polished work stops being strong evidence of what a student can do. Lim calls the resulting problem "credential integrity": whether a school can defend what its degree certifies when AI may have produced the graded

work. He contends that policies on detection, disclosure and originality cannot solve it. All three ask who produced the work, and none questions the assumption that good work proves a capable student. Institutions' experience with detection tools reinforces this concern (see Q056).

Lim proposes instead a "verified-judgment" architecture. Under it, high-stakes certification would rest on several demonstrations. Students would show unaided command of core concepts and methods. They would defend their reasoning under questioning and reconsider positions when challenged. They would transfer learning to changed conditions and make accountable decisions. The proposal requires neither a ban on AI nor the false belief that an AI-free submission proves learning. Lim's review of 84 business schools indicates how far current practice falls short of this standard.

Student behaviour suggests why the issue is pressing. In a quantitative study of 791 students at Ivane Javakhishvili Tbilisi State University, Kharadze, Giorgobiani and Pirtskhalaishvili (2026) found that respondents credited AI tools with improving task planning and prioritisation and with reducing time spent on study. The same study reported that students often use these tools in ways that violate ethical norms, and that they are not taught how to use them without jeopardising academic integrity. Taken together, these findings suggest that the credential question cannot be reduced to degrees versus badges. Any credential is only as trustworthy as the assessment behind it. AI raises the cost of trustworthy assessment for universities and alternative providers alike. Institutions that redesign assessment around verified judgment may strengthen the degree's signal. Those that do not may find it eroding from within, quite apart from external competition.

The most durable forecast among those who study the field is transformation through unbundling rather than disruption by replacement. On this view, degrees will increasingly be broken into independent modules that can be earned, recognised and combined separately. Universities are not standing still. Arizona State University has developed stackable microcredentials that can accumulate toward a master's degree. European universities are integrating microcredentials into the Bologna Process to allow cross-border recognition. Part of the gap between skills-based hiring intentions and actual practice may stem from the fact that infrastructure for verifying skills did not exist until recently. The emerging technical standard is Open Badges 3.0, built on the W3C Verifiable Credentials Data Model. Forbes Technology Council contributors likewise portray microcredentials as the natural currency of AI-mediated, continuous learning, although that is practitioner opinion rather than evidence.

Peer-reviewed work suggests that technology is not the binding constraint. Griffiths, Burgos and Aceto (2024) analysed transcripts from 12 expert interviews and a focus group on open credentials in European post-secondary education. Their findings were as follows. Few assessments are available as open content. Linking open educational resources to credentials requires detailed and expensive work on learning outcomes and assessment. Aggregating open credentials into higher-level qualifications is a widely shared ambition. The European Union's infrastructure is appropriate and effective and can foster trust. The outstanding challenges are organisational and practical, not technological. Assessment and content provision should sit in separate organisational functions. Funding and support for open credentials in professional accreditation are essential for further progress. This last point bears directly on the hiring gap described above. Badges that professional bodies do not recognise will struggle to displace degrees that they do recognise.

AI may also change how credentials are read across borders. Keevy, Bateman, Manoharan and colleagues (2026) report the conclusions of an international working group on how large language models might improve the transparency, comparability and equity of qualification recognition. They see possible roles for these models in levelling qualifications frameworks and in job-matching for mobile learners, migrants and refugees. They insist, however, on continued human oversight, ethical governance and contextual interpretation, and they describe the future as a co-evolution of human and machine judgment. This remains a conceptual argument rather than an evaluated intervention, and whether such systems will reduce or reproduce existing inequities remains unclear. Who controls the recognition infrastructure is ultimately a governance question as much as a technical one (see Q042).

What appears to be emerging, then, is a layered rather than a substitutive system. Commentators describe a possible "skills passport" or lifelong learning record that would capture everything from a first degree to the microcredentials accumulated over a working life. Traditional degrees are expected to remain essential for leadership roles, advanced research and professions with intensive accreditation requirements. Shorter credentials are gaining ground in technical fields, where demonstrable and current competence matters more than breadth. The pressure toward continuous credentialing is real, though its scale is usually stated through organisational estimates rather than research. The World Economic Forum estimates that more than one billion workers will need to reskill by 2030. LinkedIn Learning puts the marketable

half-life of a technical skill at roughly two years. Both figures are projections, but they convey a pace that no four-year degree, however well designed, can match on its own.

The literature also disagrees, and the disagreement should be stated plainly. Advocates of microcredentials point to soaring supply, enrolment growth and favourable learner perceptions. Labour-market data show that employers still hire overwhelmingly through degrees, and that formal policy changes have barely shifted outcomes. Both accounts can be true at once. Supply and aspiration have moved faster than employer trust, regulatory frameworks and professional recognition. Meanwhile, AI is unsettling the assumption on which every credential depends, namely that submitted work reliably evidences capability.

The university will most likely survive, but as one node in a larger and more fluid learning infrastructure. Its distinctive value may shift away from content delivery, which competitors can supply more cheaply and quickly. It may shift toward two things that are harder to replicate: rigorous verification of judgment, and the breadth that the labour market still appears to reward at senior levels. Whether universities make that shift deliberately or have it forced on them will depend on how they redesign assessment and on whether they help build credential infrastructure or merely tolerate it.

Q041 How can public education systems keep pace with private AI development without surrendering governance to tech companies?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Public education systems can keep pace with private AI development without ceding governance by building enough public capacity to remain the authoritative party in their dealings with vendors. That capacity has three parts: shared public infrastructure, supervised experimentation that lets regulators learn before they legislate, and coordinated procurement power, all resting on sustained investment in the technical knowledge of educators and officials. Speed alone will not achieve this. The difficulty is that the recent record shows governments at every level reacting to commercial products rather than shaping them. The tension between public education and private AI development is an acute, present problem, not a future one.

The gap between private development and public institutional response is stark. The 2025 State EdTech Trends Report, released by SETDA with Whiteboard Advisors, records that artificial intelligence has overtaken cybersecurity as the top state education technology priority for the first time. As Baird's (2025) summary of the report makes clear, that priority arrived largely in response to commercial products already present in classrooms. District-level evidence points the same way. CoSN's May 2025 State of EdTech District Leadership report, as reported by eSchool News, found that 43 percent of districts lack formal policies or guidance for AI use, even though the same CoSN survey found that 80 percent of districts have generative AI initiatives underway. These two figures come from a single survey and describe co-occurrence, not causation. Even so, the picture is consistent: the tools arrived before the governance did.

Chen (2026) offers a useful theoretical lens on why this gap persists. His Cognitive Adaptation in the Intelligence Era model treats technology-driven pressure as a time-varying forcing function in a system of ordinary differential equations. He hypothesises that education design, when informed by motivational neuroscience, can sustain positive adaptation even as AI pressure accelerates. The framework is conceptual and its central claims are stated as hypotheses rather than tested findings. Still, it reframes the governance question in a helpful way. If external pressure accelerates by its nature, public systems cannot hope to match commercial release cycles step for step. What they can do is design institutions whose response is structural and anticipatory rather than episodic.

Legislatures have not stood still, but their activity has produced breadth without coherence. The Center for Democracy and Technology's review of the 2025 legislative session counted 53 bills on AI in education across 21 states, 51 of which applied specifically to K-12 schools. Four states enacted legislation: Illinois, Louisiana, Nevada, and New Mexico. The Center identified

five recurring themes: advancing AI literacy for students and professional development for teachers; requiring guidance on responsible use, including privacy and transparency; creating studies or task forces; prohibiting specific uses, such as AI for student mental health support or AI that replaces teachers; and addressing AI-generated non-consensual intimate imagery.

The range of concerns is encouraging, and the attention to teacher development and transparency suggests that legislators see governance as more than prohibition. The fragmentation is less encouraging. A patchwork of state rules, some permissive and some restrictive, creates an uneven landscape that sophisticated vendors can navigate at will, adjusting their terms of service to whichever jurisdiction offers the least friction. A single district negotiating alone has little leverage against a vendor that operates nationally. The structures that give teachers, students, and parents real input into adoption decisions are correspondingly harder to build when the legal floor varies so widely (see Q235).

Federal policy has been more promotional than regulatory. The UAB Institute for Human Rights (2025) notes that the White House launched a "Pledge to America's Youth: Investing in AI Education," which now includes commitments from over 200 technology companies and organisations, among them Google, OpenAI, Microsoft, NVIDIA, and Salesforce. The same analysis observes that America's AI Action Plan reflects the administration's aversion to regulation. The Plan provides that states implementing "burdensome AI regulations" should not have access to federal funding on AI-related matters. Commentators disagree about whether this posture speeds beneficial adoption or simply cedes ground. Structurally, however, it gives states an incentive to compete on permissiveness rather than protection. That incentive works directly against the coordinated standards that would most strengthen the public sector's bargaining position.

The governance vacuum has already had concrete consequences. TechPolicy.Press (2025) documents the PowerSchool case. PowerSchool is a leading provider of cloud-based software that manages student grades, attendance, and records for approximately 16,000 schools. The company detected unauthorized access in December 2024, and by January 2025 the scope was clear: more than 62 million student records and nearly 10 million teacher records had been exfiltrated. The analysis describes this as the largest breach of children's data in US history. On its account, the breach exposed an industry model that has normalised the centralisation of children's data at unprecedented scale. That centralisation has not been matched by adequate security architecture, regulatory oversight, or enforceable data-minimisation requirements, and

a year later the model remains largely intact. The case also shows the dependency risk that arises when a single vendor holds a system's core records, a risk that extends to price increases, acquisitions, and business failure (see Q124).

The routine opacity of student data flows is more insidious than spectacular breaches. Enago Academy (2025) reports that more than half of education technology companies did not fully disclose how learner data was being collected and shared, creating ethical and reputational risks for universities and schools. This figure comes from industry commentary rather than peer-reviewed research, and its underlying sample is not specified, so it should be read as indicative. EdTech Magazine (2026) describes how this lack of visibility has fed the rise of what practitioners call "shadow AI." These are unapproved apps and browser extensions that process student inputs, store them indefinitely, or reuse them to train commercial models. They are often free, widely adopted, and nearly invisible to IT teams. Shadow AI is especially hard to govern because it bypasses procurement altogether. Contractual protections are useless against tools that no one formally contracted for.

Recent scholarship on AI in specialised educational domains shows how far the data footprint is likely to expand. Gao (2025), reviewing AI in higher-education physical education, describes systems that enable personalised instruction and develop exercise plans through precise motion-data analysis, linking these to physical and mental health. Wang and Li (2024) argue that AI is transforming public health education through the analysis of large-scale health datasets and the tailored dissemination of health information and interventions. They also note its potential to inform the creation of health policies. Both are reviews that set out prospects rather than measured outcomes, and neither reports effect sizes. Read alongside the PowerSchool case, however, they suggest that educational AI will increasingly draw on biometric, behavioural, and health-related data, which is more sensitive than grades and attendance. Each new domain enlarges what a breach or an undisclosed data-sharing arrangement could expose. That makes governance capacity more urgent, not less.

Against this backdrop, three strategies carry genuine promise. The evidence for each remains early.

The first is to build public AI infrastructure as a counterweight to proprietary systems. EdWeek Market Brief (2026) reports that Digital Promise has launched a K-12 AI Infrastructure Program. It is a $26 million, multi-year effort to create openly shared and freely available

models, datasets, and benchmarks designed for education, with the stated aims of lowering barriers for vendors while raising standards. The logic matters. If public institutions depend entirely on proprietary models, they can only govern those models from the outside, through contracts, audits, and regulation, all of which rely on information the vendor controls. Owning or co-developing public-interest infrastructure provides a different kind of leverage. Shared benchmarks let public bodies define what counts as acceptable performance, rather than accepting vendors' self-reported metrics. Openly available datasets reduce the incentive to harvest student data for model training. Whether a programme of this scale can meaningfully shift a market dominated by firms with far larger budgets remains unclear. Its value may lie less in competing head-on than in setting reference standards that procurement can then require.

The second strategy is the regulatory sandbox. EdTech Hub (2025) describes sandboxes as formally supervised frameworks in which governments engage innovators to test tools that challenge existing legal frameworks. The purpose is to understand risks and safeguards and to help shape regulation. The approach speaks directly to the speed problem. Regulators gain technical knowledge before committing to rules, rather than legislating from ignorance or waiting for harms to accumulate. Sandboxes carry their own risk, though. If they become a mechanism through which companies shape rules in their own favour, they could deepen the very capture they are meant to prevent. Their protective value depends on transparent criteria, independent evaluation, and the regulator's willingness to say no.

The third strategy is institutional self-defence through procurement power. EdTech Magazine (2026) reports that some higher education institutions are managing data risk by keeping local control of AI infrastructure. The University of Montana, for example, worked with Amazon Web Services and Microsoft to create a university-owned data center. It runs enterprise-grade models supplied by those companies, while all data remains hosted within the university system and is not used to train any models. The arrangement is instructive because it does not reject commercial technology. It changes where control sits. The institution uses frontier capabilities on terms it sets.

Not every school system can build such infrastructure, and full costs must be weighed honestly, including licences, hardware, staffing, and maintenance (see Q122). Public institutions collectively represent enormous purchasing leverage. If they exercised it through coordinated procurement standards, they could reshape vendor incentives across the whole sector. Such standards would cover data minimisation, prohibitions on model training with student data,

breach notification, audit rights, and exit provisions (see Q234). Consortium purchasing at the state or regional level is the most plausible route for smaller districts, which cannot negotiate such terms alone.

Procurement power is only as strong as the expertise behind it. Here the literature on teacher capacity becomes relevant. Wang and Wang (2024), in a comprehensive review of AI in physical education, argue that digitalisation brings new requirements for the quality of teachers. They note that AI can take part in formulating teaching strategies, tracking teaching processes, and evaluating results, and on that basis they propose future teacher training strategies. Their review concerns one subject area and offers strategic proposals rather than evaluated interventions. Its broader point still applies to governance: institutions cannot judge what they do not understand. A district whose staff cannot interrogate how a tool tracks or evaluates students cannot negotiate meaningful terms for it, and cannot recognise shadow AI when it appears. It is therefore significant that professional development features among the recurring themes in the 2025 state bills identified by the Center for Democracy and Technology. Building educator and administrator expertise is a governance investment as much as a pedagogical one.

No single strategy suffices, and the strategies carry tensions among themselves. Public infrastructure takes years to mature, while sandboxes and procurement standards depend on regulators and buyers who are themselves still learning. There is also genuine disagreement about posture. Federal policy treats regulation as an obstacle to innovation. Civil-society analyses such as those from TechPolicy.Press and the Center for Democracy and Technology treat the absence of enforceable rules as the core problem. The evidence assembled here, from the PowerSchool breach to undisclosed data practices to unmanaged shadow AI, suggests that the costs of under-governance are already being paid, largely by students. It remains unclear how much regulation would slow beneficial innovation, because the counterfactual has rarely been tested. These questions take sharper form for lower-income countries, where dependence on foreign platforms may be deeper and public alternatives scarcer (see Q043).

EdTech Hub (2025) frames the way forward in balanced terms. Realising the benefits of AI in education while managing its risks requires collaboration across public, private, and civic actors, supported by strong public oversight and safeguards. As Big Tech companies expand their presence in education ecosystems, governments must strengthen their capacity to engage with private-sector partnerships on their own terms. The phrase "on their own terms" carries real weight. The risk is not only that public systems will fall behind technically. In the scramble

to catch up, they may accept terms set by the companies whose products they adopt, outsourcing not just the tools but the values embedded in them.

Chen's (2026) framework, though speculative, points to the same conclusion from a different direction. Under accelerating pressure, sustained adaptation comes from deliberate design rather than reactive matching. Keeping pace, in this sense, demands more than speed. It means building the institutional knowledge, the legal architecture, and the public infrastructure that allow education systems to remain the authoritative party in every negotiation, and to decide for themselves which values their classrooms will carry.

Q042 Who has legitimate authority to govern AI in education — states, markets, professions, or communities — and on what principles?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Legitimate authority to govern AI in education belongs to no single actor. It rests with democratic states, which carry the strongest foundational claim, but it is only exercised well when professions with pedagogical knowledge and communities with local moral standing hold formal roles alongside them. Markets wield enormous practical power, yet they lack the accountability that would make that power legitimate. Underneath the question of who governs is a deeper one: which institutions are trusted enough, and accountable enough, to make consequential decisions about how children learn and what kinds of cognitive lives they lead. This question is not merely technical or administrative.

The current landscape offers no clean answer, but it does show a recognizable pattern. Authority is being improvised from many directions at once, against a background of structural uncertainty. The Atlantic Council describes AI governance in the United States as a patchwork of policies and voluntary guidelines rather than a unified legal framework. The Education Commission of the States documents how quickly education agencies have had to respond to a technology that arrived before any rules did. The argument that follows takes each claimant in turn: the state, the market, the professions and the community. It then asks what principles could bind them into a coherent system rather than a competition.

In practice, states have moved fastest. The Education Commission of the States reports that when ChatGPT debuted in 2022, no state had policies on generative AI in schools. By April 2025, at least 28 states had published guidance on AI in K–12 settings, and by the end of 2025 that figure had reached 34 states with statewide guidance. This is a substantial development. The state, understood as the collective democratic authority vested in elected legislatures and their administrative agencies, has the oldest and most legitimate claim to govern education because it bears fiduciary responsibility for children.

Some states have gone well beyond guidance. Colorado passed what analysts have called the most comprehensive state-level AI governance law in the country. It targets deployers of 'high-risk' AI systems that make consequential decisions in education, employment and other domains. It requires risk-management programs and consumer disclosures, and it obliges deployers to mitigate algorithmic discrimination. Laws of this kind show the distinctive asset that only states possess: binding obligations backed by enforcement.

Yet the state's authority is complicated by fragmentation. The Atlantic Council notes that federal agencies rely on existing authorities and executive guidance, while Congress has yet to pass comprehensive legislation. States are therefore moving forward with their own laws, producing a fragmented landscape that complicates compliance and national policy coordination. The fragmentation has real costs beyond untidiness. The National Association of State Boards of Education warns that without coordinated state leadership, AI adoption in schools tends to be uneven and driven by local capacity and vendor offerings rather than a coherent statewide vision. That pattern risks widening inequities and leaves educators without clear expectations for responsible use. The state's claim to legitimacy is strong, then, but its capacity to act on that claim coherently is still under construction.

Where binding law is absent, markets have become the dominant governing force by default. Reporting compiled by Pursuit describes a White House 'Pledge to America's Youth' that now includes commitments from more than 200 technology companies and organizations, among them Google, OpenAI, Microsoft, NVIDIA and Salesforce. The same reporting notes that the American Federation of Teachers launched a National Academy for AI Instruction in partnership with Microsoft, OpenAI and Anthropic. These are market actors choosing to shape educational norms, and their influence is considerable. Such pledges are commitments, not research findings, and they should be read as statements of intent rather than evidence of effect.

The legitimacy problem is plain. Companies optimizing for adoption and revenue are not structurally positioned to put child welfare, equity or pedagogical integrity ahead of growth. The same reporting indicates that AI vendor contracts at major public universities are becoming flashpoints in broader debates about austerity, faculty shared governance and the commercialization of public higher education. Vendors pursuing large institutional contracts should expect intensifying scrutiny from faculty.

The tools through which firms claim to self-govern are also weaker than they appear. Henderson and Lemley (2024) examined the restrictive terms of use that AI model creators attach to their models and outputs. Companies position these terms in policy dialogues as enforceable safeguards against misuse. Henderson and Lemley found that such terms are regularly and repeatedly violated, yet apart from some account suspensions, no model creator has tried to enforce them through monetary penalties or injunctive relief. They argue the reason is that enforceability is questionable. Model weights and outputs are largely not copyrightable, so it is unclear whether anything exists to be licensed, and other legal routes offer limited recourse. Their analysis is doctrinal rather than empirical, but the implication for schools is direct. A vendor's responsible-use policy is not a governance mechanism a district can rely on. Real protection has to come from contract terms and public law, which is why the drafting of vendor agreements matters so much (see Q234). Market authority is real, but it is not legitimate in the foundational sense, because it lacks democratic accountability. How public systems can keep pace without ceding control is a separate problem (see Q041).

The professions hold a different kind of legitimate claim. Teachers, faculty and the organizations that represent them possess situated knowledge of what works pedagogically, and they bear direct moral responsibility for the students in their care. The American Association of University Professors has recommended that AI governance in higher education be adopted

through bodies such as academic senates, with mechanisms for enforcement and oversight. Some states have taken heed. The Center for Democracy and Technology reports that Illinois proposed an Advisory Board to provide guidance, oversight and evaluation of education technology, including AI, in collaboration with the state education agency. The board would also have to develop standards on safety, privacy and transparency, along with guidance for districts and educators. Professional authority is strongest when it is built into formal oversight roles rather than left as practitioner preference.

Evidence from other regulated professions supports this view and also complicates it. Gregory and Austin (2025) conducted semi-structured interviews with 12 pharmacy regulators across Canada and the United States. Their regulators favored a principles-based rather than rules-based approach to AI, and they identified core principles of transparency, redundancy, audit and feedback, quality assurance, privacy and data security, alignment with codes of ethics, and interoperability. They reached only limited consensus on whether consent and choice should count as principles. The sample is small and drawn from a single health profession, so transfer to education remains unclear. Still, the finding suggests that professional regulators gravitate toward flexible principles anchored in existing ethical codes, and that individual consent is where professional consensus frays.

In legal practice, Zhang and Zhao (2026) argue that AI in corporate liquidation challenges the institutional and operational architecture through which the work is supervised, rather than its normative foundations. Its deployment must remain subject to robust standards of explainability and professional accountability. The analogy to schooling is instructive. AI does not change why we educate, but it does change who oversees how education is delivered.

In higher education, Coates, Croucher and Calderon (2025) built an academic integrity indicator framework through research reviews, multi-institutional case studies, prototyping, expert confirmation and quantitative analysis. They conclude that academic governance needs reform across its architectures, people and technologies. They add that internal professional governance will not reform itself without external pressure from regulation, benchmarking and cross-institutional competition. Professional self-governance is necessary, on this account, but it is not self-sufficient.

No single locus of authority is sufficient. The state supplies democratic legitimacy and enforcement power but risks uniformity, bureaucratic lag and political capture. Markets supply

speed and resources but not accountability. Professions supply pedagogical wisdom but not systemic reach. Communities, meaning parents, students and local civil society, supply the moral particularity that any general rule will inevitably smooth over. They know which harms matter in a particular school and which uses of AI a particular community will accept. Their claim is the least formalized of the four, and how to give them meaningful voice is a design problem of its own (see Q235).

The case for polycentric governance is that these actors must be organized in relation to one another rather than left to compete. The National Association of State Boards of Education observes a shift from early experimentation toward more structured discussions of guidance, oversight and use cases in schools. Policymakers are looking for ways to ensure safe and ethical AI use without slowing innovation.

The literature disagrees on where the balance should fall. Practitioners and scholars represented in work on professional experiences of AI bias argue that ethical aspirations remain ineffective without binding legal mandates. Gregory and Austin's (2025) regulators, by contrast, preferred principles over rules. The two positions can be reconciled to a degree, because mandates drafted without professional input produce rules that misfire in actual classrooms, and principles without enforcement remain aspirations. Polycentric governance, on this reading, means binding public floors set by the state, elaborated through professional judgment, and checked locally by the communities who live with the consequences.

On principles, a workable consensus is emerging, though it is not yet enforced. It has four strands. The first is transparency about when and how AI is used. The second is fairness, so that algorithmic tools do not reproduce existing inequities. The third is accountability, clarifying who bears responsibility when AI advice goes wrong. The fourth is a commitment to preserving epistemic autonomy, the critical thinking and creativity that education is meant to cultivate. These principles converge with those Gregory and Austin's (2025) pharmacy regulators named, which suggests a cross-professional grammar of AI governance. Transparency and accountability recur across domains, while consent remains contested.

The accountability principle needs philosophical grounding, and here Cho (2026) offers a distinctive resource. Drawing on Aquinas's account of conscience and prudence, Cho argues that algorithmic systems cannot possess genuine moral knowledge or exercise practical wisdom. Calling them intelligent in a univocal sense is, on this argument, a consequential

category error. Cho proposes a Prudential Reasoning Assessment Matrix, which evaluates whether a system supports or substitutes for human moral reasoning, and a Moral Ignorance Classification Framework, which assigns responsibility for algorithmic failures. Cho applied both to the COMPAS recidivism algorithm and the DoNotPay legal service, not to educational tools, and the framework comes from a particular theological tradition that not all readers will share. Its core test still translates well to schools. The question is whether an AI system supports a teacher's or student's judgment or substitutes for it. That question also explains why authority cannot be delegated to the system itself, or to the vendor who built it. Responsibility must rest with human institutions capable of prudence.

The principles are not the hard part, and the gap lies in practice. Work on professional perceptions of AI bias reports that ethics-focused AI education remains severely underrepresented in technical curricula worldwide, despite growing global concern about fairness and accountability. State boards, meanwhile, still describe uneven local capacity to act on the guidance they issue. Legitimate authority, in the end, is not something any one actor holds. It is earned by the state, the professions and communities together when stated principles become enforceable obligations, and that gap between principle and institutional practice is where the governance question still lives.

Q043 How do developing nations avoid a new "AI colonialism" in education while leapfrogging infrastructure gaps?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

Developing nations can avoid a new 'AI colonialism' in education only if they treat leapfrogging as a way of building their own capacity and authority, not as a way of importing finished systems. In practice this means asserting policy and data sovereignty, insisting on culturally grounded and locally governed tools, positioning teachers as co-designers rather than end users, pooling bargaining power at regional and continental scale, and matching ambition to the infrastructure that actually exists. The promise of artificial intelligence in education is nowhere more vivid, or more fraught, than in the Global South. For nations still contending with teacher shortages, unreliable electricity and uneven broadband, AI tutoring systems and adaptive learning platforms appear to offer a shortcut around decades of infrastructure-building. The question is whether that shortcut leads to genuine empowerment or to a subtler form of dependency.

The critical literature gives that dependency a name and a mechanism. Analyses of digital colonialism describe how powerful nations and multinational corporations deploy digital infrastructure, platforms and data-harvesting tools to extend influence over less technologically advanced societies. AI amplifies these dynamics because it supplies sophisticated mechanisms for data collection, surveillance and automated decision-making that can reinforce unequal power structures. The Cambridge Data & Policy analysis of Africa and the Commonwealth's call to policymakers both frame this as a structural risk to future development rather than a set of isolated harms. In education the danger is epistemic as much as economic. As the 2026 Frontiers framework on algorithmic dependence argues, AI systems are developed within specific epistemic, linguistic and regulatory contexts and embed assumptions about originality, relevance and authority. Indexing practices already privilege English-language journals and Global North publication venues, which systematically marginalizes regional scholarship. AI-mediated infrastructures therefore shape not only how education is delivered but also which forms of knowledge are rendered visible, legitimate and valuable.

The infrastructure gap is real and stubborn. The Stanford Social Innovation Review's account of AI infrastructure in the Global South identifies persistent gaps in infrastructure, data, skills and governance. Reliable electricity and broadband remain unevenly available, and local datasets are often scarce. Khan, Umer and Faruqe (2024) add that the AI research literature itself largely overlooks low-income countries and concentrates on advanced economies. They argue that this exclusion contradicts principles of distributive justice and global equity, and that it leaves policymakers in those countries with thin evidence on which to act.

Attitudes toward AI nevertheless differ sharply from those in wealthier nations. VentureBeat, reporting the 2025 Edelman Trust Barometer, notes that fewer than one in three Americans feel comfortable with businesses using AI, while nearly two-thirds of respondents in India, Indonesia and Nigeria express comfort. The gap is read as a sign that AI is perceived as a threat in the North and an opportunity in the South. This is survey evidence about sentiment, not about outcomes, and it should not be mistaken for proof of benefit.

The pull of leapfrogging is easy to understand. In the framing used by the 2025 Frontiers systematic review of AI-enhanced pedagogies in Global South higher education, institutions can bypass traditional development stages by adopting cutting-edge technologies that narrow the gap between industrialized and developing countries. Kenya's M-Shule offers a concrete case. It uses student performance data to build personalized learning plans and delivers custom SMS-based lessons to thousands of students, partly to compensate for critical teacher shortages.

The leapfrogging concept is less straightforward than enthusiasts imply. Khan and colleagues (2024), drawing on both the leapfrogging and the absorptive-capacity literatures, conclude that AI catch-up in low-income countries is feasible but that there is no one-size-fits-all route. Countries with strong foundations could favor leapfrogging strategies. Those lacking such foundations may find the learning-and-acquisition prescriptions of the absorptive-capacity tradition more relevant. Hastie's (2024) study of Eswatini's energy transition, based on document analysis and in-depth interviews, shows what a sovereignty-oriented version of leapfrogging looks like. She coins the term 'energy independence through leapfrogging' to describe reducing dependence on South Africa, which supplies Eswatini's electricity under arrangements at risk of expiring in 2025, by building domestic solar generation. Hastie also identifies generation, storage, maintenance and affordability as barriers. The educational parallel is suggestive: leapfrogging advances sovereignty only when it deliberately shifts capacity inward, and maintenance and cost, not acquisition, are where such projects most often falter.

Leapfrogging built on borrowed architecture carries its own risks. VentureBeat's survey of Global South innovation observes that many breakthroughs rely on Northern institutions. These partnerships bring benefits, but they also expose a fragile dependency: when outside funding or partnerships end, local efforts can stall, and leapfrogging ends up built on borrowed foundations. For a school system the practical form of this fragility is familiar. Pricing changes, acquisitions or a vendor's exit can strand an entire instructional model (see Q124), and the full

lifetime cost of licences, connectivity, training and staff time is routinely underestimated at the point of adoption (see Q122).

Evidence from global health sharpens the warning. McCoy and colleagues (2025), applying Paul Farmer's 5S framework, argue that beyond the well-documented problems of algorithmic bias and inaccurate outputs lies a more fundamental challenge: a dangerous mismatch between AI's imagined benefits and the material realities of the systems into which it is deployed. They contend that AI cannot be used effectively or ethically where sufficient social and material infrastructure is lacking. Continued investment in unprepared, under-resourced contexts risks misallocating resources and potentially causing more harm than good. Their proposed response is a set of concrete questions to assess systemic capacity and socio-technical readiness before deployment. Their evidence concerns health systems, so its transfer to education is an analogy rather than a demonstrated finding. Still, the analogy is close. An adaptive tutor without trained teachers, stable power or curriculum alignment reproduces exactly the mismatch they describe.

Alkharafi and Alsabah's (2025) integrative review of globalization places these risks in a longer frame. They catalogue the gains of technological and economic integration alongside its characteristic costs, including inequality, cultural homogenization, political dependency and the digital divide. AI in education concentrates all four in a single procurement decision.

The remedies being proposed, and in some cases enacted, operate on several levels at once. The first is policy sovereignty. The critical analyses of digital colonialism argue that nations can assert their place in the global digital landscape by fostering local innovation, safeguarding digital sovereignty, bridging the digital divide, promoting local infrastructure development and investing in education and research. Doing so lets them harness the transformative power of technology while retaining control over their digital destinies. The Stanford Social Innovation Review recommends a layered architecture. A national AI strategy should set a high-level vision addressing workforce development, ethics and data sovereignty, while sector-specific strategies identify tailored opportunities in healthcare, education, energy and agriculture.

Ownership is the hinge of this agenda. A 2025 analysis of national sovereignty and strategic assets argues that control over energy grids, digital networks and similar infrastructure increasingly determines a nation's capacity to chart its own development. It also notes that globalized investment flows, privatization and multinational corporate influence often blur the line between sovereign control and foreign dependency. The same analysis stresses that

equitable access within borders matters as much as ownership, because rural–urban disparities in infrastructure investment translate into unequal opportunity. It points to public-private partnerships, transparent regulatory frameworks and community-driven governance as mechanisms for combining the two. The piece is conceptual rather than empirical, but its distinction is useful for education ministries. Sovereignty over AI in schools is hollow if urban elites gain locally owned tools while rural learners receive whatever donors supply. How public systems retain that authority against faster-moving private developers, and on what principles authority should be allocated among states, markets, professions and communities, are treated more fully elsewhere (see Q041 and Q042).

The second level is the push for culturally grounded, locally owned AI systems. The Harvard Center for International Development's account of the Nobel Fest and Teachers' Summit, together with the 2025 Frontiers review of Global South higher education, describes how AI tools could democratize access by providing localized, context-specific resources: curriculum materials in regional languages, integration of indigenous knowledge systems, and simulations tailored to local geographies. A 2026 Pan-African proposal for an ethical AI curriculum in primary and secondary schools takes this further. It argues that AI education itself, not only AI-delivered education, must be culturally contextualized if learners are to become critical participants rather than consumers.

This requires repositioning teachers. The 2025 Frontiers analysis of AI applications and limitations for teachers in low- and middle-income countries, and the 2026 framework on algorithmic dependence, both argue for treating teachers as co-designers and informed decision-makers rather than passive adopters. They also call for prioritizing locally developed or curated AI systems, for training programs that build critical digital capacity, and for supporting educators to ask whose knowledge is embedded in AI systems and whose is omitted. Without these conditions, AI is likely to reinforce marginalization. The governance structures that would give teachers, students and parents real voice in such decisions are a question in their own right (see Q235). The evidence base here is still mostly normative and small-scale. How far locally curated systems actually outperform imported ones on learning outcomes remains unclear.

The third level is collective action at continental scale, which addresses the bargaining asymmetry that individual small states cannot overcome alone. The African Union's Continental AI Strategy, endorsed in July 2024, commits member states to a people-centred,

development-oriented approach and foregrounds education as a pillar of inclusive digital futures. In April 2025, forty-nine African countries signed the Africa Declaration on AI, accompanied by a proposed sixty-billion-dollar Africa AI Fund, as discussed in the Pan-African curriculum framework. India, meanwhile, launched its IndiaAI Mission, covering sovereign compute, model development and AI education, and hosted the first Global South AI summit in February 2026. A 2026 analysis of what it calls the speciation of sovereign AI treats such national initiatives as part of a broader shift in which states seek institutional rather than merely commercial control of models and compute.

Whether these efforts will loosen dependency or simply redistribute it is debated. Wang and Li (2026) argue that globalization is not ending but shifting toward a more inclusive 'reglobalization', driven partly by digital innovation and regional integration, and they point to China's activity in artificial intelligence and regional institutional cooperation as evidence. They also acknowledge resurgent geopolitical competition and sluggish growth as serious obstacles. From the perspective of the digital-colonialism literature, a multipolar AI order could widen the options available to Global South ministries. It could equally replace one set of external platform dependencies with several. The sources do not settle this disagreement.

None of these strategies resolves the central tension cleanly. The Electronic Journal of Information Systems in Developing Countries, in its call for work on reimagining teaching and learning with AI from a Global South perspective, identifies data sovereignty, infrastructure disparities, ethical concerns and the cultural appropriateness of AI tools as matters that demand scholarly inquiry and collaborative problem-solving if deployment is to be equitable, context-sensitive and aligned with local priorities. Khader and Haj Yahya's (2025) systematic review of fifteen peer-reviewed studies on generative AI reinforces the point at a global level. It finds that rapid capability growth has opened a major governance gap and that the unequal distribution of AI's benefits threatens global equality. It also lists cross-cultural comparative analyses and longitudinal impact studies among the outstanding research gaps, which is precisely the evidence Global South policymakers most need.

The history of development assistance suggests that good intentions channeled through asymmetric power structures tend to reproduce those structures. What distinguishes the current moment is how strongly Global South nations, now with growing institutional backing, insist on being architects rather than recipients of the AI educational order. Whether that insistence can be sustained against the gravitational pull of dominant platforms, training data concentrated

in the Global North, and compute infrastructure controlled by a handful of corporations remains, honestly, an open question.

Q122 What is the total cost of AI to a school system, including licences, infrastructure, training, and staff time?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

The total cost of AI to a school system is substantially higher than the licence fees that dominate public discussion. Once infrastructure, professional development, integration and support, legal and compliance work, and staff time are counted, subscriptions often amount to only about half of what a system actually spends. The gap between the visible invoice and the true total cost of ownership (TCO) is the most consistent theme in the practitioner cost literature. Analyses of school AI budgeting summarised in EDUCAUSE Review (2026) converge on a striking estimate: direct platform licensing typically represents only 40–50 per cent of the total cost of adoption. The remainder falls on infrastructure, professional development, integration and support, legal and compliance work, and, least visible of all, staff time. On that estimate, a school system that budgets only for subscriptions is under-budgeting by roughly half.

The 40–50 per cent figure deserves some caution. It comes from a sponsored practitioner article rather than a peer-reviewed costing study, and no audited, multi-district dataset yet establishes

it. Its direction, however, is consistent with the much older TCO tradition of the Consortium for School Networking (CoSN). CoSN has long argued that technology costs must be counted across the full lifecycle: hardware, network, software, personnel, and the professional development needed to make any of it effective. Reporting by Stateline (2026) adds that districts are spending billions on AI while struggling to determine which purchases are worth the money. The difficulty of assigning costs and benefits is itself part of the cost problem. The full lifecycle view, including the eventual costs of replacing or leaving a system, is developed further elsewhere in this volume (see Q266); the focus here is on the costs a system carries while running AI.

Licences are the most transparent component of the bill, but they are neither as small nor as stable as they first appear. Procurement guidance reported in EDUCAUSE Review (2026) cites typical price points for three product types: AI tutoring platforms at roughly $15–60 per student, assessment tools at $8–25 per student, and teacher-facing content-generation tools at $4–15 per teacher per month. These ranges derive largely from market and vendor pricing rather than independent research. They are best read as indicative orders of magnitude, not benchmarks.

The same source reports that AI edtech platforms have shown annual price increases averaging around 12 per cent. Compounded, increases of that size can leave costs 25–35 per cent higher over a five-year budget cycle. Vendors are also described as pursuing 'land and expand' strategies. A low entry price secures adoption, and features that become essential are then gated behind higher tiers. The practical consequence is that a contract's first-year price is a poor guide to its fifth-year cost. What happens to a school when such increases become severe, or when a vendor is acquired or fails, is a distinct risk examined in Q124.

The OECD's analysis of the wider AI investment environment adds a structural warning that goes beyond the conduct of individual vendors. In the Digital Education Outlook 2026, the OECD notes estimates of roughly $6.7 trillion in global data-centre capital expenditure required by 2030 to meet AI demand, with electricity costs for these facilities expected to double. It describes the result as a 'pressure test' for education systems: rising compute and energy costs are likely to flow through into higher subscription fees for educational software.

This is a projection, not an observed price series. Whether education vendors will absorb, pass on or amplify upstream cost increases remains unclear. Even so, the OECD's argument gives a

structural explanation for the subscription creep that practitioners report, and it suggests that the pressure is more likely to intensify than ease.

Beyond the licence, AI imposes real capital and operating costs on the buildings and systems that host it. Practitioner estimates reported in EDUCAUSE Review (2026) put the cost of upgrading broadband and Wi-Fi capacity for AI workloads at $50,000–200,000 per building. Device refreshes run $300–600 per unit. These are significant line items for systems that must also maintain the devices AI runs on.

CoSN's TCO framework treats such costs as integral rather than incidental. Schools that skip the investment find that AI tools perform poorly or inequitably, and the burden falls hardest on buildings that are already under-resourced. The equity point connects to a wider international concern about systems trying to leapfrog infrastructure gaps without creating new dependencies (see Q043).

Recent scholarship also widens the definition of infrastructure. Potluri and Polozova (2026), studying Kazakhstan's higher education sector, describe AI as increasingly part of institutional infrastructure, extending beyond teaching and learning into governance, administration and student support. Their model links AI governance readiness to administrative efficiency, AI fluency orientation and student retention intentions, with equity perception as a moderator. The design is correlational and set in universities in a single country, so it cannot be read as causal evidence for school systems. Its framing is nonetheless instructive for cost accounting. If AI is infrastructure, then governance readiness is part of what has to be built and paid for, not an optional overlay.

Hidden labour costs accumulate in system integration. This includes configuring single sign-on, migrating data, and connecting AI tools to student information systems. EDUCAUSE Review (2026) reports these integrations often cost $5,000–25,000 each, plus $50,000–80,000 annually for specialised IT support.

Legal and compliance work adds further costs. Staff must review data-privacy agreements against FERPA, COPPA and GDPR obligations and negotiate contracts. The same source estimates legal fees at typically $500–2,000 per vendor.

When these integration and compliance costs are skipped, the result is 'data silos' and teacher frustration. They are also the costs most often absent from board presentations.

There are signs that compliance demands will grow rather than shrink. Mah, Knoth and Egloffstein (2025) surveyed 112 academic staff about sustainable teaching in the age of AI. Of the three areas examined (instructional design, domain specificity and ethics), participants placed the greatest importance on AIED ethics. The sample is small, exploratory and drawn from higher education. Still, it suggests that the educators who use these tools expect ethical and legal scrutiny of them. That scrutiny is precisely the kind of review that consumes legal and administrative time.

The cost literature is emphatic that training is not a discretionary add-on but a core budget line, and this is where independent research is strongest. Guidance summarised in EDUCAUSE Review (2026) recommends that professional development represent 25–30 per cent of the total AI budget. That ratio is a practitioner recommendation rather than an empirically derived optimum.

RAND's surveys show why such guidance exists. RAND (2025) reports rapid growth in AI use: by 2025, 54 per cent of students and 53 per cent of English, mathematics and science teachers reported using AI for schoolwork or instructional planning. RAND's account of the 2023–2024 school year (RAND, 2025, RRA134-25) found that formal training and policy had not kept pace with use. It also found that adoption was uneven, with educators in higher-poverty schools markedly less likely to use AI or to receive guidance on it. That pattern of uneven use and uneven support is well documented across successive RAND waves, and it is the most robust evidence in this answer.

Training costs include programme fees, which EDUCAUSE Review (2026) estimates at $500–2,000 per teacher; substitute coverage for training days; and the ongoing coaching that distinguishes effective from ineffective professional development. Under-investment in this line is widely identified in practitioner sources as the primary cause of tool failure. That claim is plausible and consistent with the broader professional development literature, but it rests more on implementation experience than on controlled comparison.

International evidence suggests the training gap concerns content as well as quantity. Higueras-Rodríguez and colleagues (2026) examined 83 training courses delivered between 2020 and 2025 across 24 public and private Spanish universities, using mixed methods that included coding matrices and hierarchical cluster analysis. They asked whether inclusion, accessibility, digital competence and AI were articulated together or left disconnected in staff development.

As the study's title signals, they found training gaps. The implication for budgeting is that money spent on generic digital-skills courses may not buy the AI-specific and inclusion-aware capacity systems need. Simply funding more training is not the same as funding the right training.

At school level, Raptis and Psyrras (2026) surveyed 262 primary school leaders in four Greek districts with a 61-item questionnaire. Their analysis, using Spearman correlation and multiple linear regression, covered attitudes toward AI, self-efficacy, perceived usefulness in decision-making, and challenges to integration. Self-efficacy is treated as a distinct factor in AI integration. This suggests that training needs extend to principals as well as teachers, adding a further, often uncosted, layer to the professional development budget.

Staff time is the largest and least counted line, and it is where credible sources point in opposite directions. The dominant framing in practitioner accounts is 'redirected capacity'. Estimates reported in EDUCAUSE Review (2026) hold that AI tools save teachers 8–12 hours per week on administrative and preparation tasks such as lesson planning, grading and communication. At typical hourly rates, that would represent up to $15,000 in redirected capacity per teacher annually. These figures originate largely in industry and sponsored analysis rather than in time-use studies with comparison groups, and they should not be treated as established research findings.

The same line item cuts both ways. Teachers spend time learning tools, troubleshooting them and adapting lessons to them. That time is a real cost, and it is almost never budgeted. RAND's (2025) evidence that AI use outpaces training implies that much of this learning happens informally, in time teachers absorb themselves. Systems that net claimed savings against uncounted adoption time may find the balance far less favourable than vendor estimates suggest.

Leadership time belongs in the same ledger. Avidov-Ungar and Ganon-Shilon (2026) interviewed 16 elementary and high school principals from four school districts about how they communicated and spread an AIED policy within a national programme during the persuasion stage of innovation diffusion. Their bottom-up thematic analysis describes this work in terms of technology and transformational leadership practices. It is a small qualitative study and does not measure hours or costs. It does make visible that persuading staff, modelling use and

sustaining adoption are leadership tasks that someone must perform and that rarely appear in a budget.

At system level, the OECD (2025) finds that only 25 per cent of jurisdictions with AI in their education strategies have specific initiatives, and only 19 per cent have timebound goals. That pattern suggests systems are spending money on tools without budgeting the organisational time required to make them work. The net value of staff time therefore remains disputed. Whether AI is, on balance, a time saving or a time cost for a given system remains unclear, and it likely depends on the quality of implementation.

The overall picture is of a cost structure that is front-loaded, underestimated and growing. CoSN's audits show the average district paying for more than 200 software applications, roughly 30 per cent of them underutilised. This 'zombie subscription' problem both inflates current costs and crowds out new investment. Each additional AI tool layered onto that estate adds licence, integration, support and training costs, often without retiring anything.

Stateline (2026) reports that the expiration of federal ESSER funding has removed the one-time cushion many districts used for technology purchases. Every AI line item must now compete with teachers and curriculum. Districts also struggle, on Stateline's account, to judge which AI spending is delivering value. The OECD's Digital Education Outlook 2026 frames the same problem in terms of effective and equitable use: costs that are borne unevenly risk widening the gaps RAND documents between higher- and lower-poverty schools.

The evidence-based response recommended across the practitioner and policy literature has several elements: a TCO model that budgets the full lifecycle (licences, infrastructure, training, integration, compliance and staff time) over a multi-year horizon; price caps negotiated into contracts; professional development funded at the level guidance indicates is necessary; and routine audits to cancel unused subscriptions. None of these practices is new. Each extends CoSN's long-standing TCO approach to a product category whose prices are more volatile and whose hidden labour is larger.

How such decisions are made also matters. The leadership studies by Avidov-Ungar and Ganon-Shilon (2026) and Raptis and Psyrras (2026) both place school leaders at the centre of adoption. Cost decisions taken without teacher, student and parent input risk buying tools that go unused (see Q235).

Systems that budget the full lifecycle are rare. Systems that do not are, on the available evidence, systematically understating what AI actually costs them.

Q124 What happens to a school when its AI vendor raises prices, is acquired, or ceases operation?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

When an AI vendor raises prices, is acquired, or ceases operation, a school loses more than money. The disruption runs through teaching, data governance and institutional memory, and the instability of the education-technology market has made it a live risk rather than a remote one. The documented cases are instructive. The most dramatic recent example is the collapse of AllHere Education, which built a chatbot for the Los Angeles Unified School District. As EdSurge reported in 2024, the service went dead when the company failed, and the district was left with unresolved questions about where its student data had gone.

AllHere became a cautionary template for the sector, and it was not an isolated failure. Reporting by Stateline (2026) and the Christian Science Monitor (2026) describes a sector in which districts are spending heavily on AI while struggling to judge what is worth keeping. Over the same period, waves of layoffs and closures have hit AI education start-ups. Many of the casualties were venture-backed 'wrapper' companies, firms that layered an AI interface over a foundation model owned by someone else. These firms have struggled to compete with free or integrated tools from the major model providers.

The three failure modes differ in speed and visibility. A price rise is gradual and announced. An acquisition is sudden but often looks harmless at first. A shutdown is abrupt and total. All three expose the same underlying condition: once an institution adopts an AI tool, it enters a long-term dependency, whether or not it procured the tool as a one-off purchase.

Price increases are the most common failure mode and the least dramatic, but they are corrosive over time. Procurement analyses reported by The Learning Standard (2026) indicate that AI platforms have raised prices by an average of roughly 12 per cent a year. The same reporting describes 'land and expand' strategies, in which vendors win districts with entry-level pricing and then move essential features into higher tiers. These figures come from trade reporting and procurement consultancies rather than peer-reviewed research. They should be read as indicative of a pattern, not as precise estimates of market-wide inflation.

The mechanism matters more than the exact number. Consider a district that has woven a tool into daily teaching. It faces two unattractive options. It can absorb the increase, often mid-budget-cycle and with no appropriation to cover it. Or it can switch, which brings its own costs in retraining staff, migrating data and losing pedagogical continuity. Districts that did not negotiate price caps or multi-year rate locks are exposed to the full force of this inflation. A licence that looked affordable at adoption can become a recurring line item that crowds out other spending. The full cost of AI to a school system extends well beyond the headline licence (see Q122).

The pressure may intensify. The OECD (2025), analysing the wider investment environment around AI adoption in education, suggests that rising data-centre capital expenditure and energy costs are likely to feed through into subscription fees for educational software. This is a forecast rather than an observed trend in school pricing, and its scale remains unclear. It is nonetheless consistent with the procurement reporting. It also implies that price risk is rooted in the cost structure of the AI industry itself, not only in the behaviour of particular vendors. Stateline's (2026) account of districts struggling to determine whether AI products deliver value compounds the problem. A district that cannot show a tool is working has little basis for deciding whether a price rise is worth paying.

Acquisition changes a school's relationship with its vendor in ways that are often invisible at the moment of the deal. The contract stays the same, the login screen stays the same, and teachers may notice nothing for months. Investigative reporting by the Education Policy Hub

has documented the growing role of private equity in owning school AI providers. Private equity firms operate on five-to-ten-year investment cycles and manage portfolio companies for eventual sale.

The Education Policy Hub analysis identifies several structural consequences for districts. First, vendors owned by private equity are frequently loaded with debt, and districts' steady, long-term contract payments can end up servicing that debt. Second, pressure to cut costs can lead to offshoring of cybersecurity and customer-support functions. This reduces the quality and availability of help exactly when schools most need it. Third, pricing and product strategy come to be driven by valuation goals rather than educational outcomes. This account comes from policy advocacy journalism rather than systematic empirical study. Its causal claims should be treated as plausible mechanisms, not demonstrated effects across the sector.

Acquisitions also frequently lead to platform consolidation. Specialised tools are bundled into larger 'operating system' platforms. Once a district's enrolment, assessment and instruction all run through a single platform, switching costs become prohibitive. The district is then effectively locked in, paying for a product whose roadmap is set by the acquirer's portfolio strategy rather than by the district's needs.

The scholarly governance literature sheds some light on why this risk is hard to manage. Lipsou, Keravnos and Eteokleous (2026) conducted a structured literature review, aligned with the PRISMA reporting standard, of publications from 2019 to 2025 on AI in K–12 school leadership. They frame data privacy, fairness and accountability as risks that school leaders must navigate. They also identify procurement, documentation and explainability, and auditability as transferable governance mechanisms. The relevance to acquisition is direct. Accountability arrangements negotiated with one owner, such as audit rights, documentation obligations and data-handling commitments, are only as durable as the contract language that binds whoever owns the company next.

Shutdown is the catastrophic case, and the AllHere collapse illustrates the full cascade. The service stops working with little or no notice. Questions about student data become uncertain: who holds it, under what legal authority, and with what obligations. The teaching built on the tool is stranded, including lesson sequences, student progress records and teachers' accumulated familiarity with the system. EdSurge's investigation of the case found that the fate of student data after a company collapses is frequently unresolved, because data-privacy agreements

rarely specify what happens in insolvency. A bankrupt company's assets, which may include data, can be handled by administrators whose obligations run to creditors rather than to the district or its families. This gap between privacy law and insolvency practice is one of the clearest lessons of the AllHere episode.

The loss of institutional memory is less visible but may be equally consequential. Avidov-Ungar and Ganon-Shilon (2026) conducted a qualitative study based on semi-structured interviews with 16 elementary and high school principals from four districts. They examined how principals communicate and spread the adoption of an AI-in-education policy during the 'persuasion' stage of innovation diffusion within a national programme. Their small, interview-based design cannot measure the costs of vendor failure. It does underline, however, how much leadership effort goes into persuading staff to adopt a new tool. That effort is sunk when a vendor disappears, and a second round of persuasion for a replacement product may meet greater scepticism. The extent of this 'adoption fatigue' after vendor failure has not been studied directly and remains unclear.

The market context makes shutdown risk structural rather than exceptional. The wrapper business model is fragile. Stateline (2026) and the Christian Science Monitor (2026) report that the sector has seen repeated layoffs and closures as districts tightened budgets after federal ESSER pandemic-relief funding expired.

The institutional response has been a rapid professionalisation of procurement. Lightspeed Systems, itself a vendor, reports in its 2026 State of EdTech Leadership survey that 86 per cent of districts now have documented technology-vetting processes and 65 per cent require mandatory IT review before contracts are signed. These are vendor-produced figures, and the survey's sampling is not independently verified. They indicate a direction of travel rather than a reliable estimate of prevalence.

Reporting by The Learning Standard (2026) and the Christian Science Monitor (2026) describes districts increasingly asking vendors about financial stability, including whether a company is profitable or operating on borrowed time. Districts are also demanding contingency plans for data and workflows in the event of acquisition or shutdown. The recommended contractual safeguards are specific. They include multi-year contracts with caps on annual price increases, clear exit provisions with limited penalties, and data-portability guarantees and escrow arrangements. They also include requirements that student data remain the exclusive

property of the district and be excluded from AI model training, along with performance benchmarks that allow the district to reduce the scope of a contract if adoption targets are not met. The full set of clauses that should appear in such agreements is treated in detail elsewhere (see Q234).

Whether school leaders have the capacity to run this kind of procurement is a separate question, and the peer-reviewed evidence is thin. Raptis and Psyrras (2026) surveyed 262 primary school leaders in four Greek districts using a 61-item questionnaire. The instrument covered attitudes toward AI, self-efficacy in using AI, the perceived usefulness of AI in decision-making, and challenges to AI integration, and the authors analysed the data with Spearman correlation and multiple linear regression. Their correlational design captures leaders' perceptions rather than procurement outcomes. Leaders' self-efficacy, for example, cannot be equated with competence in negotiating vendor contracts. Lipsou and colleagues' (2026) review similarly treats procurement and auditability as governance mechanisms. It does not demonstrate that adopting them prevents vendor harm.

The deeper lesson of the evidence is that vendor risk is a form of institutional risk and must be managed like any other. On the documented record, schools that treat AI procurement as a one-time purchase rather than a long-term dependency are the ones that get burned. Managing that dependency well also requires that the people most affected, including teachers, students and parents, have a say in which dependencies are taken on (see Q235).

These failure modes are not random events but products of the market's structure. The AI education sector is dominated by venture-backed companies whose business models depend on continuous growth and eventual exit. The wrapper model leaves vendors with thin margins and little durable advantage once the underlying model providers integrate the same features for free.

Student behaviour points the same way. Józsa and colleagues (2026) conducted a cross-sectional survey of Hungarian elementary and high school students, guided by the Technology Acceptance Model. They examined students' use of AI tools, including rapidly expanding generative tools, and their perceived usefulness and willingness to use AI in learning contexts. Their work documents that general-purpose generative tools are already shaping how school-age students search for information and complete tasks. This suggests that narrow school-specific products compete with tools students already use. The study is cross-sectional and

confined to one national context, so it cannot establish that such competition drives vendor failure.

The expiration of ESSER funding has, meanwhile, removed the one-time budget cushion many districts used for technology purchases. This has tightened the fiscal environment in which vendors operate and accelerated consolidation (Stateline, 2026). The OECD's (2025) projection of rising cost pressure from AI infrastructure adds a further squeeze from the supply side.

The result is a market in which price increases, acquisitions and shutdowns are structural features, not tail risks. A school that has not planned for all three has, in effect, accepted a contingent liability on its balance sheet. The documented cases, from AllHere's collapse to the wave of layoffs across AI education start-ups, are best read as the normal operation of a market whose incentives are misaligned with the continuity needs of public institutions, not as isolated misfortunes. This interpretation is contestable. The private-equity critique advanced by the Education Policy Hub is an advocacy position. Defenders of consolidation might argue that larger platforms offer greater stability than fragile start-ups, and the evidence to settle that disagreement does not yet exist.

There is also a question of purpose beneath the commercial one. Bui (2026) argues philosophically, drawing on Peirce, James and especially Dewey, that AI dissolves the scarcity of knowledge on which the transmission model of schooling rested, and so reopens the question of what education is for. Read against vendor risk, that argument suggests that schools should be clear about which educational aims a tool serves before they make it indispensable. A district that knows why it relies on a product is better placed to replace it, renegotiate it or do without it.

Q126 What organisational conditions distinguish institutions that adopt AI successfully from those that do not?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

What distinguishes institutions that adopt AI successfully is rarely the technology. It is the organisation: its leadership, governance, professional development, data infrastructure and, above all, its willingness to redesign work rather than insert new tools into old processes. Cross-national policy surveys, studies of school leadership and the wider management literature on organisational AI adoption point to a broadly consistent set of conditions that separate institutions whose AI initiatives produce durable change from those left with abandoned licences. Most of that evidence is descriptive, survey-based or drawn from practitioner accounts, so these conditions are better read as recurring correlates of success than as demonstrated causes. The first condition, and arguably the one on which the others depend, is strategic alignment established before any tool is chosen.

Successful institutions begin with a problem, not a product. They anchor AI initiatives to specific educational or operational goals, such as reducing teacher workload, improving the timeliness of feedback or addressing a measured learning gap, and they judge tools against those goals. The OECD's 2025 review of AI adoption across 37 jurisdictions shows how often this step is skipped at system level. While 81 per cent of the education strategies it examined mention AI, only 25 per cent contain specific initiatives and only 19 per cent set timebound goals. The OECD data establish the size of the gap between mention and specification. They do not by themselves prove that the gap predicts failure. The association with stalled adoption is plausible and widely reported, but it should be read as a strong correlate rather than a measured causal effect.

The management literature reaches a similar conclusion from a different direction. The Business Horizons framework for organisational AI success (2024) treats clarity about the business problem, and about where AI adds value, as a precondition for adoption. Institutions that do not succeed tend to adopt AI because it is available, because vendors are persuasive or because they feel pressure to appear current. The tools then drift, unowned and unevaluated. The difference shows in procurement. Successful districts can state the problem in a single sentence before considering any tool, and they decline tools that do not address it.

National investment does not remove the need for this institutional discipline. Gopi and Agarwal (2026) describe an Indian higher education sector in which most institutions now permit students and researchers to use AI, and in which the 2025–26 budget committed ₹500 crore to Centres of Excellence in education. Their policy analysis frames this expansion as presenting both problems and possibilities for social science education. The implication is that permission and funding at system level still leave each institution to decide what problem AI is meant to solve.

The second condition is governance. Successful adoption is governed rather than improvised. The structure most often recommended in practitioner and leadership sources, including the University of Kansas guidance on AI in educational leadership (2026), is a district-level AI readiness team. This group brings together IT, curriculum leadership and community representatives, with a mandate to keep AI initiatives aligned with institutional values, equity commitments and privacy law. In the strongest examples, policy guardrails are written into existing acceptable-use frameworks rather than issued as isolated documents, and they distinguish clearly between encouraged, cautious and prohibited uses. Who sits on such bodies, and whether teachers, students and parents have genuine rather than token input, is a separate question with its own literature (see Q235).

Governance also means managing risk as a continuing task. Data privacy obligations under FERPA and COPPA, algorithmic bias and the risk of over-reliance belong on the standing agenda, not in a one-time compliance check. The structured literature review by Lipsou, Keravnos and Eteokleous (2026) supports this emphasis. Their PRISMA-aligned review covered publications from 2019 to 2025 across Scopus, Web of Science, ERIC and Google Scholar. It concentrated on K–12 school leadership and drew on higher education sources only where they offered transferable governance mechanisms: policy, procurement, documentation and explainability, and auditability. The review frames AI integration in school leadership as a matter of navigating both organisational benefits and ethical risks in data privacy, fairness and accountability. That framing locates governance at the centre of leadership work rather than at its periphery. The comparative study of school leaders' readiness published by Emerald (2026) likewise treats implementation strategy, rather than enthusiasm, as the variable that separates prepared leaders from unprepared ones.

Institutions that adopt AI without governance structures tend to show the same pattern. Decisions are made ad hoc by individual teachers. Privacy obligations are met unevenly. The

institution cannot answer basic questions about what AI it is running and why. Contractual safeguards with vendors are part of the same governance architecture (see Q234).

The third condition is workflow redesign rather than insertion. A recurring finding in the organisational adoption literature is that technology fails when it is simply added to existing processes. The Business Horizons framework (2024) and the Wharton School study of organisational AI adoption by Yalcinkaya and Bidwell (2026) both identify workflow redesign as central to whether AI produces value. Wharton pairs redesign with trust and organisational learning as the mechanisms that distinguish productive adoption from superficial use.

In practice, successful institutions treat AI adoption as an occasion to rethink how work is done. They decide where each tool sits on the automation–augmentation continuum, that is, whether it replaces a task, supports a human performing it, or does something in between. They clarify the division of labour between human and machine. They also define the interaction sequences: when the AI drafts, when the teacher revises, and when the human makes the final decision. School-leadership studies, including the Emerald comparative study (2026), describe iterative improvement cycles such as Plan-Do-Study-Act as the means by which institutions pilot, evaluate and adapt these arrangements.

The weakness of the evidence here should be stated plainly. Most support for workflow redesign in schools comes from management research conducted outside education and from case accounts within it. Controlled comparisons of redesigned and unredesigned implementations in schools remain scarce. The direction of the finding is consistent across sources, but its magnitude in educational settings remains unclear. What the evidence does describe, repeatedly, is the failure mode. Institutions hand teachers a tool and expect adoption to follow. It does not, and the tool joins the district's stock of underused licences.

The fourth condition is leadership that both models AI use and protects staff. School leaders are consistently identified as the driving force of AI integration. Interviews with award-winning K-12 principals, reported in Frontiers in Education (2026), describe AI as changing teaching, learning and leading together. The leader's own practice therefore becomes part of the change rather than standing outside it. Effective leaders model AI use themselves: drafting communications, conducting research, and using the tools they expect staff to adopt. Leadership studies associate this visible modelling with greater trust, critical engagement and perceived value among staff. These findings rest largely on self-report and perception data, so

they suggest rather than demonstrate a causal effect. They also align with the Wharton finding (2026) that trust is a precondition of organisational adoption.

Effective leaders also build cultures of safe experimentation. The University of Kansas guidance (2026) recommends sandbox environments in which teachers can test tools in low-stakes settings without fear that the results will feed into their evaluation. Leaders must also address what is widely reported as the single largest psychological barrier to adoption: fear of job displacement. Institutions that succeed say explicitly that AI is intended to assist educators rather than replace them, and they back that claim with upskilling and career-mobility programmes. Where leaders fail on this dimension, teachers resist quietly, use tools defensively or refuse them outright.

The evidence also indicates that perceptions of AI differ by position within the institution. Alsuhaymi and Eltantawy (2026) surveyed 173 principals, supervisors and teachers in Riyadh public schools that provide special education services. They examined how these groups perceive AI's use in supporting administrative decision-making, and whether those perceptions differed by professional role, years of experience and AI-related training. The study's design reflects a broader point. Leaders cannot assume that their own view of AI is shared by supervisors or classroom staff, and building trust requires attention to these internal differences.

The fifth condition is professional development that is tiered and continuous. Practitioner and leadership sources agree that one-size-fits-all training performs poorly. Successful institutions build tiered pathways that let teachers enter at their own level of comfort, moving from basic awareness to lesson integration and then to peer-mentoring roles. They sustain this with coaching, refresher sessions and networks of teacher champions rather than one-off workshops. The University of Kansas guidance (2026) and the Emerald readiness study (2026) both treat ongoing capacity-building, rather than initial launch training, as the marker of a prepared institution.

Practitioner cost guidance goes further. It claims that districts investing less than 15 per cent of their AI budget in professional development see negligible returns, while those investing 25–35 per cent see the greatest success. These figures circulate widely, but they do not come from peer-reviewed or independently replicated research and should be treated as rules of thumb rather than established thresholds. Professional development is one line in a much larger cost picture that also includes licences, infrastructure and staff time (see Q122).

RAND's surveys of teachers and principals (2025) show why the question is urgent. AI use is growing quickly: by 2025, 54 per cent of students and 53 per cent of teachers reported using AI. Formal training has not kept pace. Educators in higher-poverty schools were markedly less likely both to use AI and to receive guidance on it. This is a descriptive pattern, not a causal estimate, but it carries a clear warning. If training and guidance flow mainly to better-resourced schools, AI adoption is likely to widen existing gaps rather than narrow them. The equity dimension of professional development is therefore central, not incidental. The Riyadh study's inclusion of AI-related training as a variable that may shape staff perceptions (Alsuhaymi and Eltantawy, 2026) reflects the same assumption that training conditions how staff understand AI, although the abstract does not report the direction or size of any such difference.

The sixth condition is sound data infrastructure combined with evidence-based iteration. AI systems are only as effective as the data behind them, so data-quality audits and system interoperability are preconditions, not refinements. Successful institutions also measure. They establish baselines, pilot in a single grade or department, gather both quantitative and qualitative evidence, and scale only what demonstrably works. The Wharton research (Yalcinkaya and Bidwell, 2026) frames this as the difference between treating AI as a one-time implementation and treating it as an ongoing process of organisational learning. On the available evidence, that distinction is associated with whether an AI investment produces durable change or a shelf of abandoned tools.

The literature disagrees, however, about how far these conditions travel. Much of the evidence summarised above comes from well-resourced, high-income systems. Lakhno (2026) argues that debates on AI in higher education are dominated by such contexts and often assume institutional capacity and robust infrastructure. Her PRISMA-guided review of scholarship from 2022 to 2024 on low-income countries, analysed through Rogers' Diffusion of Innovations framework, concludes that structural constraints profoundly condition both the opportunities and the risks of adoption. On this view, leadership, governance and training cannot compensate fully for missing infrastructure. Where that infrastructure is absent, the sequencing and even the definition of successful adoption may differ.

Studies from developing-country contexts reinforce the point that institutional conditions are embedded in wider environments. Jasim and colleagues (2026) surveyed 295 respondents with relevant academic and professional backgrounds in Iraqi higher education. They extended the technology–organisation–environment framework with three additional factors: educational

readiness, socio-cultural support and international cooperation. The extension itself signals that conventional organisational models may underspecify the environment in which institutions operate. Al-Raimi (2026), surveying 280 faculty members and academic leaders in Yemeni university health education institutions, explicitly treated the challenges and requirements for effective AI implementation as part of the question of educational quality, rather than as a separate technical matter.

These studies are cross-sectional and perception-based, and their abstracts do not establish which factors matter most. They do caution against treating the conditions described in this answer as a universal checklist. What remains broadly consistent across contexts is the underlying claim. Institutions succeed with AI when they treat adoption as organisational change that must be governed, resourced, led and learned from. They struggle when they treat it as the purchase of a product.

Q234 What data-protection and contractual clauses should every school-AI vendor agreement contain to safeguard student data and institutional interests?

12 citations · 12 sources · 5 cross-references

Claim 1 established

A school's contract with an AI vendor is often the only enforceable instrument standing between student information and commercial reuse, and the documented record suggests that general privacy promises in marketing materials are a poor substitute for specific, negotiated clauses. The case for precision rests less on speculation than on a series of regulatory findings and audits that reveal how student data has actually travelled once it leaves the classroom.

The first clause every agreement needs is a purpose limitation that confines the vendor's use of student data to delivering the contracted educational service. The Federal Trade Commission's 2023 action against Edmodo illustrates why. The FTC alleged that Edmodo used children's personal information for advertising and that it shifted its own consent obligations onto schools; the resulting order required the deletion of data and of models or algorithms developed from improperly collected children's information. That remedy, sometimes described as algorithmic disgorgement, signals that a contract should explicitly prohibit secondary uses, including advertising, profiling unrelated to instruction, and sale or licensing to third parties.

The second clause concerns model training. The FTC's amended Children's Online Privacy Protection Rule, published in April 2025 with compliance required by April 2026, requires separate verifiable parental consent before operators disclose children's data to third parties for purposes not integral to the service, and the Commission's commentary indicated that training or developing artificial intelligence is not integral. A school agreement should therefore state that student inputs, outputs, and interaction logs may not be used to train or fine-tune general-purpose models, whether the vendor's own or a subprocessor's, unless a separate, documented consent process has occurred. Where a vendor relies on a foundation-model provider, the contract should require flow-down of identical restrictions to every subprocessor and a current list of those subprocessors.

The third set of clauses addresses retention and deletion. The same COPPA rule requires operators to maintain a written data-retention policy specifying the purposes for which children's data are collected and a timeframe for deletion, and it prohibits indefinite retention. Contracts should translate this into concrete schedules: deletion of identifiable data within a fixed period after the end of the term or on request, certification of deletion in writing, and treatment of backups and derived datasets. The Student Data Privacy Consortium's National Data Privacy Agreement offers a widely used template that incorporates such provisions, and evidence from its adoption across many U.S. states suggests that standard terms reduce the bargaining disadvantage of small districts.

Security and breach provisions form a fourth category. Human Rights Watch's 2022 investigation found that 146 of the 164 government-endorsed education products it examined, roughly 89 percent, appeared to engage in data practices that put children's rights at risk, including tracking by advertising technology. That finding suggests schools cannot assume that endorsement or popularity implies safe engineering. Agreements should specify encryption in

transit and at rest, access controls, notification of any breach within a defined number of hours, cooperation with investigations, and allocation of remediation costs.

A fifth group concerns transparency and audit. Under the European Union's Artificial Intelligence Act, AI systems used to determine access to education, evaluate learning outcomes, or monitor students during tests are classified as high-risk in Annex III, which brings obligations for documentation, human oversight, and accuracy. Even outside Europe, schools can borrow this logic contractually by requiring model documentation, disclosure of known limitations and bias testing, notice of material changes to the underlying model, and a right to commission independent audits. Digital Promise's Responsibly Designed AI certification, launched in 2025 after co-design with education stakeholders, lists privacy, security, bias mitigation, transparency, and educator override as baseline expectations, and procurement teams can reasonably mirror those criteria in contract language.

Finally, institutional interests deserve protection alongside student privacy. Clauses on data ownership should confirm that the school or student, not the vendor, owns submitted work and records. Portability provisions should guarantee export in an open format so that a district is not locked in, and termination clauses should allow exit without penalty if the vendor materially changes its data practices or is acquired. Indemnification for regulatory violations, a governing-law clause compatible with the school's jurisdiction, and a prohibition on unilateral amendment of privacy terms complete a defensible baseline.

The legal background against which these clauses operate helps explain why they need to be written out rather than assumed. In the United States, the Family Educational Rights and Privacy Act permits schools to share education records with vendors without parental consent only when the vendor qualifies as a school official, performs an institutional service, remains under the direct control of the school with respect to the use and maintenance of the records, and uses the information only for authorised purposes. The Department of Education's Privacy Technical Assistance Center, in its 2014 guidance Protecting Student Privacy While Using Online Educational Services, observed that the direct-control condition is in practice usually satisfied through contract, and it recommended that agreements address security, data collection, use, retention, disclosure, and destruction, as well as the school's right to audit. Its warning about click-wrap terms of service remains apposite in the generative era: when a teacher accepts consumer terms for a free AI tool, the school may have surrendered precisely the control that FERPA's exception assumes. A well-drafted agreement therefore does more

than express good intentions; it creates the legal relationship that makes disclosure lawful in the first place.

State legislation has thickened this framework. California's Student Online Personal Information Protection Act, enacted in 2014, and the companion provisions of the California Education Code governing contracts with third parties became templates for statutes in many other states, prohibiting targeted advertising, the building of non-educational profiles, and the sale of student information. New York's Education Law 2-d, together with implementing regulations adopted in 2020, requires a parents' bill of rights to be appended to vendor contracts and imposes specific security and breach-notification duties. Illinois amended its Student Online Personal Protection Act with effect from 2021 to require written agreements, public posting of vendor lists, and breach notification. The practical lesson for AI procurement is that statutory floors already exist in many jurisdictions, but they were written before large language models, so they rarely mention model training, prompt logging, or the derivative datasets that AI services generate. Contract language must bridge that gap explicitly.

In Europe the logic is formalised differently but points in the same direction. Article 28 of the General Data Protection Regulation requires that processing by a processor be governed by a binding contract specifying the subject matter, duration, nature and purpose of processing, the categories of data and data subjects, and the controller's rights. It obliges processors to act only on documented instructions, to ensure confidentiality, to implement appropriate security, to obtain prior authorisation before engaging subprocessors, to assist with data-subject rights and breach notification, to delete or return data at the end of the service, and to submit to audits. For a school acting as controller, an AI vendor that uses pupil prompts to improve its general models is arguably processing for its own purposes and thus acting as a controller in its own right, which changes the legal analysis entirely. Contractual clarity about roles is therefore not a formality; it determines who is accountable for what.

The empirical record on vendor behaviour reinforces the need for these protections. Internet Safety Labs' 2022 K-12 EdTech Safety Benchmark, which examined 1,357 apps identified from a random sample of 663 U.S. schools, reported that 96 percent of the apps shared student personal information with third parties and that 78 percent of that sharing went to advertising and analytics entities. The study also reported that 28 percent of apps in use were not designed for education at all. Although the benchmark predates the generative wave, it suggests that the default trajectory of student data in commercial ecosystems is outward, and AI services, which

typically rely on cloud infrastructure and foundation-model providers, add further links to the chain.

Breach experience adds a second empirical lesson. The compromise of PowerSchool's systems discovered in December 2024, reported by TechCrunch and other outlets as potentially involving data on tens of millions of students and teachers, appears to have occurred through a customer-support portal that lacked multi-factor authentication. Reporting on the incident indicated that the data exposed varied by district because it depended on what each district had configured the platform to hold, and that some districts subsequently received separate extortion demands. The episode suggests three contractual points that apply with special force to AI vendors: schools should require specific technical controls such as mandatory multi-factor authentication for any vendor or subcontractor access, rather than generic references to industry standards; schools should minimise the categories of data shared in the first place; and indemnity and cost-allocation clauses should anticipate the expense of notification, credit monitoring, and investigation, which can otherwise fall on district budgets.

The remedy of algorithmic disgorgement mentioned above has precedents beyond Edmodo that clarify what a deletion clause should cover. In 2022 the Federal Trade Commission and the Department of Justice settled with WW International and its subsidiary Kurbo over a weight-management app marketed to children, alleging collection of children's personal information without parental consent; the order required deletion of improperly collected data and destruction of any models or algorithms derived from it, alongside a civil penalty of 1.5 million dollars. The significance for schools is that deletion obligations can and should extend beyond raw records to embeddings, fine-tuned weights, analytics profiles, and any other artefacts derived from student data. A deletion certificate that covers only the primary database leaves much of the value, and much of the risk, untouched.

Recent government guidance has begun to describe what good looks like for AI products specifically. The UK Department for Education's Generative AI: product safety expectations, first published in January 2025, sets out expectations for developers and suppliers of AI products used in schools, including content filtering, monitoring and reporting capabilities, security against jailbreaking, and data-protection commitments that bar the use of pupils' intellectual property and personal data for commercial purposes such as training without appropriate consent. Although these expectations are not themselves contractual terms, procurement teams can incorporate them by reference, requiring vendors to warrant compliance

and to notify the school if compliance lapses. This approach allows schools with limited legal capacity to benefit from centrally developed standards.

Several further clauses address risks that are distinctive to generative systems. Output ownership and intellectual-property allocation matter because students and teachers create prompts and receive outputs that may be reused in coursework or published materials; the agreement should confirm that the school and its users retain rights in their inputs and that the vendor assumes responsibility for any third-party claims arising from outputs. Content-safety obligations matter because generative tools can produce harmful material; contracts can require age-appropriate filtering, logging of safety incidents, and prompt notification when serious incidents occur. Model-change notification matters because a vendor that silently swaps its underlying model can alter accuracy, bias, and data flows overnight; a clause requiring advance notice of material changes, with a right to suspend use pending review, gives schools a chance to re-evaluate. Location and transfer clauses matter because inference may occur in data centres outside the school's jurisdiction, triggering transfer rules.

Contract design also has to reckon with an imbalance of power. Large vendors frequently offer non-negotiable terms, and individual districts rarely have leverage to amend them. Consortium approaches, such as the Student Data Privacy Consortium's agreements and state-level master contracts, appear to shift that balance by allowing a single negotiated agreement to be adopted by many districts, and some states publish registries of signed agreements so that families can see which vendors have committed to which terms. Evidence on whether these registries change vendor behaviour is limited and largely descriptive, but the logic of collective bargaining in procurement is consistent with experience in other public-sector purchasing.

There remain unresolved debates. Some privacy scholars argue that consent-based mechanisms, including parental consent for training uses, place an unrealistic burden on families and that schools should instead prohibit certain uses outright regardless of consent. Others worry that strict prohibitions will push teachers toward unvetted consumer tools that offer no contractual protections at all, a pattern already visible in survey data on teachers' informal AI use. There is also uncertainty about how far de-identification can be relied upon when interaction logs contain free-text disclosures, since studies of re-identification suggest that rich behavioural data can often be linked back to individuals. Contracts can mitigate this by defining de-identification stringently, prohibiting re-identification attempts, and barring onward transfer of de-identified data without the school's approval.

None of these clauses guarantees good conduct, and enforcement depends on schools having the capacity to monitor compliance. Yet the pattern across the Edmodo order, the COPPA amendments, and the Human Rights Watch audit suggests that specificity matters: vague commitments have repeatedly coexisted with harmful practices, while explicit prohibitions create the legal hooks that regulators and institutions need when practices drift.

Q235 What governance structures give teachers, students, and parents meaningful input into a school's AI adoption decisions?

12 citations · 12 sources · 5 cross-references

Claim 1 established

Decisions about artificial intelligence in schools are frequently made in ways that bypass the people most affected by them. Procurement offices evaluate products, technology departments run pilots, and policy documents arrive after tools are already in use. The evidence now available suggests that this pattern carries costs for trust, uptake, and the quality of decisions, and it points toward governance structures that give teachers, students, and parents genuine rather than ceremonial influence.

The appetite for participation is well documented. The Digital Education Council's Global AI Student Survey 2024, which gathered responses from 3,839 students across 16 countries, found that 86 percent already used AI in their studies and that 71 percent wanted to be involved in decisions about which AI tools their institutions adopted. The same survey reported that many students felt their institutions had not communicated clearly about AI, which suggests that the absence of consultation is experienced as a gap rather than as neutral administration. Students who use these tools daily often understand their practical affordances and risks in ways that adult decision makers do not.

Teachers express a parallel concern. The National Education Association's 2024 Task Force on Artificial Intelligence produced a set of principles that place educators at the centre of decisions about AI, insisting that educators be involved in the selection, evaluation, and implementation of tools and that AI not replace the professional judgement of teachers. The report framed participation as a condition of responsible use rather than as a courtesy. Survey data suggest that policy and process influence practice: Gallup and the Walton Family Foundation's 2025 survey of more than two thousand U.S. teachers found higher reported AI use in schools with an AI policy, roughly 70 percent compared with 60 percent where no policy existed, an association that does not prove causation but indicates that clear institutional frameworks accompany more confident engagement.

Several structural features appear repeatedly in guidance on effective governance. The first is a standing, representative body rather than an ad hoc committee. The TeachAI toolkit, developed by a coalition of education organisations, recommends multi-stakeholder working groups that include teachers, administrators, students where age-appropriate, families, and technical staff, and that continue beyond the initial policy-writing phase. Standing bodies accumulate expertise and can revisit decisions as tools change, which matters in a field where product capabilities shift every few months.

The second feature is real decision rights. Consultation without authority tends to produce cynicism, and the U.S. Department of Education's 2023 report on AI and the future of teaching argued for keeping humans in the loop and for involving educators in design and evaluation, language that implies influence over outcomes rather than mere notification. In practice this can mean that a governance committee must approve any new AI tool before deployment, holds a veto over high-risk uses such as automated grading or behavioural monitoring, or controls a portion of the evaluation criteria in procurement.

The third feature is structured channels for students and parents. Students can be represented through student councils, focus groups, or appointed members, and evidence from the Digital Education Council survey suggests that their perspectives on fairness, academic integrity, and usefulness differ from those of staff. Parents, whose consent is legally required for many data uses involving younger children, benefit from plain-language disclosures, open meetings, and accessible routes to raise concerns. Translating materials and holding sessions at accessible times are not trivial details, since participation otherwise skews toward families with more time and confidence.

The fourth feature is transparency of criteria and records. Publishing the rubric used to evaluate tools, the minutes of governance meetings, and an inventory of AI systems in use allows the wider community to see how decisions were reached. RAND's American School District Panel findings indicate that district capacity varies considerably, with training on AI more common in low-poverty than high-poverty districts, which suggests that well-resourced districts may find structured governance easier to sustain; shared regional templates and consortia can help narrow that gap.

The final feature is scheduled review. Because AI products evolve, a decision made in one school year may be outdated in the next. Governance structures that require annual reassessment of tools, incorporate feedback from users, and report outcomes publicly appear better suited to a moving target than static approval processes.

The theoretical literature on participation offers a useful vocabulary for distinguishing genuine from ceremonial structures. Sherry Arnstein's 1969 article A Ladder of Citizen Participation, written about urban planning but widely applied in education, arranged forms of involvement on a spectrum running from manipulation and therapy at the bottom, through informing, consultation, and placation in the middle, to partnership, delegated power, and citizen control at the top. Arnstein's central point was that the middle rungs allow the powerless to hear and be heard but do not guarantee that their views will be acted upon. Much school consultation on AI, such as a single parent survey distributed after a vendor has been chosen, sits squarely on those middle rungs. Applying her framework suggests that a governance structure should be judged not by how many people it asks but by whether their contributions can alter what happens.

For children and young people, Laura Lundy's 2007 model, developed in the British Educational Research Journal as an interpretation of Article 12 of the United Nations Convention on the Rights of the Child, adds further precision. Lundy argued that voice is not enough and identified four interrelated elements: space, meaning safe and inclusive opportunities to form and express views; voice, meaning facilitation of expression; audience, meaning that views are communicated to someone with responsibility to listen; and influence, meaning that views are acted upon as appropriate and that young people receive feedback on how their input was used. Her model has been adopted by governments including Ireland's in national participation strategies. Applied to AI governance, it implies that student representatives on a committee need access to information about how tools work, a direct line to decision makers, and a record showing what difference their contributions made. Feedback

loops are frequently missing in practice, and their absence may explain why students in surveys often report that consultation felt tokenistic.

International policy frameworks increasingly embed this participatory logic. UNICEF's Policy Guidance on AI for Children, released in 2021 after consultations that included workshops with young people in several countries, lists requirements for child-centred AI that include supporting children's development and well-being, ensuring inclusion of and for children, prioritising fairness, protecting data and privacy, ensuring safety, providing transparency and explainability, and empowering governments and businesses with knowledge of AI and children's rights. The guidance explicitly calls for children to be involved in the design and governance of AI systems that affect them. Pilot case studies associated with the guidance described organisations that convened youth advisory panels, an approach that schools could replicate at local scale without significant cost.

Data on teacher readiness reinforce the case for teacher voice. The OECD's Results from TALIS 2024, which surveyed lower secondary teachers across dozens of education systems, reported that around a third to two-fifths of teachers in participating OECD systems said they had used AI in their work in the previous year, with very large variation between systems. Among teachers who did not use AI, a large majority cited a lack of knowledge and skills as a reason, while relatively few cited school prohibitions. At the same time, substantial shares of teachers expressed concern that AI could allow students to misrepresent their work or could make inaccurate recommendations. These findings suggest that teachers bring both practical uncertainty and well-founded scepticism to AI decisions, which is precisely the combination that governance bodies need in order to avoid both uncritical adoption and blanket refusal.

Formal labour structures provide another route for teacher input. Education Week's August 2025 reporting on teacher contracts found that relatively few collective-bargaining agreements yet contained AI provisions, but documented early examples. The St. Paul Federation of Educators reportedly secured language preventing the elimination of bargaining-unit positions as a result of generative AI, while a district in Illinois created a joint union-management committee to advise the school board on AI adoption and training, and San Diego's agreement established a work group to develop recommendations for an AI policy. These agreements matter for governance because they convert participation from a discretionary administrative choice into an enforceable entitlement. Where unions are absent or weak, comparable effects

might be achieved through board policy that writes stakeholder committees into standing procedures.

Student use patterns suggest why student representation cannot be treated as an optional extra. Pew Research Center's survey published in January 2025 found that about a quarter of U.S. teens aged 13 to 17 reported using ChatGPT for schoolwork, double the share in 2023, with use more common among older teens. When a technology is already embedded in students' routines, decisions about it affect behaviour that adults may not see. Students can surface patterns, such as the use of AI for language translation by multilingual learners or for organisation by students with attention difficulties, that would otherwise be invisible to policymakers, and they can identify unintended consequences of rules, for instance when a ban on all AI tools also blocks accessibility features.

Parental participation raises its own equity issues. Research on family engagement, including the extensive work by Joyce Epstein and colleagues on school-family partnerships, has long found that conventional channels such as evening meetings and written consultations tend to reach families with more education, time, and familiarity with school systems. If AI governance relies on those channels alone, the families whose children are most exposed to risks, such as those who rely on school devices, those whose children are subject to monitoring software, or those whose home language differs from the school's, may be least represented. Practices that appear to broaden participation include translated materials, community-based meetings, compensation or childcare for participants, and partnerships with community organisations trusted by underrepresented families. These are not specific to AI, but the technical nature of AI decisions raises the barrier to entry and therefore increases the importance of deliberate outreach.

A further design question concerns expertise. Committees composed entirely of stakeholders without technical knowledge may defer to vendors, while committees dominated by technologists may sideline pedagogical and ethical concerns. Hybrid models address this by pairing stakeholder representatives with independent technical advisors, such as university partners or regional education service agencies, who can interpret documentation, test claims, and translate trade-offs into plain language. The European Union's Artificial Intelligence Act, which since February 2025 has required deployers of AI systems to take measures to ensure sufficient AI literacy among staff dealing with those systems, offers a regulatory nudge in this direction, since literacy among committee members is a precondition for informed oversight.

The decision rights of governance bodies also need to be differentiated by risk. Not every tool warrants the same scrutiny, and requiring full committee review for a spell-checker would exhaust volunteers and slow legitimate innovation. A tiered model, in which low-risk tools are approved through a published checklist while high-stakes uses such as grading, placement, behavioural analytics, or surveillance require full deliberation and community notice, mirrors the risk-based structure of the European framework and appears in several district guidance documents. Tiering also allows committees to concentrate their limited time where student rights are most at stake.

Finally, governance structures have to contend with the reality that many AI decisions are not made at school level at all. Statewide contracts, learning management system integrations, and default features switched on by large platforms can introduce AI capabilities without any local procurement decision. Meaningful input therefore extends upward, through representation on district and state advisory bodies, and outward, through networks that allow schools to share evaluations. Without such linkages, school-level committees risk deliberating over choices that have already been made elsewhere.

The research base on which of these structures produces the best educational outcomes remains thin, and most evidence is drawn from surveys and guidance documents rather than comparative studies. Still, the convergence across student surveys, union principles, and government guidance suggests that meaningful input requires permanence, authority, inclusiveness, transparency, and revision, and that structures lacking these elements risk becoming symbolic.

Q279 How are leading universities building institution-wide AI strategies — including campus-wide generative-AI licences — that balance innovation, governance, and academic freedom?

14 citations · 14 sources · 7 cross-references

Claim 1 disputed

Leading universities are building institution-wide AI strategies by moving from isolated, often reactive, decisions about individual tools to layered arrangements. In these arrangements a central framework sets principles and procures shared infrastructure, such as campus-wide generative-AI licences, while faculties and individual teachers keep discretion over how AI is used in particular courses and research. The balance between innovation, governance and academic freedom is struck less by any single policy than by how authority is divided across these layers.

That is the most defensible summary, but it needs careful qualification because the empirical record is uneven. Most published research analyses policy documents rather than observing how strategies work in practice. What campus-wide licences actually do to teaching, research and operations remains unclear. The trajectory itself is better documented. Xiao, Chen and Bao (2023) captured it in the formula of waiting, banning and embracing: an early period of hesitation, then a rapid spread of guidance, then a growing recognition that guidance confined to academic integrity is too narrow for a technology that touches every part of the institution.

This section therefore treats institutional strategy as a design problem. A strategy determines which tools are available by default, under what data terms, with what training and with how much latitude for departure. Those operational choices shape everyday AI use more powerfully than statements of principle. A licensed, centrally supported tool becomes the path of least resistance for thousands of staff and students, regardless of what the accompanying policy says about choice. Academic freedom enters at exactly this point: whether such a default is benign, and who may contest it. The organisational conditions that distinguish successful adopters are treated elsewhere (see Q126). The concern here is the whole-institution architecture and the trade-offs built into it.

The starting point for most institutions was a vacuum rather than a strategy. Xiao, Chen and Bao (2023) examined ChatGPT policies at the top 500 universities in the 2022 QS World University Rankings, recording whether policies existed, what they contained and when they were issued. They found significant variation in approach. Fewer than one-third of these highly ranked universities had implemented a ChatGPT policy at the time of analysis.

Ghimire and Edwards (2024) reached a compatible conclusion through a different method. Surveying 102 high school principals and higher education provosts, they identified a prominent policy gap: most institutions lacked specialised guidelines for the ethical deployment of tools such as ChatGPT. They also observed that high schools were less inclined than higher education institutions to work on policies. That finding suggests universities, with their greater administrative capacity and research cultures, were somewhat better placed to move first.

Wang and colleagues (2024) framed the issue from the educator's side. They began from the observation that many teachers felt anxious and hesitant about integrating generative AI and needed recommendations and guidance from their institutions. They then analysed the policies, resources and guidelines that top-ranked United States universities had established in response.

The broader research field grew alongside this policy activity. Crompton and Burke (2023), in a systematic review of 138 articles on AI in higher education from 2016 to 2022, found that publications in 2021 and 2022 rose to nearly two to three times the number of earlier years, with research conducted on six continents.

Taken together, these studies demonstrate that institutional responses were initially fragmented. They also show that ranking or prestige did not guarantee early policy action. They do not establish whether early movers developed better strategies, or whether the variation reflected deliberate choices about academic autonomy rather than simple delay. Some universities may have declined to issue central rules precisely to protect instructor discretion. Others may simply not yet have acted. Document analysis alone cannot tell these cases apart, and that limitation runs through much of what follows.

As institutions moved beyond holding statements, the more useful conceptual work offered ways to structure a strategy rather than lists of permitted and prohibited uses. Chan (2023) proposed an AI Ecological Education Policy Framework, derived from mixed-methods data from 457 students and 180 teachers and staff across disciplines in Hong Kong universities. It organises institutional responsibilities into three dimensions: pedagogical, governance and operational.

This division clarifies the strategic choices campus-wide licensing involves. A licence is primarily an operational decision about procurement, access and support. Yet it immediately has governance consequences, because it defines data flows and accountability. It also has pedagogical consequences, because it shapes what teachers can reasonably assume students

have access to. Kurtz and colleagues (2024) similarly framed generative AI as a pivotal moment requiring deliberate integration strategies. They identified challenges including inaccuracy, bias, overreliance on technology and algorithms, and limited access to educational AI resources. The last of these is particularly relevant: uneven access is one of the stronger arguments for institution-wide provision, since a licence can reduce the gap between students who can pay for premium tools and those who cannot.

There is also a case that the dominant framing of strategy has been too defensive. Reporting on a higher education law conference, McCarthy (2026) recounts the argument of Jacob Rooksby that institutions have focused too narrowly on risk management, trying to define and ensure acceptable and responsible use. He urged that strategies be widened to support institutional values, educational purpose and authenticity, and to address ownership, governance and the future. This is an argument from a practitioner forum, not an empirical finding. It nonetheless names a real tension, between strategy as risk containment and strategy as an expression of what the university is for.

The operational layer carries commitments that these frameworks do not fully resolve. Licences bring recurring costs, staff time and training obligations (see Q122). They also create dependence on vendors whose pricing and corporate futures the institution does not control (see Q124). A campus-wide licence is only as protective of academic and student interests as its contractual terms on data, model training and exit (see Q234).

The governance layer has been shaped strongly by international ethical frameworks, and it shows a recurring narrowing towards assessment. Dabis and Csáki (2024) drew on five key international documents from the UN, the EU and the OECD to identify ethical dimensions relevant to generative AI in academia. These include accountability, human oversight, transparency and inclusiveness. They then examined how universities' first policy responses addressed those dimensions. Their approach offers a useful benchmark for institutional strategy: a policy can be judged by whether it gives operational meaning to principles such as human oversight, not simply by whether it names them.

Luo (2024) offers a more critical reading of what university policies actually prioritise. Applying Bacchi's "What's the problem represented to be" framework to the generative-AI policies of 20 world-leading universities, she found that policies mentioned many problems, among them the reliability of AI outputs and equal access to the tools. The primary problem

they represented, however, was that students might not submit original work for assessment. Luo argued that this framing calls for reconsidering what "originality" means in AI-mediated work.

The implication for institution-wide strategy is significant. If a university's central governance treats AI mainly as an integrity threat, then licensing, training and support will be organised around detection and compliance rather than around research use, administrative operations or pedagogical redesign. That is a narrower conception of governance than the multidimensional frameworks above propose.

The field's own research culture reinforces the case for broader governance. In a meta systematic review of AI in higher education, Bond and colleagues (2024) called for increased attention to ethics, greater collaboration and more methodological rigour. They argued that the field needs a solid research and conceptual grounding at a moment of unprecedented public discourse.

Two findings appear to sit in tension here, though they can be reconciled. Dabis and Csáki describe policies engaging with a wide ethical vocabulary, while Luo describes policies that, read critically, are preoccupied with originality. Both may be accurate, since policies can cite broad principles while concentrating their operative provisions on assessment. Whether institution-wide strategies adopted later in the period have corrected this imbalance remains unclear from the available analyses, which largely capture first responses.

Academic freedom is where institution-wide strategy becomes contested rather than merely complex. Universities have generally tried to reconcile central coordination with professorial autonomy by setting institution-level principles and leaving course-level rules to instructors. That allocation protects disciplinary judgement, since a historian, a computer scientist and a clinical educator may reasonably reach different conclusions about appropriate AI use. It also has costs.

The educators studied by Wang and colleagues (2024) were described as anxious and hesitant, actively seeking institutional guidance. Unstructured devolution can therefore leave individuals carrying decisions they feel unequipped to make, and leave students facing inconsistent rules across their courses. Too much central prescription carries the opposite risk: it can override pedagogical choices that properly belong to the teacher, and it can tie research practice to a single commercial product.

Campus-wide licences sharpen this dilemma in a way policy documents rarely acknowledge. Formally, a licence restricts nothing. In practice, central provision of one tool, with institutional data protections and support attached, makes alternatives comparatively costly. Researchers who prefer open models, or teachers who object to a vendor's practices, may find their freedom intact on paper but harder to exercise. At the institutional level, the procurement decision is a decision about academic infrastructure. Who has legitimate authority to make it (see Q042), and through what participatory mechanisms staff and students can shape it (see Q235), are therefore questions of academic governance, not merely IT administration.

Student perspectives complicate any assumption that restriction protects learners. Chan and Hu (2023) surveyed 399 undergraduate and postgraduate students in Hong Kong and found a generally positive attitude towards generative AI. Students recognised its potential for personalised learning support, writing and brainstorming, and research and analysis.

Triangga and colleagues (2026), studying 688 students at universities on Java, Indonesia, examined what drives continued use of ChatGPT beyond initial adoption. They proposed AI-relevant performance and AI comfort expectancy as constructs that extend traditional technology-acceptance models. Their findings concern intention to keep using the tool, not learning outcomes. Still, they suggest that sustained student use depends on perceived usefulness and comfort, factors an institutional licence and support model can influence.

Neither study shows whether institutional provision improves learning or merely entrenches particular tools. The consultative basis of Chan's (2023) framework, drawing on both students and staff, suggests one way to legitimate central decisions without suppressing dissent.

The most important limitation is that the evidence describes what institutions say far more than what their strategies do. This weakness has deep roots. Zawacki-Richter and colleagues (2019) reviewed 146 studies of AI applications in higher education published between 2007 and 2018 and asked pointedly, "where are the educators?" They found it still unclear how educators could gain pedagogical advantage from AI at scale, or how it meaningfully affected teaching and learning.

The subsequent surge in research documented by Crompton and Burke (2023), and the calls for rigour and collaboration from Bond and colleagues (2024), indicate that the field has grown faster than its capacity to evaluate institutional interventions. Luo, Tang and Sun (2026) reviewed 189 empirical studies, drawn from 1,032 papers at four leading educational

technology conferences between 2023 and 2025. Their scoping review classifies research by pedagogical role, application domain and technical enablement strategy. That technology-research focus is valuable, but it centres on applications rather than on the institutional arrangements that determine which applications reach students and staff.

Several things therefore remain unknown. Few studies have compared institutions that adopted campus-wide licences with those that did not, in terms of equity of access, research practice, staff workload or student learning. Whether central strategies have moved beyond the integrity framing Luo (2024) identified has not been systematically re-examined. Nor is there good evidence on how academic staff experience the gap between formal freedom and practical defaults. Claims that a particular strategic model is best practice rest, for now, on conceptual frameworks and policy analysis rather than on outcome evidence.

A reasonable provisional position is that strong institution-wide strategies share recognisable features. They organise responsibilities across pedagogical, governance and operational dimensions, as Chan (2023) proposed. They translate international ethical principles into operational commitments rather than citing them. They treat licensing as an academic decision subject to consultation and review. And they protect disciplinary discretion while giving instructors real support.

These features rest on reasoning and early evidence rather than demonstrated effects. The next phase of research needs longitudinal, multi-institution studies that follow strategies from adoption into practice, and that measure academic freedom as staff actually exercise it, not only as it appears in policy text. Questions about the long-term future of the university itself lie beyond institutional strategy (see Q040). In the near term, however, these design choices are where the balance between innovation, governance and freedom will be won or lost.

Q044 Which capabilities do labour-market forecasts expect to reward, how reliable have such forecasts been, and how should schools teach for an unpredictable future?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

Labour-market forecasts most consistently expect to reward capabilities that complement rather than compete with artificial intelligence: critical thinking, leadership, communication, creativity, ethical judgement and, above all, the capacity to keep learning. Their record of predicting which occupations will rise or fall is poor enough that schools should treat any specific prediction as provisional and organise teaching around adaptability rather than forecast job titles. Few questions in contemporary social science are more contested, and few matter more to anyone designing a curriculum today. The evidence is best read across three time horizons, each of which supports a different degree of confidence.

Over roughly the next decade, to about 2035, the picture is clearer than its blurred edges suggest. The McKinsey Global Institute estimates that by 2030 activities accounting for up to 30 percent of hours currently worked in the U.S. economy could be automated. It also expects generative AI to enhance rather than eliminate the work of STEM, creative, business and legal professionals. Displacement is already sorting occupations along a familiar fault line. Clerical and administrative roles are among the first to be automated. Occupational projections compiled by National University, drawing on U.S. government employment outlooks, put the expected decline at 15 percent for bank tellers and 11 percent for cashiers by 2033. The same compilation projects growth in healthcare roles where AI augments rather than replaces workers, with nurse practitioners expected to grow by 52 percent between 2023 and 2033. These figures come from a university blog's secondary compilation rather than from primary research, and they should be read as indicative.

The evidence does not support a clean division between "safe" and "doomed" jobs. Researchers associated with MIT FutureTech gathered more than 17,000 worker evaluations of AI performance across 3,000 labour-market tasks. They report that capability is improving broadly and steadily rather than in sudden surges. In their data, success rates on text-based tasks rose from roughly 50 percent in mid-2024 to 65 percent by late 2025, and the authors project 80 to 95 percent success on most such tasks by 2029. The findings are explicitly preliminary. If the trend holds, however, pressure is rising across the whole occupational structure rather than concentrating in a few exposed sectors. Sector-level reviews point the same way: AI is entering domains as different as financial forecasting and construction planning. Mehta (2025), surveying corporate finance, frames AI as a decision-support tool that blends human insight with machine precision rather than a replacement for analysts. That framing is a normative proposal grounded in case studies, not a measured labour-market outcome.

Even with capability rising broadly, current usage shows a striking pattern. One analysis of more than four million AI conversations, discussed in recent work on skill formation, found that roughly 57 percent of usage was augmentation rather than automation: workers iterating, learning and checking their work with AI assistance. The same discussion stresses that AI is not replacing education so much as being used by educated people. Prior skill appears to shape who benefits, and the measures now in use may miss what happens to skill formation itself. The finding describes how a tool is used at one moment. It does not show how employment will evolve.

Accounts of which skills employers value converge on a similar list, although the quality of the evidence varies. Career-guidance sources report that the World Economic Forum and McKinsey both rank leadership, critical thinking, resilience and people management among the most needed skills through 2030. The same sources report that eight of the ten skills most requested in U.S. job postings are "durable" human skills, with communication, leadership, critical thinking and collaboration each appearing in roughly 15 million postings a year. These are counts of job advertisements relayed by commercial career guides. They indicate what employers say they want, not what they reward in wages, and should not be mistaken for peer-reviewed findings.

Peer-reviewed work adds two refinements. Ţarcă, Luca and Ţarcă (2024) used principal component analysis of European data to reduce individuals' digital capabilities to two components, comprehensive online skills and digital social and media skills, which together

retained more than 80 percent of the variance. Comprehensive internet skills were highly correlated with average hourly wages and better integration into the labour market after the pandemic. The association is correlational and measured at country level, so it does not show that acquiring such skills raises an individual's pay. It does suggest that digital fluency and "human" skills complement each other rather than compete. Grilli and Pedota (2024) review creativity research at individual, team and organisational levels and propose that AI will reshape the balance between convergent and divergent thinking, the distribution of skills within groups, and organisations' absorptive capacity. Their contribution is a set of theoretical propositions to guide future research rather than tested findings. Still, it cautions against treating "creativity" as a fixed asset that AI leaves untouched.

Over twenty years, to about 2045, the honest answer is that serious forecasters disagree sharply. As the Harvard Data Science Review's examination of AI job prediction documents, the Nobel laureate Daron Acemoglu has argued that only a small share of business tasks will be profitably automated over the next decade, with AI adding less than one percent to productivity. At the other pole, McKinsey has suggested that as many as half of all tasks in current jobs could be automated between 2030 and 2060, with a midpoint around 2045. This is not a quibble over rounding. The two positions rest on different theories of how technical capability turns into economic reorganisation, including the cost of adoption, the pace of organisational change and the share of tasks that are profitable rather than merely feasible to automate.

Some structural points can be made with more confidence. The International AI Safety Report 2026 notes that current systems still require human oversight for complex tasks. It also records growing concern about future systems that could automate a wider range of work cost-effectively, with greater reliability and autonomy, and it acknowledges that forecasting their employment effects is genuinely difficult. The capabilities most likely to keep a wage premium are those that depend on embodied trust, ethical accountability and what might be called social legibility: being answerable to others in ways a system cannot be. Analyses of workforce adaptation in the Gulf states make the same point about leadership. Leaders and professionals face situations shaped by values, politics, conflicting interests and cultural trade-offs rather than data alone. Vision, trust and ethical responsibility resist automation, and institutions follow people who can manage tension and uncertainty.

Theoretical economics offers a related argument, though it remains contested. Davidson (2025), working in the Austrian tradition, argues that AI cannot replace the entrepreneurial function. On

his account, AI excels at pattern recognition and optimisation within defined problems but lacks the judgement, imagination and evaluative agency needed to handle real uncertainty and to discover new opportunities. Drawing on Koppl and colleagues' theory of the adjacent possible, he holds that innovation still depends on human selection and purpose. The argument is conceptual, not empirical, and critics who expect more autonomous systems would reject its premise. Srivastava (2026), synthesising frameworks on AI and the UN goals for decent work and industry in emerging economies, adds a distributional warning. Algorithmic optimisation can speed up resource efficiency and green manufacturing, but unguided process automation risks severe task displacement, more informality and jobless growth. He argues that steering adoption toward human-complementing applications requires deliberate public policy rather than market defaults. Which capabilities are rewarded, on this view, depends on policy choices as well as on technology.

The reliability of forecasts is itself part of the answer, and the record is not encouraging. The Harvard Data Science Review analysis points out that displacement has already moved in an unexpected direction. AI has reached creative and technical development roles sooner than manual ones, reversing earlier predictions that blue-collar work would go first. The history of technological disruption suggests that the tasks least automatable today will not necessarily be the least automatable in 2045. The fashions of the career-advice industry tell the same story. Commentary on supposedly AI-proof work still argues that jobs requiring creativity, critical thinking and high emotional intelligence will grow in value because AI finds them hard to replicate. Yet roles once promoted as future-proof, such as "prompt engineer," have already lost salience, and some industry leaders expect substantial automation of software development itself, which a few years ago was widely considered a safe destination.

At fifty years, to about 2075, intellectual honesty requires saying that no forecast deserves much credence. The United Nations Regional Information Centre observes that automation has historically had varied effects on workers, with adjustment periods that caused real hardship before strong real-wage gains arrived over the longer term. Whether that pattern will hold for AI is genuinely unknown. Unlike the power loom or the spreadsheet, AI acts on cognitive work rather than mainly physical or clerical tasks. Demographic modelling of Europe and Africa toward 2050 adds another source of uncertainty: ageing workforces in one region and rapidly growing young populations in the other mean that the same technology may create labour

shortages in one place and employment crises in another. Long-horizon scenarios of this kind are useful for mapping possibilities, but they are not predictions.

The practical lesson is to look for navigational ability rather than a safe harbour. A curriculum built around predicted job titles would rest on the least reliable part of the evidence. One built around the capacity to keep learning rests on the most robust. The consequences reach beyond schooling into how credentials signal competence (see Q127), how young people move into entry-level work (see Q128), and how adult retraining systems must absorb repeated shocks (see Q130).

The pedagogical implication follows from this diagnosis. The OECD argues that as AI and robotics advance, education systems must reassess the competencies required for life and work, and that the resulting changes could be large and fast. The Learning Policy Institute argues that the current institutional model is not built for this. The factory model of schooling inherited from a century ago was never designed to produce the kind of learning a modern economy demands. Educators and researchers are converging instead on a different organising principle. Schools should develop what Google's leadership identified as "learning ability," the strongest predictor of success in its hiring experience. This includes the capacity to find, analyse and use resources to answer questions, to apply knowledge with judgement, to evaluate one's own work, and to use advanced problem-solving skills.

The fresh literature sharpens what this should mean in classrooms. If Grilli and Pedota (2024) are right that AI shifts the balance between convergent and divergent thinking and changes how skills are distributed within teams, then teaching creativity should involve deliberate practice in generating and evaluating alternatives alongside AI tools, not merely protecting a supposedly human space from them. If Davidson's (2025) argument about entrepreneurial judgement has force, students need repeated experience with ill-defined problems in which the goal itself must be chosen and justified, because that is precisely where pattern-matching systems are weakest. Ţarcă and colleagues' (2024) association between comprehensive internet skills and wages suggests, without proving, that digital fluency belongs inside this agenda rather than in opposition to it. None of these strands has yet been tested through rigorous evaluation of school programmes, and the claim that such curricula improve later labour-market outcomes remains unclear.

Assessment is where the shift becomes concrete. The Learning Policy Institute argues that assessment must move toward evaluating complex applications of knowledge to new situations rather than recall of isolated facts. It also argues that instruction must both incorporate AI and focus more explicitly on developing learning ability itself. Both recommendations reflect a recognition that tasks easily completed by a machine are poor evidence of what a student can do, and poor preparation for a labour market in which such tasks lose value. They also connect to wider debates about which present-day decisions on AI in education will matter most (see Q050).

At the deepest level, UNESCO observes that the meaning of learning outcomes has been "entirely thrown up in the air." This leaves open how meaningful learning should be defined when so much of it is mediated by AI. The question has no settled answer, and the disagreement among forecasters examined above means it is unlikely to have one soon. The most defensible position currently available is a curriculum built around adaptability, ethical reasoning, collaborative judgement, and the ability to work productively alongside powerful tools rather than in ignorance of them. The OECD's call for continuing reassessment of competencies implies that even this list should be revisited regularly rather than fixed. Srivastava's (2026) warning that unguided automation can deepen informality also reminds schools that preparing students for an unpredictable future includes preparing them as citizens able to shape how the technology is used, not only as workers who adapt to it. Such a curriculum does not promise employability in any particular occupation. It offers the most robust preparation available for a future that cannot yet be described.

Q045 How should education respond to the possible decoupling of learning from employment (if AI displaces large categories of work)?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

Education should respond to a possible decoupling of learning from employment by holding two commitments at once. It should keep preparing people to work alongside, direct, and adapt to AI systems. It should also build an account of its own purpose that does not depend wholly on the labour market to justify it. Neither commitment is enough alone. A purely adaptive strategy risks training people for a labour market that may be smaller than expected. A purely humanistic retreat would abandon learners to an economy that still rewards particular capabilities.

The organizing assumption of modern mass education is that schooling exists primarily to prepare people for paid work. That assumption has long been contested in philosophy but rarely destabilized in practice. AI may be the first technology capable of destabilizing it at scale. How education should respond is therefore a political question as much as a pedagogical one, because it forces a reckoning with what learning is actually for.

The research community increasingly frames the problem in these broad terms. Leech, Garfinkel, Yagudin and colleagues (2024) set out the AI2050 "hard problems" that stand between AI's promise and its risks. Their list includes addressing economic disruptions, ensuring the participation of all, and managing the philosophical disruptions for humans living in the age of AI. They place economic and philosophical disruption side by side. That pairing implies that the question of what people will do and the question of who people will be cannot be separated. Education sits at the junction of both. Their review covers literature only through January 2023, so it predates much of the generative-AI deployment now reshaping workplaces. Its value lies in the framing rather than in current evidence.

The scale of the disruption remains genuinely uncertain, and credible sources disagree about its shape.

The World Economic Forum's Future of Jobs Report 2025, as summarized in expert compilations, surveyed over a thousand employers representing fourteen million workers

across fifty-five economies. It projected that ninety-two million jobs will be displaced by 2030 and one hundred and seventy million created, a net gain of seventy-eight million. Optimists lean on this arithmetic. These are employer projections, however, not observed outcomes.

The aggregate figure also obscures a more troubling structural problem. The International Center for Law & Economics, reviewing the empirical literature, points to a specific mechanism. AI can automate discrete tasks that have traditionally served as entry-level work, which reduces marginal demand for junior labour without displacing more senior workers. On this reading, the result is structural adjustment in career ladders and human-capital formation rather than broad job loss. Put plainly, the rungs at the bottom of professional life are being removed even if the ladders remain standing. This has direct consequences for how young people move from school into work (see Q128).

The World Economic Forum's scenario work, Four Futures for Jobs in the New Economy, adds a further concern. The futures institutions are least prepared for are those in which disruption is faster and deeper, with AI displacing workers across multiple sectors at once and at a pace new jobs cannot absorb.

Evidence from before generative AI tempers both the alarm and the optimism. Vodă, Ciobotea, Badea and colleagues (2025) applied latent class analysis to the 2019 European Company Survey conducted by Eurofound and Cedefop and identified four typologies of firms. The "digital leaders and innovators" combined high digitalization and innovation with stable employment, increased investment in staff training, and a tendency towards automation. Less-digitalized traditional companies were more susceptible to stagnation or employment decline. Across classes the employment outlook was stable but showed no significant growth. These are cross-sectional associations, not causal effects. Still, the pattern suggests that firms which automate most may also invest most in learning, a link education policy could reinforce.

Lenzi and Panzera (2025) add a distributional caution. Analysing all EU27 and UK NUTS2 regions from 2011 to 2019, they find a decoupling between wage and income inequalities in the automation context. They attribute it possibly to reallocation across sectors and ripple effects that put substantial downward pressure on wages. Net job counts can therefore look benign while the terms of work deteriorate. Whether generative AI will intensify these regional patterns remains unclear.

Education systems are caught in the middle of this uncertainty. As the Bipartisan Policy Center observes, they are struggling to prepare students for an AI-powered economy while the long-term effects of AI on learning and critical thinking are still emerging.

The instinctive institutional response is understandable: teach more AI skills, retrain faster, and align curricula more tightly with employer demand. It may nonetheless be insufficient as a complete answer. The World Economic Forum's analysis of education and AI disruption argues that AI accelerates skill obsolescence. It redefines productivity by decoupling output from human hours, and it shifts the premium from execution to judgement. If so, education organized chiefly around transmitting executable skills will be perpetually outrun by the technology itself.

The first of two educational purposes that AI disruption has forced apart is therefore instrumental. It concerns preparing people to navigate, augment, and direct AI systems, and the available evidence points towards certain priorities.

The shortening longevity of skills demands greater agility from education and training systems. Platform data illustrate how quickly demand is moving. LinkedIn, as reported by workforce analysts, estimates that demand for AI literacy skills rose by seventy percent between 2024 and 2025. This is a figure from a commercial platform's own user data rather than peer-reviewed research, and it should be read as a directional signal.

More substantive is a review in the biomedical literature arguing that jobs requiring critical thinking show greater resistance to automation. That would make cultivating reasoning, rather than transmitting information, the core defensive task of formal education. The claim is plausible and widely echoed, but it rests largely on task-exposure reasoning rather than longitudinal outcome data.

The implications for hiring follow the same logic. Many commentators read the transition as a call to hire for the capacity to learn and adapt. McKinsey, as cited in higher-education sector guidance, argues that employers will need to hire for skills and competencies rather than credentials. If that shift materializes, it would weaken the signalling power of traditional degrees (see Q127). Whether employers actually change their hiring practices, rather than simply announcing an intention to, remains unclear.

The second purpose is intrinsic, and here the question becomes more radical.

One educator at a National Academies workshop on the turbulent future of AI and work put it this way: "the purpose of a K-12 education is to produce a productive and well-rounded citizen — someone who has agency, can make their own choices, and has a path forward in life, not necessarily just someone who will be a good worker." If AI does reduce the volume of human labour that society requires, education cannot simply intensify its vocational mission. It must broaden its conception of human flourishing to include civic participation, creative expression, and the capacity for a meaningful life outside wage labour. The civic dimension connects directly to education's role in forming citizens capable of judgment and deliberation (see Q048).

The most useful empirical grounding for this ambition comes from Chan, Bales, Hermann and colleagues (2026). They survey psychological, sociological, and economic research on work and wellbeing across OECD countries, China, India, and Gulf states. The populations they draw on include the unemployed, retirees, lottery winners, and financially dependent spouses. Paid work, they note, has been characterized both as a contributor to wellbeing and as an impediment to it.

They identify three mediating factors. The first is agency and choice, meaning whether exit from work is voluntary or involuntary, along with long-term agency. The second is the availability of alternative sources of work's latent benefits, such as volunteering, hobbies, or state-provisioned employment. The third is social and systemic context, including cultural norms around work and the robustness of social safety nets.

This framework gives the intrinsic purpose of education a concrete agenda. It does not rest on a sentimental appeal to "the whole person." Schools and universities cannot guarantee that a transition out of work will be voluntary. They can, however, cultivate the second factor: the interests, communities, and practices of contribution that supply structure, purpose, and social connection when employment does not. It remains unclear how far evidence from retirees or lottery winners transfers to an involuntary, society-wide contraction of work. The review itself frames these as lessons for prospective transformations rather than predictions.

The organizational imagination matters as well. Vijay, Berkowitz, Huybrechts and colleagues (2025) reviewed fifty years of research on alternative organizing, including cooperatives, commons, and other non-dominant forms. They propose that such organizing is constituted through imaginaries, alterity, and subjectivities. An education that takes post-employment life

seriously could introduce learners to these plural ways of organizing contribution and livelihood, rather than presenting the wage relation as the only model of a productive adult life.

A common move in this debate is to argue that creativity, contextual reasoning, and ethical judgement are capabilities no algorithm can fully replicate. On that view, they are also precisely the capacities that purely vocational education has historically neglected. The second half of this claim is well supported. The first is increasingly disputed, and educators who build their case for the humanities on machine incapacity are building on unstable ground.

McLoughlin (2024) argues that deep-learning models producing novel images in a vast range of subjects and styles expose serious inadequacies in our ethical, aesthetic, epistemological, and legal frameworks for categorizing art. In his view, convincing AI creative output, artistic or literary, requires a re-appraisal of foundational ideas about authorship and creativity, with significant long-term implications for the humanities. The same questions confront assessment of student work (see Q102).

Butaru and Mateescu (2025) document how this plays out in practice. Their study of graphic illustrators in Eastern Europe during the emergence of text and image generators draws on cultural materialist anthropology. It explores why "undervalued talent" is so easy to price, and why skills sometimes gain more appreciation than creativity. They also describe the latent tensions that arise when automation disrupts long-standing beliefs about the role of creativity, talent, and labour in the economy. Their ethnographic, regionally specific evidence suggests that creative capacity offers no automatic labour-market shelter.

The conclusion for education is subtle. Creativity and judgement should be cultivated not because they guarantee employability, which they may not, but because they are constitutive of a flourishing life whether or not markets reward them.

Theoretical political economy offers a contrasting frame. Zhang (2026), in an explicitly conceptual study awaiting empirical validation, treats AI as constant capital rather than labour and argues that living labour remains the sole source of new value. On this account, human work does not disappear in value terms; what changes is the distribution of the surplus it produces. The disagreement between this view and displacement-focused accounts is unresolved.

Structurally, the most significant shift may be temporal.

The Cognizant chief executive, writing in Fortune, argues that in a future augmented by AI, learning should take place throughout adulthood alongside careers, providing on-ramps to new chapters. In this view the lines between learning and work are already dissolving. Analysts at Boston College's Center for International Higher Education draw the institutional consequence. Higher education will have to fundamentally rethink its educational portfolios and reassess the competencies developed during initial education and lifelong training. It will also need to monitor the employability of older cohorts, not only recent graduates.

The old model was to front-load credentials in youth and deploy them for decades. It cannot survive an environment in which, according to the World Economic Forum's Future of Jobs Report 2025, thirty-nine percent of key job skills are projected to change by 2030. Adult retraining and mid-career systems, long the neglected margin of education policy, move to its centre (see Q130).

The European firm-level evidence from Vodă and colleagues (2025) offers a modest encouragement. Firms that digitalized most also invested more in staff training. Lifelong learning, then, need not be imposed on employers entirely from outside. Lenzi and Panzera's (2025) findings on wage pressure caution, however, that access to such learning may be distributed unequally across regions and sectors.

What this moment demands is therefore a philosophical reorientation, not merely a curriculum update. Education systems must hold two truths at once. Practical adaptability to AI is urgently necessary. Yet reducing education to that adaptability would produce people well suited to a labour market that may be smaller than anticipated, and poorly equipped for everything else.

The wellbeing evidence reviewed by Chan and colleagues (2026) suggests what is at stake. Where people lose work involuntarily, lack alternative sources of meaning, and live in weak social contexts, outcomes are poor. Education can influence at least the second of these conditions directly. The decoupling of learning from employment, if it comes, need not be a catastrophe. That holds only if education has already developed an account of itself that does not depend entirely on the economy to justify its existence.

Q046 What is the role of education in a society where economic productivity no longer requires most human labor — education for meaning rather than for jobs?

21 citations · 21 sources · 5 cross-references

Claim 1 disputed

In a society where economic productivity no longer requires most human labour, education's central role would shift from preparing people for jobs to forming people for lives: cultivating judgement, civic capacity, creativity and the ability to construct meaning. That shift would mark a sharp break with the past. The industrial model of schooling was, at its core, an economic instrument. It sorted children into future roles, credentialed them for employers and measured success by earning capacity. That arrangement made rough sense when human labour was the main engine of economic output.

The Learning Counsel describes the collision now visible as one between education systems built in the industrial age and technologies of an exponential age. UNESCO frames the present moment in terms of disruptions, dilemmas and directions rather than settled outcomes. Writing in Entrepreneur, commentators observe that AI, funding cuts and shifting skill demands are together redefining what schools and universities are expected to deliver. Taken together, these accounts show that the question of what schooling is for has moved to the centre of education policy. For most of the twentieth century it was treated as a philosophical afterthought, because the answer seemed obvious: schooling was for work. Once that answer weakens, the question becomes practical and urgent.

The scale of coming displacement is contested, and an honest answer to this question has to begin by saying so. At the high end, an estimate attributed to Oxford Economics, as reported by the Tech for Impact Summit, holds that up to 300 million full-time jobs globally could be

exposed to AI automation by 2030. Exposure is not the same as elimination, but the figure signals the order of magnitude some forecasters have in mind. Commentary in Entrepreneur adds a more pointed observation. Current institutions are still educating for a workforce defined by static roles, predictable career ladders and siloed knowledge, which is precisely the category of work most vulnerable to automation.

The empirical economics literature is considerably more cautious, and in places it points the other way. Saam (2024) reviews theoretical and empirical arguments about AI's macroeconomic effects. She concludes that research has so far found no indication that the productivity effects of AI's diffusion are likely to exceed those of the internet boom around 2000. She also notes that a calibration exercise by Acemoglu suggests the effects might be much lower. Shen and Zhang (2024) used panel data from 30 Chinese provinces between 2006 and 2020, with two-way fixed effects and two-stage least squares estimation. They found that installing industrial robots increased overall employment. In their account, gains in labour productivity, capital deepening and a finer division of labour offset the damaging effect of robot adoption on jobs. Saba and Ngepah (2024) studied BRICS economies from 2012 to 2022 and found a long-run equilibrium relationship between AI investment, employment and growth. They also found that the causal patterns differed between the employment and growth models, and that governance quality conditioned the outcomes.

The post-work premise is therefore a scenario, not a forecast on which the evidence converges. Davidson (2024) supplies a further caution from institutional economics. AI may reduce bounded rationality by processing data and generating predictions, but it cannot resolve the Hayekian knowledge problem. On that view, the economy will continue to depend on dispersed human judgement in ways that automation does not erase. Even so, the question deserves a serious answer. A partial post-work transition, in which large groups face precarious, intermittent or diminished paid work, would still unsettle the economic rationale on which mass schooling rests (see Q128 on entry-level work and the school-to-work transition).

What fills the gap depends on what one believes education is fundamentally for. The dominant response from policy circles remains instrumental. It calls for reskilling, pivoting and preparing students for the next economy, rather than acknowledging that the economy may need fewer of them. The growth economics literature offers some support for this response. Gomes (2025) models the gradual substitution of labour by automated processes and identifies a symbiotic relationship between AI expansion and human capital accumulation as the driver of sustained

long-term growth. His model is equally clear, however, that who benefits from labour-saving technology depends on institutional arrangements. In one version of the model, a capitalist planner optimises while heterogeneous workers live hand to mouth. In the other, every agent plans over time and may be both worker and investor. The distributional outcomes differ sharply between the two. Human capital, in this framing, sustains growth without guaranteeing that the people who hold it share in the gains.

Scholars writing on education for a post-work future have pressed the critique further. They argue that continued pressure on educational systems to perform for the economy will deepen social conflicts over access and stratification. Narrow human capital models, they contend, reduce the capacity of formal education to meet the wider challenges of a post-work landscape. Commentators on post-work society make a related point. They observe that the question of what gives life meaning once economic productivity stops being society's organising principle is moving from academic journals onto policy agendas. Put plainly, the utilitarian framework undermines itself as automation advances. The more thoroughly machines take over economically productive tasks, the weaker the case for an education justified only by productivity becomes. The rise of alternative credentials shows how persistent the instrumental logic remains, even as it is reconfigured (see Q262).

A more durable alternative reaches back past the industrial era entirely. The Roman artes liberales were a programme of study meant to give citizens the skills free persons needed to flourish and to take part actively and wisely in civic life. Liberal education in this original sense prioritises the cultivation of intellectual faculties, critical reasoning and moral discernment. It seeks to free the mind from narrow utility and to build habits of inquiry and ethical judgement that let individuals pursue knowledge for its intrinsic value. The irony is sharp. An education designed for people who did not need to work for a living may be exactly what a post-work society requires.

Advocates of liberal education as civic education argue that, in seeking to know what is good, it cultivates minds that help people lead flourishing lives of purpose and meaning. It also prepares them to participate better in shared political life. On this account, practising liberal learning equips a person with habits of mind and character for constructing a vision of the good life and the good society. Such an education forms students with the hearts and minds of engaged citizens, who have thought deeply with others about what it means to be human. The American Academy of Arts and Sciences, writing in Daedalus, advances a parallel agenda under the name

of the positive humanities. It treats human flourishing as an explicit aim of humanistic study rather than an incidental by-product.

These arguments are normative rather than empirical. They describe what liberal education aims to do. They do not show, with controlled evidence, that it produces flourishing at scale. That limitation matters, but it does not invalidate the vision, which also bears on which shared culture and values education should transmit (see Q049).

This is not mere nostalgia. The Stanford Accelerator for Learning frames the question as how, not whether, to prepare students for an AI-shaped world: how to do so while keeping human flourishing, not just employability, at the centre. Microsoft's education blog likewise presents human-centred foundations for reshaping education around AI, although a vendor's framing should be read as advocacy rather than research. Stanford's Rob Reich has highlighted the tension between using AI for automation and using it for augmentation. He argues that building AI tools to mimic humans is misguided, and that the focus should be on how AI can amplify and cultivate human intelligence.

Recent research gives this distinction more analytical precision. Fügener, Walzner and Gupta (2025) model judgement tasks and validate the model with experimental data on image classification. In their optimal configurations, AI automates relatively easy tasks and augments humans on tasks where human and AI performance is similar, while humans work without AI on relatively difficult tasks. The balance between automation and augmentation depends on the type of human-AI complementarity involved. Zhou and Lee (2024) analysed more than 4 million artworks from over 50,000 users. They found that text-to-image AI raised human creative productivity by 25 per cent and increased value, measured as the likelihood of receiving a favourite per view, by 50 per cent. Average content novelty declined, however, and both peak and average visual novelty fell. The artists who benefited most were those who explored more novel ideas, which led the authors to identify ideation and filtering as the skills that matter.

Both studies are narrow in scope, one confined to image-classification experiments and the other to a single creative platform. Still, they suggest that what remains distinctively valuable is judgement about what is worth doing, not execution. On this view, education's proper task is not to compete with machines. It is to develop capacities that machines do not supply: ethical reasoning, aesthetic experience, civic deliberation and the construction of a meaningful life.

Whether these capacities are structurally beyond machines, or merely not yet automated, remains unclear. The question also connects to how knowledge changes in value when it is no longer scarce (see Q003).

The deepest difficulty is maintaining a sense of purpose and identity in a world where traditional job roles have diminished. Writers envisioning a post-labour society argue that people must rediscover purpose beyond economic productivity, finding meaning in relationships, creativity, learning and contribution to their communities. Sterling's account of post-work society makes the same case, treating it as a cultural reorientation as much as an economic one. Whether institutions designed for granting credentials and sorting workers can reinvent themselves as schools for living remains genuinely open.

UNESCO warns that, depending on the choices made now, the future of education will be marked either by expanded opportunity or by deepened inequality. Broad syntheses of AI's social effects reach similar conclusions. Brandão (2025) stresses that proactive governance and ethical frameworks are needed if AI's benefits are to be realised while its risks are contained. Chhillar (2024) argues that AI's developmental value depends less on technological advance than on institutional capacity, regulatory oversight and equitable implementation. He identifies unequal digital access and workforce displacement as persistent risks. Both are reviews rather than original empirical studies, but they converge with the distributional warning in Gomes's growth model.

The material conditions cannot be separated from the philosophical vision. Meaningful education requires leisure, and the question of who has access to that leisure is a question of economic justice. An education for meaning that ignores economic justice risks becoming a privilege of those who are already free, much as the artes liberales once were. These are among the most consequential choices facing policymakers (see Q050). They bear on whether liberal learning becomes a common inheritance in a post-work society or a marker of its inequalities.

Claim 1 disputed

Managing the transition for workers whose skills are expiring faster than retraining systems can respond means separating their economic security from the speed at which those systems work. That requires income continuity during transition, infrastructure built for mid-career rather than only early-career moves, and mechanisms that share the gains of automation with those who bear its costs. Retraining alone, as currently organised, has not kept pace, and the evidence accumulated over decades suggests it is not becoming adequate fast enough to matter.

The arithmetic of the current moment is alarming. The World Economic Forum's 2025 Future of Jobs report, as summarised in industry analyses, estimates that workers can expect two-fifths of their existing skill sets to be transformed or to become outdated over 2025–2030. SHRM's 2025 research, reported in the business press, estimates that 19.2 million U.S. jobs face a high or very high risk of automation displacement across clerical, logistics, and finance work. Both figures are projections rather than observed outcomes, and their precision should not be overstated. Their direction is nonetheless consistent with a broader critique that retraining, treated for nearly a century as the default answer to technological displacement, has rarely delivered at the scale its advocates promise. The systems expected to absorb this disruption were not built for its scale or its velocity.

Velocity is the distinctive feature of the present problem. Earlier waves of displacement, from mechanised agriculture to offshored manufacturing, unfolded over decades and concentrated in identifiable regions and industries. Current projections describe a faster process spread across white-collar and service occupations at the same time. Institutions that respond on multi-year

planning and funding cycles therefore face a structural lag that more money alone may not close.

The public architecture of worker support shows a structural underfunding that predates the current crisis. By one widely cited estimate, federal workforce development spending has fallen from 0.35 percent of GDP in the 1980s to under 0.1 percent today. In absolute terms, the United States spends roughly five billion dollars a year on public workforce programs. That sum is modest beside the scale of projected displacement and beside the estimated $380 billion spent across the broader retraining industry, public and private, whose outcomes critics describe as weak despite ninety years of evidence. The Bipartisan Policy Center's guide to displaced-worker programs describes a fragmented landscape. Unemployment insurance, the Workforce Innovation and Opportunity Act (WIOA), and trade-specific assistance each serve different populations under different eligibility rules, and none is designed for rapid, economy-wide skill obsolescence.

The historical record of dedicated programs such as Trade Adjustment Assistance (TAA) is damning across administrations and decades. The Washington Center for Equitable Growth's review of past trade adjustment policies concludes that efforts to respond to economic displacement have not lived up to the hopes of those who devised them. It attributes this to failures of both design and implementation, with major consequences for workers and for the broader political landscape. TAA is the closest historical analogue to an AI-displacement program: a targeted response to a recognisable external shock. Its shortcomings therefore carry weight. They suggest that the problem is not simply insufficient funding but programs that reach too few eligible workers, steer them into training of uncertain value, and leave them without income support long enough to complete it. These findings are established in the sense that multiple evaluations across decades point the same way, though they concern trade displacement and must be extrapolated cautiously to AI.

The private sector offers some countervailing examples, but they remain exceptional rather than systemic. The most frequently cited is AT&T, which committed one billion dollars to a multiyear program called Future Ready to retrain about 100,000 employees for new technology roles. The company partnered with online education providers and universities to build tailored courses, and by 2020 tens of thousands of workers had reportedly completed training in software development, data science, and cybersecurity. The account circulates largely through vendor and corporate sources rather than independent evaluation, so it demonstrates feasibility

more than effectiveness. Such cases show that large-scale internal retraining is technically possible within a single well-resourced firm that chooses to undertake it.

That choice appears rare. A 2025 Brookings survey of human-resources leaders at companies that had deployed AI tools found that only 7 percent were working on reskilling strategies for AI-affected roles, while 62 percent were focused on piloting AI in HR management itself. Firms, in other words, are more likely to automate their human-resources departments than to retrain the workers that automation displaces. Brookings' broader argument about occupational transitions with dignity places responsibility partly on employers, who hold the earliest information about which roles are changing and could warn and prepare workers well before layoffs.

A related question is whether displaced workers might create their own opportunities. Fossen, McLemore and Sorgner's 2024 review of AI and entrepreneurship, drawing on German Socio-economic Panel survey data, reports that entrepreneurs, particularly those with employees, are aware of and use AI technologies significantly more often than paid employees. The review also examines how AI may affect entrepreneurship indirectly through local and sectoral labour markets, distinguishing technologies designed to automate jobs from others. The finding is correlational. It cannot show that AI adoption causes entrepreneurial success, nor that displaced employees could readily follow this path, and the authors caution that ambiguous definitions of AI in empirical studies may obscure the evidence. Self-employment is at most a partial outlet, and it risks widening an existing gap in AI familiarity between owners and employees.

Three structural failures recur through the research with uncomfortable consistency, though the first remains contested. The standard retraining theory assumes that for every automated job that disappears, a new skilled job emerges elsewhere. Brookings-linked analysis suggests instead that technological change can reduce the number of middle-wage positions faster than workers can retrain into them. If so, no one can retrain into a job that does not exist. Optimists counter that historical waves of automation eventually generated more jobs than they destroyed, and the literature genuinely disagrees about whether AI will follow that pattern or break it. What is less disputed is that any eventual equilibrium may arrive too late for the workers displaced first.

Second, the people who need retraining most are often the least able to get it. Retraining takes weeks or months of classes, often without income, and workers living paycheck to paycheck

cannot afford to stop earning. Program completion is therefore selected for workers with savings, family support, or fewer care obligations. This selection effect also inflates the apparent success of programs that serve them.

Third, even when workers do retrain, the destination may be insecure. Research affiliated with the Harvard Kennedy School found that retraining raises earnings on average but produces smaller gains when workers move into occupations with high AI exposure. It concluded that retraining works best when it targets roles with long-term stability rather than roles vulnerable to further automation. This is a moving target, and existing programs have no mechanism to track it in real time.

Rahman and colleagues' 2026 framework for managing expiring knowledge offers useful vocabulary here, even though it concerns organisational information rather than worker skills. They distinguish four types of knowledge expiry: event-triggered, continuous decay, context-dependent, and structural. They propose strategies such as temporal tagging and decay monitoring so that knowledge systems respond to time rather than store information statically. Applied by analogy to workforce systems, the framework suggests that curricula and occupational classifications need explicit, regularly reviewed expiry assessments. Most current systems approve training lists that can outlast the relevance of the skills they certify. This application is the present author's extrapolation, not a finding of the study.

A further problem concerns what gets taught. The 2025 paper "Training for Obsolescence? The AI-Driven Education Trap" argues that the skills AI is perceived to be most useful in teaching, namely procedural and closed skills, appear to be the same ones most susceptible to workplace automation. The result is a potential trap in which educational systems inadvertently prepare workers for roles that will not exist by the time they finish their programs. This matters directly for AI-enabled retraining platforms, whose efficiency gains may be greatest exactly where their labour-market value is weakest (see Q130).

On what workers should learn instead, the evidence points in a consistent direction but remains thin. Oliveira, Carvalho and Faria's 2024 systematic review of the "Feeling Economy" analysed 21 studies following PRISMA methods. It identified three themes: the characterisation of multiple intelligences, the responses of employees and consumers to them, and AI's effects on job skills and tasks. The review highlights the possibility of significant job change and an increasing emphasis on skills related to feeling, empathy, and emotional intelligence, alongside

human–AI complementarity. A body of 21 studies is small, and the review maps a research agenda more than it establishes effects.

Profession-specific reviews suggest that even augmentation transforms the skills required rather than preserving them. Chávez-Díaz and colleagues' 2024 bibliometric analysis of Scopus literature from 2020 to 2023 concludes that accountants' and auditors' work will become increasingly computerised and that the professional profile must shift toward analysis in synergy with AI. Cetera and colleagues' 2024 narrative review in gynaecology notes that professionals worry AI may make certain specialists obsolete, while judging AI more likely to become a team member than a usurper. Van Zyl's 2026 commentary on psychologists warns that cognitive offloading and automation bias may erode clinical judgment, and that moral deskilling, technostress, and vendor lock-in threaten practitioner wellbeing. For transition policy, the implication is that workers who stay in place also need ongoing support, because augmentation can quietly hollow out expertise that later makes them vulnerable.

Current reform proposals cluster around three approaches, none yet proven at scale. The first is structural overhaul of public programs. As TechPolicy.Press notes in proposing WIOA reforms, workforce programs are currently judged on how participants are doing a year after completing training. That metric creates an incentive to nudge workers into the first available job rather than a better long-term alternative, and the authors argue that program incentives should instead reward long-term, meaningful employment. The second concerns income continuity. A 2024 study, discussed in Equitable Growth's review, found that wage insurance increased employment and long-run earnings by cushioning wage losses and encouraging displaced workers to accept new jobs. This suggests that bridging income, rather than mandating rapid retraining, may paradoxically produce better outcomes. The finding is promising but rests on limited evaluations. The third approach is distributional. Some economists propose sharing productivity gains more broadly through profit-sharing plans that extend to all employees, or through new taxes under which companies that benefit greatly from AI contribute to retraining funds or basic income for displaced workers. These proposals divide credible observers, who disagree about their efficiency, feasibility, and likely effects on investment.

What the evidence converges on, in Brookings' framing, is the need for a system that lets exposed and displaced workers prepare for and move into future occupations mid-career rather than only early-career. No country yet operates such infrastructure at meaningful scale. Its

design is bound up with how credentials signal competence (see Q262) and with how entry-level pathways are themselves being reshaped (see Q128).

The retraining gap is not primarily a pedagogical problem. It is a problem of political economy: the costs of displacement fall on individuals and communities, while the gains from automation accrue to firms and shareholders, and no durable mechanism yet redistributes between the two quickly or adequately enough. Zhang's 2026 conceptual analysis approaches the same asymmetry from a Marxian angle. It classifies AI as constant capital rather than labour, analyses new mechanisms of surplus-value distribution in platform economies, and proposes institutional frameworks for realising labour value. Zhang acknowledges that these propositions require empirical validation. One need not accept the labour theory of value to recognise the policy point both perspectives share: a just transition is ultimately decided by who captures the productivity gains, more than by the quality of any training curriculum.

Q048 How does AI in education affect democracy — the formation of citizens capable of judgment, deliberation, and resistance to manipulation?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

AI in education can either strengthen or erode the capacities democracy depends on, and current evidence points in both directions at once. It may deepen students' ability to judge, deliberate and resist manipulation when teachers use it deliberately to provoke inquiry. It may weaken those same capacities when it is deployed mainly to remove effort, tailor content and

supply answers. Democracy needs more than voters. It needs people who can form independent judgments, tolerate disagreement, deliberate with those who hold different views, and resist the sophisticated manipulation that modern information environments make ever easier. Whether educational AI builds or depletes these capacities is one of the most consequential questions now facing schools.

The stakes are clearest in recent political and philosophical work. Subías-Beltrán and colleagues (2025) argue that AI systems increasingly shape not only the outcomes but also the conditions of everyday decision-making. In doing so, they directly influence the capacity for free and informed choice, which the authors call central to democratic participation. They also observe that most existing governance approaches overlook or marginalise autonomy. Schwarting and Reihlen (2026) frame the danger in Enlightenment terms. They ask whether AI leads humanity back into a 'self-imposed immaturity' that challenges autonomy, responsibility, individuality and human dignity. Hidalgo (2026) offers a necessary counterweight. He accepts that the dominant diagnoses in political research link digitisation to both post-democratic technocracy and resurgent populism. But he insists that a focus on risk must not obscure the genuine opportunities digital tools offer for participation and deliberation. Education sits at the hinge of this debate, because it is where the habits of autonomous judgment are first formed or first neglected.

The cognitive dimension is the most immediate concern. Research on AI's broader impact on human thought identifies a 'cognitive offloading effect': when mental functions are handed to AI, intellectual engagement can fall and critical thinking can weaken. This is not a fringe worry.

A 2025 study presented at the ACM CHI conference surveyed 319 knowledge workers. It found that generative AI tools often prompt a kind of quality-checking vigilance. The authors also highlight a key irony of automation, however. By mechanising routine tasks and leaving exception-handling to the human, automation deprives users of routine chances to practise judgment. Their cognitive capacities may then atrophy, leaving them unprepared when harder cases arise. Because these findings rest on self-reports from adults at work, they suggest rather than demonstrate a mechanism. The classroom is not exempt from this logic, and young learners may be more exposed to it than adults.

Work in educational settings points the same way, though the evidence remains early. A study of AI tutor features in high school STEM education suggests that AI assistance may be more effective for knowledge-based recall than for higher-order skills in Bloom's taxonomy. Those higher-order skills are analysis, synthesis and evaluation, which are precisely what democratic deliberation demands. An evaluation of generative AI in vocational education uses the term 'metacognitive laziness' for a related risk. Learners may let the tool regulate their thinking instead of monitoring their own understanding.

Sharadin (2026) gives this concern its sharpest philosophical form. He argues that we owe young people special moral consideration because of their developmental immaturity. We must not foreclose their futures by impeding the capacities they need for autonomous agency. On his account, 'extreme cognitive assistance' is help that is ubiquitous, domain-general and largely substitutive of the child's own effort. Children who rely on it routinely fail to exercise core regulatory skills: inhibitory control, working memory, cognitive flexibility and planning. Capacities that go unexercised predictably fail to develop normally. Sharadin adds that assistance need not be maximally substitutive to impede development. He also judges the prospects dim that compensating demand for cognitive exercise will arise elsewhere. His is a normative argument, not an empirical trial. Still, it names the democratic stake plainly: a citizen who never practised self-regulation is poorly equipped to deliberate.

Personalisation compounds the problem. Critics of high-level AI personalisation argue that over-tailored content may create 'filter bubbles' or 'knowledge silos.' In these, students are shielded from the productive struggle needed for deep conceptual change. This line of commentary, voiced for example on an education-technology company blog, draws an analogy with social media. Just as recommendation algorithms can narrow our worldview by showing us opinions we already hold, hyper-optimised AI tutors might stunt intellectual resilience by removing the struggle from learning. The same commentary links this to collective life. At the social level, algorithmic personalisation limits the diversity of opinions a person meets and can lead to homogenised thought and polarisation. This is a plausible argument from analogy, not research evidence. The direct effect of adaptive tutoring on students' political or civic outlooks remains unclear.

Ferdman (2025) supplies the stronger theoretical case. She draws on the idea of public reason: a standard of reciprocal justification among citizens who disagree. On the 'civic friendship' conception she adopts, public reason is grounded in embodied joint action and shared

experience. It therefore requires skill in human capacities such as justice, joint action, patience and moral attention. AI tools such as recommender systems, personalised AI aids and AI deliberation platforms afford disembodied, mediated interaction. Ferdman argues that they threaten to deskill people in these capacities because they offer fewer occasions to practise them. She grants that such tools can bring efficiency, scale and better understanding of policy issues. On balance, however, she concludes that their uncritical integration could erode the capacities public reason needs. A student raised inside a perfectly tailored learning environment may develop competence within a narrow range. Meanwhile, the student may lose both the habit of encountering genuinely alien ideas and the appetite for doing so. What shared culture education should transmit against such fragmentation is taken up directly elsewhere (see Q049).

Today's learners are digital citizens first. They meet AI in social media feeds, search engines and recommendation systems long before they meet it in a lesson. Democratic competence must therefore include a critical understanding of AI itself. As the European Democrat project argues, learners need to recognise how AI shapes their exposure to information and how biases can be embedded in systems. They also need to see how automated tools can empower or constrain civic engagement. This is a relatively new but serious demand: the citizen must now read not only texts but the architectures that select them.

Palese (2026) shows why this matters. He introduces the concept of 'Artificial Truth' to describe how recommendation systems, generative AI and automated fact-checking act as epistemic devices. These devices shape what counts as credible, authoritative and true in public discourse. He traces three shifts. First, epistemic authority moves from institutional expertise towards platform-native capital based on engagement and affective proximity. Second, generative AI produces 'synthetic truth' through linguistic fluency rather than propositional understanding. Third, algorithmic fact-checking converts situated judgments into probabilistic classifications that are presented as neutral. A student who takes a fluent chatbot answer as authoritative has learned the very habit Palese warns against.

Seceleanu and Stoia (2026) extend the concern to societal security. They argue that cognitive liberty, mental privacy, mental integrity and cognitive sovereignty become strategically relevant once AI-mediated systems displace human agency. Protecting people's capacity for judgment becomes part of protecting collective stability. Both contributions are conceptual, not empirical.

Together, though, they explain why AI literacy cannot be treated as a technical add-on to civic education.

Yet the picture is not only one of erosion. Civic educators writing in the eJournal of Public Affairs argue that AI could move students beyond memorising facts. It could give them an 'opportunity to practice the skills of negotiation, the skills of engagement, the skills of give-and-take' that democratic life requires. The Democrat project notes that AI-powered platforms can simulate scenarios involving misinformation. These let learners practise telling credible content from misleading content, a skill whose civic importance is self-evident.

Research on teaching AI literacy directly to young adolescents is promising. A study of two middle-school modules on algorithmic bias and filter bubbles starts from a specific concern. Adolescents' nascent digital footprints make them particularly susceptible to misrepresentation by AI systems. In early trials, the modules produced substantial learning gains. These are early, bounded results. It remains unclear whether such gains persist, or whether they translate into changed behaviour online or in political life.

Rieger and Haim (2026) offer a broader framework for this optimism. They describe AI as both a source of threats to democratic discourse and a potential remedy. On the threat side, it can amplify harm through automated content generation, coordinated manipulation and the algorithmic mainstreaming of borderline content. On the remedy side, they list proactive strategies such as prebunking, friction design and AI-mediated dialogue. They argue that effective counter speech increasingly depends on human-AI collaboration. In this model, AI supplies factual resources, emotional scaffolding and scale, while humans preserve the authenticity and agency that make counter speech normatively meaningful. Their inclusion of friction design is telling for education. It concedes that a democratic use of AI may sometimes need to slow users down rather than speed them up.

The condition on which the optimistic case depends is demanding. Heafner and Maxwell (2025) set out five pillars for using AI in social studies. In their account, genuine civic co-intelligence emerges when teachers and students co-create a culture of inquiry, skepticism and ethical responsibility around AI use. AI then becomes a catalyst for deeper thinking and democratic citizenship, not a substitute for creativity, empathy or human judgment. That condition places heavy weight on teachers' professional discretion. It is therefore threatened wherever AI use is mandated from above (see Q214).

A cross-faculty study of AI-enhanced civic character education adds a further caution. It finds evidence that teacher care and relational engagement are fundamental to students' character development and well-being. This raises a real doubt about whether AI-mediated education can replicate the affective and relational dimensions that authentic moral growth requires. Ferdman's (2025) emphasis on embodied joint action points the same way. The capacities of civic friendship are cultivated among people, not between a person and an interface.

The literature does not agree on how far these risks can be managed. Hidalgo (2026) and Rieger and Haim (2026) see a path in which careful design and governance keep the opportunities while limiting the harms. Subías-Beltrán and colleagues (2025) propose diagnostic questions that link design choices to concrete dimensions of autonomy, with responsibility distributed across organisational roles. Sharadin (2026) and Schwarting and Reihlen (2026) are more pessimistic. Sharadin notes that the world's largest technology companies are investing hundreds of billions of dollars to build precisely the kind of assistance he considers developmentally harmful. Who profits from student-facing AI, and how its business models shape design, is therefore a democratic question as well as an economic one (see Q131).

The deepest worry, then, is not that AI will teach students wrong answers. It is that AI deployed without pedagogical intention will teach students to outsource the hardest parts of thinking: sitting with uncertainty, weighing competing claims, arguing a position across genuine disagreement. No algorithm can practise these skills on a student's behalf. They require friction, and friction is precisely what the most commercially successful AI tools are designed to remove. Decisions about where to preserve that friction in schools rank among the most consequential choices now facing policymakers (see Q050).

Q049 What shared human culture and values should education transmit when AI fragments information into personalized realities?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Education should transmit three things in common when AI fragments information into personalized realities. The first is a disciplined capacity for epistemic agency. The second is a shared commitment to evidence and to collectively validated ways of knowing. The third is a lived practice of solidarity built through encounter with people unlike oneself. Together these sustain a shared world in which citizens can at least argue about the same facts. The deepest threat posed by AI-driven personalization is not misinformation in the conventional sense. It is the dissolution of that shared world.

The technical trajectory of the field makes this concern concrete. A recent position paper argues that large language models should learn individual rather than aggregated human preferences, and it acknowledges the societal cost of that design choice. If everyone interacts with differently personalized systems calibrated to their particular preferences and beliefs, shared reality and common knowledge may erode. The engineering case for personalization is real. Systems tuned to an averaged user serve many actual users poorly. But the same logic that improves individual fit loosens the common reference points on which public reasoning depends. This is the civilizational wager now sitting, largely unexamined, at the heart of educational policy.

The question for educators is therefore not only what children should learn, but what they must learn in common. It is also why that commonality is itself a moral and political good. Carlos Alberto Ávila Araújo (2026) frames a related problem through the concept of information integrity, which the UN and G20 have proposed against disinformation, hate speech and conspiracy theories. Analysing institutional documents through Habermas's theory of communicative action, Araújo argues that generative AI poses new challenges to the concept's three founding principles: accuracy, consistency and reliability. He also notes that these

challenges are not yet reflected in the documents that define the concept. A dual taxonomy of AI's opportunities and risks for democracy makes the parallel point that personalized content can quietly hollow out the informational preconditions of self-government.

The problem is more layered than early warnings about filter bubbles suggested. A social-psychological analysis published in Frontiers in Psychology observes that personalized media environments expose individuals to information aligned with their existing beliefs. This raises concerns about polarization, intergroup hostility and the erosion of shared political reality. Its central contribution is to reject a purely technological account. Filter bubbles emerge from the recursive interaction of three forces: motivated cognitive processing, identity-based social networks and algorithmic amplification. In that analysis, emotion operates across all three layers. The implication for education is sobering. Removing a recommender system would not by itself restore a common world, because the habits of selective attention it reinforces are partly human habits that schooling must address directly.

AI does not simply distort the information landscape from the outside. It reshapes the internal habits by which people seek, weigh and revise knowledge. A Frontiers in Education study of epistemic authority in generative AI learning spaces argues that these systems affect not only beliefs but belief revision itself. In the classroom, this means students may update their knowledge in response to algorithmic authority, without recourse to further justification or reflection. A fluent, confident and personalized answer can acquire the standing once reserved for a textbook or a teacher, while lacking the accountability structures that made such authorities trustworthy. The question of how a generated answer differs epistemically from a discovered one is taken up in its own right elsewhere (see Q005). For present purposes, the relevant point is that fragmentation operates on two levels at once: what people believe, and how they come to believe it.

Araújo's (2026) Habermasian framing sharpens why this matters collectively and not merely individually. Communicative action presupposes participants who can raise and redeem validity claims against a background of shared understanding. When the background itself is personalized, the conditions for reaching understanding are weakened before any argument begins. How large this effect is in practice remains unclear. The filter-bubble literature itself disputes the magnitude of algorithmic, as opposed to self-selected, exposure effects, and the educational evidence specific to generative AI is still thin.

This is where the educational stakes become philosophical rather than merely technical. Drawing on Wieczorek's 2025 analysis, a commentary from the National Education Policy Center argues that the values underpinning current educational AI work directly against much of how democratic education has been understood since John Dewey. Those values are individualism, mastery-based learning and the automation of teaching. Personalized learning optimizes the individual learner's trajectory through content. Democratic education, by contrast, has always been partly about friction: encountering minds unlike one's own, negotiating disagreement, and building the civic capacity to inhabit a world held in common. Wieczorek's conclusion is pointed. The current push for educational AI is producing technologies that diminish students' opportunities for communication and collaboration with others.

The literature does not speak with one voice here, and the disagreement should be stated plainly. Empirical work on personalization reports genuine gains. Junzhen Wang (2026) ran a 12-month longitudinal experiment with 360 children with special needs in China. The study reports significant improvements in attention, memory and problem-solving relative to traditional methods, and the author attributes neuroplastic changes in key brain regions to the system. Effects varied by disorder type, including ADHD and autism spectrum conditions. Wang also reports a dose-response relationship between system usage and cognitive gains, although the abstract leaves open whether the design separates usage from other learner differences. The author also flags challenges of resource equity and teacher adaptability. Jurgita Bagdonaitė and Valentina Dagienė (2025) synthesized 94 empirical studies of AI in primary education from 2020 to 2025. They find that AI adds most value when it personalizes feedback and practice, scaffolds inquiry and computational thinking, and supports teacher decision-making through learning analytics. Reported gains include reading fluency, problem-solving, motivation and participation among diverse learners.

These findings do not refute the democratic critique, but they reframe it. The benefits Wang and the Bagdonaitė and Dagienė review document concern individual cognitive and skill outcomes. The Deweyan concern is about what happens to the shared, deliberative dimension of schooling when individual optimization becomes the organizing principle. Notably, Bagdonaitė and Dagienė find that the most sustainable outcomes came from human-in-the-loop approaches in which teachers interpret and moderate AI insights. Even the strongest case for personalization therefore depends on a human, relational frame around the technology. The related risk that

individualized pathways harden into algorithmic determinism is examined separately (see Q013).

What, then, should education transmit? Three clusters of value emerge from current scholarship as non-negotiable, whatever AI systems can deliver efficiently.

The first is epistemic agency: the cultivated capacity to interrogate sources, tolerate uncertainty and resist the seduction of algorithmic fluency. A recent analysis of AI in education beyond learning outcomes argues that tools prioritizing speed and convenience risk three harms: amplifying automation bias, reducing cognitive struggle and weakening critical thinking. Its remedy is that AI must preserve cognitive friction. It should prompt retrieval, offer delayed feedback and frame uncertainty as opportunity, so that it fosters the intellectual resilience and critical thinking that democratic societies require. This value cannot be transmitted by software alone. It requires teachers who model doubt, not just delivery. The Frontiers analysis of epistemic authority reinforces the point. If students learn to defer to algorithmic outputs without justification, the habit of asking how anyone knows something is lost precisely when it matters most.

The second is shared factual ground: a curriculum that insists certain things are true, contested or false independent of any individual's preference profile. The dual taxonomy of AI and democracy warns that algorithmic filtering and personalized content can nudge people toward particular viewpoints without their awareness. This limits exposure to diverse information and weakens their capacity for independent thought. The resulting manipulation diminishes people's ability to make informed choices and undermines democratic participation. Education's answer must be a commitment to evidence, method and the disciplines that have developed collectively validated ways of knowing. These include scientific reasoning, historical analysis, literary interpretation and mathematical proof. Araújo's (2026) three principles offer a useful vocabulary for what such a curriculum protects. Accuracy concerns correspondence to evidence. Consistency concerns coherence across sources and occasions. Reliability concerns trustworthy procedures for producing claims. A personalized system can be locally accurate while undermining consistency across users, which is exactly the property a common curriculum exists to secure.

Neither value implies hostility to AI. The argument is that these goods must be designed for deliberately, because the default incentives of engagement-optimized personalization run in the

opposite direction.

The third value is solidarity through encounter: the experience of being educated alongside people whose lives, backgrounds and conclusions differ from one's own. The European DEMOCRAT project describes education for democracy as a holistic and participatory approach. It aims to foster the knowledge, skills, values and attitudes that active and responsible citizenship requires. The project's account goes beyond textbooks, emphasizing experiential and inclusive learning that strengthens democratic competencies such as critical thinking, dialogue, agency and meaningful participation. No AI tutor, however sophisticated, replicates the moral education that occurs when a classroom must reach understanding across genuine disagreement.

A shared culture need not mean a single, homogenized one. Simona Tiribelli and colleagues (2024) note that AI now analyses vast historical datasets and catalogues cultural collections at scale. They show that this raises unresolved ethical questions of authenticity, subjectivity and interpretive bias in AI-reproduced or generated works, and they observe that these questions remain largely unaddressed in scholarship. Huimeng Wang and colleagues (2025) propose guidelines for the sustainable use of AI in heritage preservation. Their guidelines stress inclusive data governance, protection of data authenticity, AI as a complementary rather than substitutive tool, and balancing innovation with cultural values. They illustrate these with cases including educational dissemination through Google Arts & Culture. For education, the lesson is that cultural inheritance can be widely shared through AI, but only if questions of authenticity and interpretation are kept visible rather than smoothed away by fluent generation.

The common ground can also draw on plural moral traditions. Milton Maldonado and Daniela Córdova-Pintado (2025) present Indigenous Andean ethics of reciprocity as both epistemology and moral system. Their sources are Mauss's theory of the gift and practices such as ayni (reciprocal labour), minka (collective work) and randi-randi (generalized reciprocity). In this framework, giving, receiving and returning are sacred obligations that secure continuity, balance and mutual recognition across generations. Wealth is understood as relational abundance, measured by kinship networks and the capacity to meet communal obligations. Such traditions offer a counterweight to the individualism Wieczorek identifies in educational AI, and a reminder that a curriculum can be common without being culturally narrow. Jeffrey Gardiner's (2026) theory of knowledge capital adds an economic register. It distinguishes commons and public knowledge from enclosed forms and names the risk of cognitive

enclosure. Read alongside the educational literature, this suggests that shared knowledge is a form of public infrastructure whose governance, not just its existence, determines who benefits from it.

These three values converge on formation rather than information. Laura Maska, Dimitrios Kalamaras and Charalambos Tsekeris (2026) argue that higher education remains governed by a scarcity model built on knowledge transmission, durable credentials and economic productivity. They claim this model is structurally misaligned with societies shaped by AI, ecological destabilization, labour-market reconfiguration and declining institutional trust. In their account, the central challenge is shifting from knowledge scarcity to power abundance. The deeper crisis is a deficit of formation: universities have underdeveloped the human capacities needed to use technologically amplified power wisely, meaningfully and responsibly. Their proposed first principle, flourishing stewardship, means cultivating persons and institutions able to pursue meaningful lives while preserving the conditions for shared human and planetary flourishing. The argument is conceptual, built on a systematized scoping review rather than outcome data. It aligns closely with questions about whether knowledge loses value when no longer scarce (see Q003) and about education for meaning rather than employment (see Q046).

The analysis of AI in education beyond learning outcomes states the stakes directly. An ethical use of AI in education is about preserving education as a space for autonomy, critical inquiry and democratic formation. If AI systems undermine these values, they risk weakening not only learning outcomes but the social institutions that depend on educated, reflective and empowered citizens. The evidence reviewed here supports a cautious synthesis. Personalization appears to deliver real individual gains, particularly when teachers remain in the loop. Whether it erodes common knowledge at scale remains unclear and contested. Education therefore needs to secure the commons by design rather than assume it will survive by default.

The curriculum of the future will need to be deliberately, even stubbornly, common. Uniformity is not a virtue in itself. The reason is that a democracy requires citizens who can, at minimum, argue about the same world.

Q050 Which current decisions about AI in education do researchers and policymakers identify as most consequential, and on what grounds?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Researchers and policymakers increasingly identify three clusters of present-day decisions as the most consequential for AI in education. The first concerns whether AI is allowed to substitute for the cognitive effort through which learning happens. The second concerns whether access to well-guided AI use is distributed equitably or along existing lines of privilege. The third concerns whether governance can keep pace with the incentives to deploy quickly. The grounds offered differ by cluster: developmental risk to skills and habits, the amplification of educational inequality, and structural pressures that reward speed over evaluation. Underlying all three is a judgement about irreversibility, the sense that choices made in a period of rapid, improvised adoption may harden into institutional architecture that outlasts the people who made them.

History rarely announces the moments that will matter most, but there are reasons to suspect that the present is one of them. Viewed from 2050, this decade may look like an inflection point comparable to the arrival of mass printing or compulsory schooling. In such periods the architecture of human learning was renegotiated under enormous pressure, and the consequences outlasted everyone who made the choices. The decisions now being taken are rushed, improvised and only partially understood. Commentators on higher education such as Legatt (2025), writing in Forbes, frame the coming year as one in which a small number of institutional AI decisions will define the sector's trajectory. That framing is journalistic rather than empirical, but it captures a widely shared intuition that the window for deliberate choice is narrow. The International AI Safety Report 2026 gives the intuition more sober grounding. It

observes that organisational and governmental incentives to deploy AI systems quickly can limit opportunities to evaluate their effects carefully and to implement appropriate safeguards. What makes a decision consequential, on this account, is that it shapes conditions that are hard to observe and harder to reverse, as well as producing immediate outcomes.

The decisions most likely to be judged harshly in retrospect concern the heedless substitution of AI for cognitive effort. The scale of the shift is documented in RAND's American Youth Panel. The share of middle-school-and-older students who reported using AI for help with homework rose from 48 percent in May 2025 to 62 percent in December 2025. If that trajectory continues unchecked, it points toward a generation that has rarely had to sustain the productive discomfort of not knowing. Whether such a generation will in fact emerge remains unclear. Usage figures say nothing by themselves about how the tool is used, and that is precisely the variable on which outcomes appear to turn.

The emerging research is nonetheless sobering. A study of learners' AI dependence published in Acta Psychologica (2025) reports that overreliance on AI tools is associated with declines in critical and analytical thinking. The association is strongest when students become heavily dependent on AI-generated content, and over-reliance is also linked to diminished creativity and increased dependency. The study identifies fatigue as a psychological mechanism and AI literacy as a social buffer. Its findings are correlational, so they show an association between dependence and weaker critical thinking rather than proof that one causes the other. A review of generative AI and personalised learning in Social Sciences & Humanities Open (2025) adds a more specific pattern. The largest gains from AI assistance appear at lower levels of the cognitive taxonomy. This suggests AI may be more effective for knowledge-based recall than for the higher-order thinking of analysis, synthesis and evaluation. The gap between recall gains and higher-order gains is the same uncertainty that runs through the broader tutoring evidence base (see Q051). Work on vocational education reaches a similar conclusion through the lens of co-design (arXiv, 2025). It reports that generative AI can shift effort away from the self-regulatory work learners would otherwise perform, a pattern its authors call 'metacognitive laziness'.

The International AI Safety Report 2026 states the deeper stakes plainly. Children's early interactions with AI systems may influence how their key skills and habits develop over time. The report adds that it can be difficult to assess whether observed changes in behaviour are short-term adjustments or more persistent shifts that could affect autonomy. This acknowledged

difficulty is itself a reason the decision is consequential. Harms that are slow and hard to measure tend to be discovered late, after the habits they concern have already formed. The same concern extends to dispositions such as curiosity, which answer-on-demand tools may either weaken or redirect (see Q105).

Students themselves already sense the danger. In the same RAND panel, 67 percent of students in December 2025 agreed that the more students use AI for schoolwork, the more it will harm their critical thinking skills. That figure was more than ten percentage points higher than ten months earlier. Usage and concern are therefore rising together. A society whose children recognise a trap they feel unable to avoid has failed at the level of institutional design, not individual virtue. The finding shifts responsibility away from exhortations to student self-discipline and toward the choices that schools, systems and vendors make about how AI is embedded in learning tasks.

A second class of decisions concerns equity, and here the grounds are distributive. Who benefits from AI in education depends on the conditions under which it is introduced. An Emerald Publishing call for papers on AI-integrated education (2025) frames the problem directly: unequal access to AI is widening the gap between privileged and underprivileged learners. As a call for papers it states a research agenda rather than a finding, but the agenda reflects a growing concern in the field.

EdTech Hub's AI Observatory (2025) has begun mapping the emerging geography of this divide, and its distinction is subtle and important. In tech-rich cities, students use AI to think critically and solve problems, with expert guidance ensuring that they learn rather than merely use. Elsewhere, students may have good connectivity but little oversight. There they tend to offload work to AI, gaining convenience while missing real learning. The divide this describes is less about devices and connectivity than about pedagogical scaffolding, which is far harder to distribute. Practitioner forecasts collected by eSchool News (2025) point in the same direction. They anticipate that fragmented adoption driven by decentralised decision-making will produce inequities, with some districts using AI effectively and others struggling to integrate it. These are predictions from educators and industry figures rather than research findings, and they should be weighted accordingly.

The cruel irony is that the same technology capable of acting as a private tutor for every child could be a democratising force of enormous potential. Instead, it risks reproducing and

amplifying the very hierarchies it might have dissolved. The 2025 review of generative AI and the educational divide puts the warning concisely: without adequate safeguards, the systems that promise to close learning gaps may reinforce them. Evidence from outside education hints at a further, less obvious mechanism. In a factorial survey experiment with 578 participants, Schenk, Müller and Keiser (2024) found that using AI was judged less morally acceptable than employing human agents for tasks such as cancer diagnostics. They also found that AI used in high-status organisations was judged more morally acceptable than AI used in low-status ones, and they detected no effect of anthropomorphic or gender framing. The study did not examine schools, so any extension to education is speculative. Still, it suggests that elite institutions may enjoy a 'moral surplus' that makes their AI adoption appear legitimate. Comparable adoption in under-resourced settings might then be read as cost-cutting. If so, equity decisions involve the social meaning attached to AI use as well as access and oversight. Who profits from these arrangements is a related and equally contested question (see Q131).

The third set of decisions concerns governance, and here the picture is more ambiguous. The Education Commission of the States (2025) reports that by April 2025 at least 28 US states had published guidance on AI in K-12 settings. This is an encouraging sign of institutional attention, but guidance documents are not the same as considered policy. Most are advisory, many were drafted quickly, and their effect on classroom practice is largely unmeasured. The pressure to adopt comes from vendors, from parents worried their children will fall behind, and from administrators attracted by efficiency. That pressure is structurally different from the pressure to reflect. The International AI Safety Report 2026 identifies this asymmetry as a general feature of AI deployment: incentives to move quickly can crowd out careful evaluation and safeguards.

Scholarship on AI governance more broadly helps explain why decentralised guidance may prove insufficient. Emery-Xu, Jordan and Trager (2024) develop a taxonomy of technology governance forms. Their analysis is oriented toward advanced AI with military and dual-use implications rather than toward schools. However, one of their conclusions travels well. They argue that subnational governance, though prevalent and capable of mitigating some risks, is insufficient when the individual rewards from societally harmful actions outweigh normative sanctions. Nationally enforced standards are more promising, in their analysis, but less viable in the 'race-to-the-bottom' environments that are becoming common. Education is not arms

control. Even so, the dynamic is recognisable in schools and districts that fear competitive disadvantage if they slow adoption while neighbours accelerate.

Bagonza and Ndungu (2026) offer a scenario-based forecast of generative AI regulation from 2025 to 2035. They identify two critical uncertainties: the degree of international regulatory coordination and the pace of advances in AI safety and interpretability. From these they construct contrasting futures. In 'Regulated Convergence', international cooperation strengthens and oversight institutions consolidate. In 'Fragmented Acceleration', geopolitical competition and institutional fragmentation hinder effective governance. Their forecast is qualitative and should not be read as a prediction. Its value for education is in showing that the governance environment surrounding school AI is not fixed, and that today's choices about coordination, transparency and oversight help determine which path becomes more likely.

A less visible governance decision concerns the people who will run these systems. Osadchyi and colleagues (2026) argue that AI-related harms are increasingly attributed to governance failures rather than isolated technical malfunctions. They identify recurring failure modes: authority drifting from human decision-makers to automated systems, diffusion of accountability, the accumulation of 'governance debt', and reliance on average-case performance metrics that obscure worst-case risks. Each has an obvious analogue in education. A grading or early-warning tool can quietly acquire authority it was never formally granted. Responsibility for a flawed recommendation can dissolve among vendor, district and teacher. A tool that performs well on average can fail the students who most need it. The authors' exploratory survey of senior university students produced an AI Governance Readiness Composite Score. They are explicit, however, that it illustrates preliminary patterns in self-assessed readiness and supports no statistical generalisation.

Bashir and Lapshun (2025) reach a compatible conclusion from within management education. They propose matrices to help teachers, trainers and policymakers balance the gains of generative AI against ethical concerns including bias, privacy, accountability and intellectual property. Those gains include efficiency, a better learning experience, skill formation and resource availability. Drawing on technology-adoption models and on utilitarian, deontological and virtue ethics, they stress continuous evaluation and the collective effort of diverse stakeholders. They also call for further research on long-term change and cross-cultural adaptation. Their contribution is conceptual rather than empirical. It nonetheless reinforces a point that recurs across this body of work: consequential decisions about AI in education are

also decisions about who participates in governing it. That includes the parents and communities whose consent is too often assumed rather than sought (see Q086).

What, then, does choosing wisely look like? Here the field genuinely disagrees. One camp, represented in commentary such as Legatt's (2025), emphasises that assignments built on assumptions of no AI use are increasingly disconnected from how students actually work. On that view, institutions must redesign learning around AI rather than against it. The other camp draws on cognitive research and warns against surrendering the design of learning to the convenience of the tool. The vocational education study (arXiv, 2025) gives this concern its sharpest form. When students externalise cognitive tasks to AI systems, internal cognitive demands fall, but deeper processes such as inference, synthesis and evaluation may be compromised. Over time, habitual offloading may foster cognitive laziness and impede the development of higher-order thinking.

The two positions are less opposed than they first appear. Neither supports a moratorium on AI in education, which would be neither desirable nor achievable. What they share is a distinction between AI that amplifies what teachers do and AI that replaces the cognitive struggle that is the mechanism of learning itself. The Acta Psychologica findings on AI literacy as a buffer suggest one practical route. Teaching students when and how to rely on AI may weaken the link between dependence and declining critical thinking, though causal evidence for that intervention remains thin.

The decisions that 2050 is likely to celebrate are those made now with deliberate restraint. They will belong to institutions that asked not 'what can AI do in our classrooms?' but 'what must humans still do for themselves, and why?' Those institutions paired guidance with evaluation, attended to who receives expert scaffolding and who receives only convenience, and kept accountability with identifiable people. The regrets will belong to those who moved fast and assumed that what was efficient was therefore good.

Q127 Which educational credentials are losing labour-market signalling value because of AI, and which are gaining it?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

AI is eroding the signalling value of credentials that certify routine, automatable or easily simulated skills, above all the general four-year degree as a blanket signal of white-collar readiness. At the same time it is raising the value of credentials that certify applied, verifiable and AI-adjacent competence, together with skilled-trade licences that certify hands-on work AI cannot easily perform. The result is a labour market in which the traditional credential hierarchy is flattening at the bottom and fragmenting at the top. It is a re-sorting of the credential market rather than a collapse.

The underlying logic follows signalling theory. A credential is valuable to an employer only insofar as it reliably separates candidates who possess a competence from those who do not. Generative AI disrupts this in two ways. It automates some of the competences that credentials certified, and it makes it harder to tell whether a credential-holder or a machine produced the work on which the credential rests.

The second problem is not unique to education. In a legal and economic analysis of the art market, De Cooman (2025) notes that preliminary studies find human-made works valued significantly more highly than machine-enabled ones, all else being equal. He also observes that this premium depends on the two being distinguishable, and at present they are not. When provenance becomes opaque, the signal carried by a product weakens. The analogy to educational credentials is direct, although De Cooman's argument concerns artworks and rules of origin, not diplomas. A degree whose underlying coursework could plausibly have been produced by a model faces the same erosion of distinguishability. The sections that follow trace which credentials are exposed to this erosion and which are insulated from it.

The most consequential loss is the erosion of the 'college premium' as a default signal of employability. The mechanism has two parts.

First, AI has automated many of the entry-level white-collar tasks for which the degree historically certified readiness: document drafting, basic coding, standardised data analysis and clerical work. A 2026 U.S. Census Bureau working paper reports that employment among 22-to-25-year-olds in AI-exposed occupations has declined significantly since large language models were widely adopted in 2022. It also reports that the steepest declines are concentrated among graduates of mid-tier institutions rather than elite ones. These are associations between occupational exposure and employment trends. They do not isolate AI as the sole cause, and the same period saw interest-rate and hiring-cycle effects. Press reporting on recent graduates (CNBC, 2026) and institutional commentary from Ohio State University (2026) describe the same squeeze on the first rung of graduate careers, and Ohio State frames it as a problem colleges now recognise they must address. The broader implications for the school-to-work transition are taken up elsewhere (see Q128).

Second, the degree's signal has been degraded from within, through grade inflation and declining foundational skills. Analyses of university grading patterns, discussed in the University of Southern California's 2026 review of the value of degrees in the AI era, report that the share of 'A' grades in writing and coding courses has risen sharply since ChatGPT launched. Employers increasingly read this as evidence that AI is completing assignments rather than that students are learning. These grading analyses are descriptive, and causal attribution to AI remains unclear. Montebello (2026) nonetheless provides a conceptual account of why such a pattern would be expected. He argues that assessment historically did two jobs: it measured learning, and it implicitly enforced cognitive engagement. With generative AI, learners can increasingly produce assessment outputs without engaging in the cognitive processes those outputs were meant to evidence. He describes this as a decoupling of assessment performance from cognitive engagement. If grades no longer require the engagement they once compelled, the transcript and the degree built on it carry less information. When a credential no longer certifies the skills it nominally certifies, its market value falls, and at the margin this happens regardless of the issuing institution's prestige.

Students are responding to this uncertainty. Gallup's 2026 polling of college students finds them actively reweighting majors and career plans in response to perceived AI exposure. This

is a measure of perception and intention rather than of realised labour-market returns, but it shows that the credential's perceived value is already shifting on the demand side.

The erosion of degree signalling is being accelerated by a structural shift in employer behaviour towards skills-based hiring. Employer surveys reported in press coverage (CNBC, 2026) put the share of employers who say they prioritise skills over traditional degrees at roughly 70 per cent. The same coverage reports that hiring managers increasingly weight demonstrated project portfolios at least as heavily as formal credentials, and that a substantial share say a strong portfolio can entirely compensate for a lack of credentials. These are self-reports from commercial surveys, not audited hiring outcomes. Stated preferences for skills-based hiring have historically outrun actual changes in who gets hired, so the figures indicate direction more reliably than magnitude.

Read carefully, this is not a rejection of higher education but a reweighting of its signal. The degree is becoming a necessary-but-insufficient condition. The marginal credential that moves a candidate is increasingly a demonstrable skill rather than an additional certificate. What is losing value, therefore, is not the degree per se but the degree as a complete signal: the assumption that holding one certifies readiness for a broad class of work.

Universities are beginning to respond by unbundling the degree's signal into finer-grained, labour-market-aligned units. Government Technology (2026) reports that AI is driving demand for credential programmes within higher education itself. Jēkabsone and colleagues (2026) offer a concrete method for this alignment. In a mixed-methods study combining AI-assisted analysis of approximately 30,000 online job advertisements in Latvia with ESCO-based skill mapping, curriculum analysis and expert interviews, they develop and validate a three-layer framework. The framework links labour-market demand, professional standards and programme learning outcomes, and it is used to inform targeted micro-credentials. The study shows that such alignment is technically feasible. Its evidence concerns curriculum design in a single national labour market, not the wage returns of the resulting credentials, so whether employers will reward these micro-credentials remains unclear. The emerging traction of micro-credentials, digital badges and AI-verified competency records is examined in detail elsewhere (see Q262).

A new credential market has emerged around AI itself, and its internal hierarchy is steep. Industry tallies, compiled largely by training providers and recruiters rather than by

independent researchers, describe a saturated field. More than 400 AI credentials now exist, most with employer recognition below 20 per cent. The same tallies report a short list of credentials with genuine signalling power: Google's Professional Machine Learning Engineer (61 per cent employer recognition), AWS Certified Machine Learning – Specialty (58 per cent), Microsoft Azure AI Engineer Associate (54 per cent), DeepLearning.AI specialisations (47 per cent) and IBM's AI Engineering certificate (31 per cent). These figures should be read as market indicators, not as research findings. Their sampling and definitions of 'recognition' are not publicly validated, and several issuers have commercial stakes in the results. The pattern they suggest is nonetheless consistent with independent evidence: value accrues to credentials that are proctored, third-party-validated and occupationally relevant.

The most robust independent evidence comes from the Brookings Institution's research on the credential boom. Brookings finds that wage premiums are driven almost entirely by job relevance, with a job-relevant credential commanding a premium more than double that of a non-relevant one. The implication is that the AI label itself confers little. What matters is whether the credential maps onto tasks an employer actually needs performed.

'Literacy-level' badges and generic AI certificates, by contrast, carry little weight unless paired with tangible work output. AI literacy is becoming a baseline expectation embedded across ordinary degree programmes, which weakens its scarcity value as a stand-alone credential. Schröder and colleagues (2026) evaluated curricular adaptations in physiotherapy education using a repeated cross-sectional design. They assessed students' generative AI literacy in semester 1, before structured learning activities, and in semester 3, after them. This is an example of literacy being built into a disciplinary programme rather than certified separately.

Literacy is also not a single dimension that a badge can capture. Yong, Wu and Wei (2026) surveyed Chinese arts-university students, with a quality-screened primary sample of 355 questionnaire records after excluding 105 of 460 eligible records (22.8 per cent) for straightlining. They treat engagement with generative AI as involving practical literacy alongside distinct learning, professional, sociotechnical and configuration concerns. If competence with AI is multidimensional and context-specific, a generic certificate is a weak proxy for it, and employers' scepticism towards literacy-level badges is understandable.

The other major gainer is a credential system that AI cannot easily devalue: skilled trades and vocational certification. Severe labour shortages in electrical, plumbing, welding and related

trades have driven up wages and job security. These sectors are largely shielded from AI-driven automation, and they certify through apprenticeships and licences rather than degrees.

The signalling logic here is different. Trade credentials certify hands-on, inspected and often legally required competence. The competence is demonstrated in physical settings, verified by licensed assessors and backed by regulatory liability. That makes trade credentials largely immune to the distinguishability problem De Cooman (2025) identifies in AI-saturated markets: a weld or a wiring installation cannot be outsourced to a language model. Their value is rising precisely because the supply of certified workers is falling, a straightforward scarcity effect. It is reinforced by the relative decline of entry-level white-collar alternatives described above.

Two cautions apply. The shielding of trades from automation reflects current robotics and the economics of non-routine physical work. It is not a permanent guarantee, and forecasts of which capabilities the labour market will reward have a mixed record (see Q044). Rising trade wages are also partly cyclical, tied to construction and infrastructure investment, so not all of the gain can be attributed to AI.

The broader lesson still holds across both gaining categories. Credentials gain value when they certify something scarce, verifiable and non-automatable. They lose it when they certify something abundant, unverifiable or automatable. The proctored machine-learning certificate and the electrician's licence look very different, but both certify competence that is hard to fake and in short supply.

Taken together, the evidence points to a re-sorting of the credential market rather than its collapse.

At the top, elite-institution degrees and advanced applied credentials retain and may even gain value, because they signal access to networks, selection effects and hard-to-fake competence. The Census Bureau's finding that employment declines are steepest among mid-tier graduates is consistent with this. There is a tension worth stating plainly, however. Elite degrees are not exempt from the grading and assessment problems described above. Their resilience may therefore rest more on selection and networks than on what the degree certifies about learning. The literature has not resolved how far prestige can substitute for verifiable competence.

In the middle, the general degree is losing its automatic premium. It is being supplemented, and in some cases replaced, by portfolios, skills transcripts and occupationally relevant certifications.

At the bottom, generic and literacy-level credentials are being commoditised to near-zero signalling value.

For education systems, the implication is that a credential's value is shifting away from the institution that issues it and towards the verifiability and scarcity of the competence it certifies. That shift rewards the kind of assessment reform AI is itself forcing on schools and universities. Montebello (2026) argues that institutions must confront the decoupling of performance from engagement rather than treating the issue as one of academic integrity alone. Bikanga Ada (2026) offers one practical route at the level of the highest-stakes taught credential. Her Master's Dissertation Marking Framework was developed through design-based research that began with a literature review, survey and interviews in 2022, before generative AI emerged, and continued with empirical phases between 2023 and 2025. Its aim is fairer and more transparent dissertation assessment. Frameworks of this kind matter for signalling because a credential is only as credible as the assessment beneath it.

Universities that make their assessments demonstrably resistant to AI substitution, through oral defence, observed performance, process evidence and transparent criteria, may restore part of the degree's informational content. Those that do not are likely to see employers rely further on portfolios, proctored certifications and their own screening. Whether institutional assessment reform can move fast enough to arrest the erosion of the general degree remains unclear. So does the question of how much of that market migrates instead to commercial certifiers and employer-run verification.

Q128 How is AI changing entry-level work, and what does that mean for the school-to-work transition?

10 citations · 10 sources · 5 cross-references

Claim 1 disputed

AI is changing entry-level work by automating the tasks that used to define it. The routine, foundational work of junior employees includes data cleaning, meeting summarisation, basic research, document drafting and standardised coding, and large language models now perform much of it. The labour-market consequences are becoming visible: fewer entry-level postings, rising underemployment among young graduates, and a structural 'experience gap' in which the bottom rungs of the career ladder disappear before new workers can climb them. For the school-to-work transition, the deepest consequence is not the loss of particular jobs. It is the erosion of the informal training system that early employment used to provide, which pushes responsibility for forming applied competence back towards schools, universities and employer partnerships.

The evidence of contraction is substantial, although its causal interpretation is still being worked out. Reporting by Fortune (2026) and CBS News (2026) draws on job-posting analyses showing declines of roughly a third in entry-level roles in recent periods. These are journalistic syntheses of industry posting data rather than peer-reviewed estimates. Postings measure employer intentions, not realised hiring, so the figure is best read as an indicator of direction rather than a precise magnitude. More rigorous evidence comes from a U.S. Census Bureau working paper (2026). It documents falling employment among 22-to-25-year-olds in AI-exposed occupations such as software development, clerical work and editing since large language models were widely adopted in 2022. Over the same period, employment for more experienced workers in those occupations has continued to grow. The age-specific pattern within the same occupations is what makes the finding notable. A general downturn would be expected to hit all experience levels, whereas this decline concentrates where AI substitutes for junior tasks. Even so, the Census evidence is correlational, and a working paper has not yet passed full peer review. Macroeconomic tightening, a post-pandemic correction in technology hiring and sector-specific factors cannot be fully separated from AI adoption on current data.

Harvard Business School's Joseph Fuller describes the dynamic as a 'talent shift' in which AI hollows out the bottom of the career ladder. Companies automate the tasks junior staff used to

do and reduce entry-level hiring. They then discover that they have depleted the pipeline of talent needed for future mid-level and senior roles. The efficiency gain is real, but the long-term cost is structural.

The most consequential effect for the school-to-work transition is the erosion of the training function that entry-level work used to perform. Traditionally, the first years of employment were where graduates built professional judgement, communication skills and workplace confidence through supervised practice on routine tasks. Drafting a first memo, cleaning a messy dataset or writing a minor module of code under review were valued less for their output than for what they taught. Through repetition and correction, they built the tacit knowledge that later allows a professional to recognise when something is wrong.

The Stanford Social Innovation Review's analysis of AI and entry-level jobs names this the 'experience gap'. When AI performs routine tasks, junior workers are increasingly expected to operate at a higher level immediately. They supervise AI outputs and take on complex, judgement-based responsibilities without the gradual learning curve that once built the capacity to do so. Reporting in Fortune (2026) frames the same problem as one for higher education. If graduates arrive without the practice that early employment used to supply, universities face pressure to supply it themselves.

The concern, voiced by Fuller and in the SSIR analysis alike, is that workers who skip the 'task rungs' of routine work may never develop the foundational understanding needed to oversee AI agents, spot hallucinations, or exercise the judgement the new division of labour demands. This creates a circularity. Verifying a machine's output requires knowing what a correct output looks like, and that knowledge has historically come from producing such outputs by hand. The experience gap is therefore not simply a hiring problem. It is a capability-formation problem that compounds over a career. Whether it will materialise at scale remains unclear, because the cohorts affected since 2022 have not yet reached the mid-career stage at which a deficit in judgement would become measurable. The argument rests on a plausible mechanism and early labour-market signals rather than longitudinal evidence.

The skill requirements of entry-level hiring are shifting in response. Employers increasingly prioritise AI fluency, meaning the ability to define problems, orchestrate models, and use tools ethically and effectively. Alongside it they value the human capabilities that remain scarce: critical thinking, collaboration, empathy and communication. Cengage Group (2026) describes

the emerging formulation as a shift from 'pedigree' to 'proof'. Candidates are evaluated on demonstrable ability to use AI tools, verify outputs and solve problems, rather than on the institution that issued their degree. Cengage is an education company with a commercial interest in skills-based learning, however, so its account is best read as an industry perspective rather than independent research. How far hiring practice has actually moved away from degree signals remains unclear (see Q262 on the labour-market traction of micro-credentials and verified competency records).

Deloitte's analysis of AI in the workplace frames the new entry-level profile as someone who works alongside AI as a 'digital teammate'. Such a worker accelerates their own output while keeping ownership of the final result and the judgement behind it. On this account, rules-based, procedural skills that AI can now perform are losing value. Verification, interpretation, stakeholder management and the ethical application of machine outputs are gaining value. The analyses agree on direction but carry a tension. The skills now in demand are largely ones that traditionally developed through the procedural work that is disappearing. Employers want graduates who can judge AI output, yet the route by which such judgement was built is being automated. This tension, rather than a simple list of 'future skills', is what education systems have to resolve.

The implications for education systems are profound and are already reshaping institutional strategy. First, the transition can no longer be assumed to happen after graduation. Because of the experience gap, work-based learning such as internships, apprenticeships and project-based learning is moving from optional enrichment to core curriculum. Institutions are partnering with employers to embed real work into academic programmes. The SSIR analysis concludes that organisations must redesign their training models, creating new infrastructures of work-based learning and performance-based hiring to replace the training ground that routine work used to provide.

Evidence on how learners respond to AI-mediated work-based learning is only beginning to appear. Negm (2025) applied Venkatesh's technology acceptance model 3 to the question of what leads employees in different fields to intend to enrol in educational programmes that use AI. The model covers individual differences, system features, social influence and facilitating conditions. The study surveyed employees enrolled in higher-education programmes for work-based learning in Egypt, using digital questionnaires distributed in January 2024. Its value lies in treating AI-enabled work-based learning as something learners must choose to adopt, not

something that succeeds simply because institutions offer it. Because it draws on a single national context and measures intentions rather than outcomes, it cannot show that such programmes close the experience gap.

Second, the portfolio is becoming the credential. Students are encouraged to build performance-based projects, skills transcripts and documented evidence of capability, because employers increasingly weight demonstrated work alongside or above degrees. Third, the transition is becoming a two-way street. As entry-level work disappears, the bridge from school to work must be built earlier, with schools taking more responsibility for the applied, judgement-based learning the first job used to provide. Hou (2025) helps clarify what this asks of institutions. Hou observes that 'AI integration' remains conceptually underdeveloped and proposes a typology. One dimension treats AI as pedagogical infrastructure, meaning tools and platforms that support instruction and operations. Another treats AI as curricular or professional content, meaning the teaching of AI-related knowledge and skills. Preparing students for an AI-reshaped entry level belongs mainly to the second dimension. Institutions that invest only in AI infrastructure may conclude they have 'integrated' AI while leaving the school-to-work problem untouched.

For schools, the transition has two direct consequences. The first is curricular. If the first job no longer provides the training ground it once did, the applied, judgement-based learning that used to happen in the workplace must move into the school. This can happen through project-based assessment, work placements, and explicit instruction in verifying and supervising machine outputs. Such instruction is demanding. It asks students to produce work themselves before checking machine work, so that they acquire the reference knowledge that verification depends on. It also implies assessment designs that reward judgement and explanation rather than polished output alone.

Whether teachers are equipped to deliver this is a binding constraint. Buele and Llerena-Aguirre (2025), reviewing faculty perceptions of AI in higher education, identify limited AI literacy among educators as a central problem. They find that many university faculty still struggle to incorporate AI tools in a critical, ethical and pedagogically meaningful way. They document resistance and substantial training needs. If those responsible for teaching verification and supervision of AI outputs have not developed these capabilities, the curricular response risks becoming superficial. The burden of closing the experience gap would then fall on the educators least supported to carry it.

The second consequence is informational. Students need accurate, current guidance about which pathways lead to work, and the traditional advice to 'get a degree and the rest follows' is no longer reliable. Career education must now teach students to read the labour market itself. That means understanding which of their prospective tasks are automatable and building portfolios of demonstrated work rather than relying on credentials alone. The practical guidance reported by CBS News (2026) and Cengage Group (2026) is consistent. Students should keep ownership of outcomes rather than offloading judgement to AI. They should build relationships and mentorship that machines cannot provide. And they should treat AI as an accelerator of higher-value work rather than a substitute for the human capabilities that entry-level roles increasingly demand. This guidance comes largely from journalism and industry commentary rather than outcome studies, so it should be offered to students as reasoned advice, not proven strategy.

The school-to-work transition is thus becoming less a handover and more a shared responsibility. Schools keep students longer in the formation of applied competence, and employers redesign entry-level roles to preserve the training function that automation has eroded. The sources disagree, at least implicitly, about where the main burden should fall. Fuller's account emphasises employer self-interest, since firms that stop hiring juniors will lack the senior talent they later need, and it implies that firms will eventually rebuild their own pipelines. The SSIR analysis likewise places the onus on organisations to redesign training. Fortune's framing of a 'higher education experience gap', by contrast, puts more pressure on universities to absorb work formerly done on the job. These positions are not mutually exclusive, but they lead to different policies. One points towards employer-funded apprenticeships and protected junior roles. The other points towards placement-heavy degrees and expanded applied curricula. Which balance will emerge remains unclear.

Several limits on current knowledge deserve emphasis. The strongest quantitative evidence, the Census Bureau working paper, is recent and correlational. The posting-decline figures come through journalism. The skills narratives originate partly with organisations that sell training or consulting. The empirical education studies, Negm (2025) and Buele and Llerena-Aguirre (2025), address learner adoption intentions and faculty readiness rather than graduate employment outcomes. No study yet demonstrates that any particular curricular redesign restores the capability formation that routine work once provided.

The broader stakes connect to questions treated elsewhere in this chapter. If contraction at the entry level proves durable, it is an early form of the possible decoupling of learning from employment (see Q045). The retraining systems that already struggle to keep pace with skill obsolescence for current workers (see Q047) will face a cohort that never acquired foundational experience in the first place. For now, the most defensible conclusion is a modest one. The ladder's lowest rungs are weakening, the training they provided has no settled replacement, and education systems are being asked to fill part of that gap before the evidence on how best to do so exists.

Q129 What is happening to the economics of private tutoring, test preparation, and supplementary education?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

AI is enlarging the market for private tutoring, test preparation, and supplementary education while reorganising its cost structure. Inexpensive machine assistance is compressing the low end, human tutoring is moving upmarket, and the middle is turning into hybrid human-AI services. The pattern is expansionary and disruptive at once. AI drives much of the projected growth, but it also forces every incumbent, from the neighbourhood tutor to the national test-preparation chain, to renegotiate its position. Human tutors, AI tutors, and free general-purpose tools now compete within the same household budget. The industry's boundaries are being redrawn: what counts as tutoring, who supplies it, and what families will pay for are all in flux. The overall pie is getting larger, but no player can assume its slice is secure.

The quantitative picture comes almost entirely from commercial market-research firms rather than peer-reviewed research, and it should be read accordingly. These firms sell forecasts, define their segments in proprietary ways, and rarely disclose their methods in full. With that caveat, the estimates point in a consistent direction. IMARC Group (2026) values the global private tutoring market at roughly $133.8 billion in 2025 and projects $248.4 billion by 2034, a compound annual growth rate of around 7 per cent. Technavio (2025) forecasts that the US market alone will grow by about $28.85 billion between 2025 and 2029, at an accelerating rate of roughly 11 per cent, and explicitly names AI as a force driving market evolution. MarketIntelo (2026) treats AI tutoring and personalised-learning platforms as a distinct and much faster-growing segment. It projects that segment to rise from about $6.8 billion in 2025 to $37.4 billion by 2034, a compound annual growth rate near 20 per cent. Different firms using different definitions agree on the direction of travel. The precise magnitudes, however, remain unclear and should not be quoted as settled fact.

The demand drivers behind this growth are structural and largely predate generative AI. Technavio (2025) and IMARC Group (2026) both trace growth to high-stakes examination systems, intensifying academic competition, and the expansion of STEM-focused supplementary education. Parents buy tutoring because selection points in the education system are consequential and competitive, and AI has not altered that underlying logic. What AI changes is the supply side.

Traditional tutoring is labour-intensive. One tutor's hour serves one student, or a small group, so the service is expensive and hard to scale; its cost falls only slowly as demand grows. AI tutoring inverts this arithmetic. Once a system is built, the marginal cost of serving an additional student is close to zero, apart from the computing cost of each interaction discussed below. This is why the market forecasts treat AI as the industry's principal growth vector. It explains why MarketIntelo (2026) projects the AI segment growing at nearly three times the rate IMARC Group (2026) reports for the sector as a whole. It also explains why online provision features so prominently in Grand View Research's analysis of the US online private tutoring market.

The consequence is a bifurcating industry. A premium segment is built around human tutors whose time is scarce and priced accordingly. A commodity segment is built around AI systems whose output is abundant and priced towards zero. Between them sits a growing band of hybrid models that try to combine the scalability of the second with the trust and accountability of the

first. How large each band will become remains unclear. The underlying cost asymmetry, however, is a durable feature of the technology rather than a temporary market fashion, and it shapes every competitive move described below.

The most instructive case of the new economics is Khan Academy's Khanmigo, the highest-profile student-facing AI tutor. J-PAL's evaluation programme on AI-powered tutoring and the National Bureau of Economic Research working paper on AI tutoring and student engagement (NBER, 2026) both use it as a test of whether personalised machine tutoring can deliver at scale.

The first lesson concerns cost. 'Near-zero marginal cost' is an approximation. Running large language models for individual users incurs real inference costs, and early AI tutors found that these costs threatened profit margins. Industry experience suggests the economics work only when usage is structured, batched, or subsidised, for instance through philanthropic funding, district contracts, or bundling with other services.

The second lesson concerns engagement, and it has proved more consequential. The NBER (2026) analysis reports that nearly all students tried the tool, but median usage was low: students engaged on only a fraction of their practice days. A Stanford study documented a 60 per cent drop in engagement after three weeks of unfacilitated use. Part of the explanation lies in what might be called the Socratic paradox. Khanmigo is designed to avoid giving direct answers, which is pedagogically defensible. It also generates friction for students who want immediate help, and those students can obtain answers instantly from general-purpose chatbots. Engagement, not technical capability, therefore became the binding constraint on the business model.

Related survey evidence points in a similar direction while remaining correlational. Wang and Sun (2026) studied 314 Chinese university students, selected through multi-method and multi-stage sampling, to examine how AI-based tutoring, cognitive engagement, and teacher feedback relate to academic performance. They note that the absence of human feedback in AI tutoring has caused unrest among students. Their design cannot establish causation. Still, it reinforces the view that AI tutoring's value depends on how it is embedded in human relationships rather than on the software alone.

The market has responded with a split. Teacher-facing productivity tools for lesson planning, rubric generation, and grading support have seen strong adoption and viable procurement

economics. General-purpose student-facing chatbots have struggled with churn. Their developers are redesigning them around gamified interfaces, multi-agent orchestration, and stricter compliance (see Q131 on the business models emerging around students).

Competition is being redrawn on three fronts.

First, free and near-free tools are compressing the bottom of the market. General-purpose chatbots offer high-quality assistance at no cost, and platforms such as Khanmigo are available at low subscription prices. Together they undercut low-end paid tutoring, particularly routine homework help and basic test preparation. These were historically the high-volume, low-margin services that sustained many small providers. They are also the services most easily replicated by a system that can explain a quadratic equation or generate a practice reading passage on demand.

Second, the premium segment is consolidating upward. Market analyses, including Grand View Research's report on US online tutoring and Research and Markets' academic tutoring report, describe 'premiumisation'. In this pattern, high-income households pay more for human tutors who offer verified credentials, guaranteed outcomes, and personalised service, qualities AI cannot yet convincingly replicate. As instructional content becomes cheap, what is scarce and therefore valuable shifts towards accountability, mentorship, motivation, and the social signal of having a known expert in a child's corner.

The conceptual literature helps clarify what that scarce human element might be. Ecker, Eckert and Cummings (2025) propose a theoretical framework for integrating AI tutoring into gifted education across four dimensions: affect, content, process, and product. They frame AI as augmenting rather than replacing the 'meaningful mentor relationships' that gifted programmes require. Their work is conceptual, not empirical. Even so, its implicit division of labour, with AI extending content and process while humans anchor affect and mentorship, mirrors the logic by which premium providers are repositioning themselves.

Third, the middle is being squeezed and hybridised. Traditional tutoring companies are integrating AI into their offerings. They use it for diagnostics, practice generation, and between-session support, while retaining human tutors for the core instructional relationship. Whether such hybrids lower prices or mainly widen margins remains unclear. The available evidence on this point comes from vendors rather than independent study.

These dynamics play out most intensely where supplementary education is most deeply rooted. Research and Markets estimates that the Asia-Pacific region accounts for roughly 35 per cent of global tutoring revenue. The region has the deepest culture of 'shadow education', the term scholars use for private supplementary tutoring that mirrors the school curriculum outside school hours. It is therefore the leading laboratory for the interaction of AI with an existing tutoring economy.

The scholarly literature on shadow education provides a necessary counterweight to market forecasts. It asks not only how large the market is but what it achieves and for whom. Karakus, Tlessov, Hajar and colleagues (2024) used PISA 2022 data from 55 countries to examine the association between participation in shadow education and mathematics achievement. They compared how this relationship differs across developed, developing, and East Asian regions, and tested whether socio-economic status moderates it. Because the design is observational, any relationship it identifies is an association rather than proof that tutoring causes higher scores. Its framing nevertheless underlines two points that market reports tend to pass over. The returns to supplementary education may vary systematically by region, so a single global growth figure conceals very different educational economies. And the benefits of tutoring cannot be separated from the family resources that determine who buys it.

The region also shows the sector's political fragility. China's 2021 'double reduction' policy sharply restricted for-profit tutoring in core school subjects. It demonstrates that the industry is exposed to sudden regulatory shocks capable of forcing rapid restructuring, wiping out business models that market forecasts had treated as secure. Any projection of AI-driven growth therefore carries an unpriced regulatory risk. Governments that view supplementary education as a driver of family stress and inequality may intervene again, and AI tutoring could become a target as easily as a beneficiary of such policy.

The economic transformation has a clear equity dimension, and the evidence cuts in both directions.

On one side, AI's cost structure makes reasonably high-quality supplementary help cheaper than ever at the margin. In principle, this narrows the gap between households that can afford tutoring and those that cannot. A student without access to a paid tutor can now obtain explanations, worked examples, and practice questions at little or no cost.

On the other side, three forces push towards greater stratification. The premiumisation of human tutoring concentrates the most valued services among wealthy families. Free and paid AI tiers differ in quality. And the market forecasts themselves, including Technavio (2025), note that affordability barriers for lower-income households are contributing to a widening attainment gap.

The quality of AI assistance may also be uneven across learner groups. Akinwumi and Qian (2026) developed an equity-aware tutoring framework that combines GPT-generated feedback with rule-based feedback on learner spelling errors. They used TOEFL-Spell data annotated with learners' first language and English proficiency to examine feedback quality, accessibility, personalisation, and potential disparities between subgroups. The study addresses a narrow task. Its premise, that AI feedback must be audited for differences across linguistic and proficiency groups, implies that 'cheap' tutoring is not automatically equal tutoring. Karakus and colleagues' (2024) attention to socio-economic moderation points the same way: whatever advantages supplementary education confers are likely to be distributed unevenly.

Whether AI on balance narrows or widens educational inequality remains unclear, and credible sources lean in opposite directions. The overall shape of the emerging economics is clearer. AI is expanding the market, compressing its low end, and inflating its high end. It forces every provider, human or machine, to compete on the specific value it adds that the other cannot. For schools and families, supplementary education is now more favourable than at any point in history for basic assistance. It is also more stratified than ever for the premium services that confer positional advantage. That positional logic connects directly to debates about which credentials retain signalling value (see Q127).

Q130 How is AI affecting adult retraining and mid-career education systems?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

AI is affecting adult retraining and mid-career education in two connected ways. It is sharply enlarging the demand for retraining, and it is changing the systems that deliver it. On the demand side, the World Economic Forum's 2025 career guidance circulates the estimate that roughly 40 per cent of core worker skills will be disrupted by 2027. Survey data cited in the same policy debate indicate that nearly half of US workers were using AI at least monthly by 2025. Both figures are projections or self-reports rather than measured labour-market outcomes, but they convey the scale of the adjustment that workers, employers and educational institutions now face.

On the supply side, retraining is being reshaped by AI-powered learning platforms, new credential structures, and a reorientation of community colleges and corporate training toward applied AI competence. The evidence on whether these systems can meet the demand is sobering. The National Academies of Sciences, Engineering, and Medicine describe a chronically underfunded public infrastructure. The Brookings Institution's analysis stresses that training outcomes are hard to measure. Both point to a real risk that workers will be reskilled into roles that are themselves automatable.

One feature distinguishes this transition from earlier waves of technological retraining. The technology driving the disruption is also the technology being deployed to respond to it. That recursion shapes almost every part of the system, from what adults are taught to how, by whom and with what tools they are taught it.

The workforce-development literature now distinguishes two strategies for responding to AI-driven change. Harvard's Division of Continuing Education sets out the distinction in its reskilling guidance. Upskilling augments an employee's existing skill set to improve performance or to advance within a current career path. Reskilling trains workers for entirely new competencies, typically because their current role is being altered or automated.

The distinction matters for system design because the two strategies have different economics and different success criteria. Upskilling is cheaper and faster, and it is easier to justify to

employers, who capture its returns directly. Reskilling is expensive and slow. It also carries a distinctive risk: the new occupation may itself be disrupted before the worker has recouped the cost of the transition. This risk is especially acute for younger workers whose first jobs are being reshaped at the point of entry (see Q128).

Credible sources disagree about how far retraining can carry the adjustment. Practitioner and policy-forum sources, including the Harvard guidance and the World Economic Forum, treat continuous reskilling as a workable route through the transition. The Brookings Institution's analysis of AI labour displacement and the limits of worker retraining is the most sceptical major treatment. It argues that public retraining programmes face a fundamental economic mismatch. Workers may be reskilled into occupations that are also susceptible to automation. Alternatively, they may join a surplus of 'skilled' workers relative to the number of high-quality jobs actually available.

Brookings adds a methodological objection. It is difficult to separate the effects of training from the self-selection of motivated participants, who might have found better work anyway. As a result, the evidence base is weaker than the policy enthusiasm suggests. The disagreement is not a matter of tone. One side treats skills as the binding constraint on good employment, while the other treats the supply of good jobs as the constraint that training alone cannot relax.

Whatever the merits of retraining in principle, the infrastructure meant to deliver it is thin. The National Academies' assessment of retraining for the age of AI documents a structural funding problem. US workforce development spends only about 0.1 per cent of GDP on active labour-market policies, a level the Academies regard as chronically insufficient to scale successful training models to the population that needs them. Promising programmes therefore tend to remain pilots. Proven designs reach a fraction of eligible workers, and the system lacks the capacity to absorb a sudden rise in displacement.

Individual barriers compound the system-level ones. The National Academies identify three in particular. Lost wages during training impose a heavy opportunity cost on adults with families and fixed obligations. Take-up is lower among older workers. Competing social and health concerns suppress participation even when places are available. The systems most in demand are thus the least funded. The gap between the scale of AI-driven displacement and the scale of the retraining response is one of the defining features of the current transition.

The health dimension has received growing attention in adult education scholarship. McClain and Wade (2026) argue that mental well-being is central to adult learner success. They observe that many adult education institutions lack the capacity to provide timely and accessible support. Drawing on adult learning theory, the educational interface perspective and stepped-care principles, they examine how AI might strengthen mental health-adjacent supports. They distinguish tools designed to detect distress from tools that enhance accessibility and personalised learning.

Their contribution is conceptual rather than an outcome evaluation, so whether such tools raise retention among displaced mid-career learners remains unclear. The argument does, however, connect the National Academies' list of participation barriers to a concrete design question for institutions. It also shows that the barriers to retraining are not purely financial.

Against this backdrop, the clearest evidence on effective design comes from large corporate reskilling initiatives. These include billion-dollar programmes at Amazon, JPMorgan and AT&T, whose lessons are synthesised in Harvard's Division of Continuing Education guidance. That synthesis identifies four features that distinguish effective from ineffective training.

First, successful programmes begin with broad AI literacy for all staff, explaining what AI can and cannot do before any specialised technical training. Second, they use blended learning, combining self-paced online coursework with live cohort sessions and real-world project applications. The Harvard guidance reports completion rates of up to 65 per cent for such models, against roughly 8 per cent for purely self-paced ones. These are practitioner-reported figures rather than peer-reviewed estimates, and they are best read as indicative. Third, effective programmes tie training to concrete career pathways, such as specific role transitions, salary increases or title changes, rather than vague mandates to 'learn AI'. Fourth, they integrate 'learning in the flow of work', embedding bite-sized micro-learning into daily tasks so that new skills are applied immediately.

The pattern is consistent with the wider learning-science evidence. Adult retraining tends to work when it is contextual, social and career-anchored. It tends to fail when it is abstract, solitary and credential-agnostic. Pandya and Samuel (2026) make this argument explicitly for AI-enabled workforce training. Organisations are adopting AI to personalise learning pathways, automate feedback, support simulations and provide just-in-time assistance. In their account, however, the effectiveness of these tools depends on alignment with andragogy, situated

learning and experiential learning, with emphasis on learner agency, prior experience and contextual practice.

Lin and Schmidt (2025) offer a small-scale illustration. Their comparative case study analysed three instructional uses of ChatGPT in online adult learning: supporting discussions, simulating professional interviews and providing assignment feedback. They report that these uses can motivate learner autonomy, provide timely feedback and encourage reflective engagement with AI-generated content. The study examines three cases and does not measure employment or skill outcomes.

The priority given to AI literacy finds indirect support in Güler and colleagues' (2026) cross-sectional study of 438 physiotherapy and rehabilitation undergraduates in Ankara and Konya. In that sample, career optimism was more closely associated with AI literacy than with AI anxiety. The finding is correlational and concerns students rather than displaced mid-career workers, so it cannot show that literacy training causes optimism. The Brookings self-selection critique also applies to the corporate evidence. Workers who complete employer programmes are not a random sample, which is why the corporate evidence, though clearer than the public evidence, remains emerging rather than established.

In the United States, the institutional response has centred on community colleges. The Hechinger Report and Delgado's analysis in Issues in Science and Technology both describe these colleges as uniquely positioned to serve as the primary engine of AI reskilling. Their advantages are structural. They are deeply integrated with local labour markets, they can adapt curricula quickly to regional economic needs, and they are accessible to mid-career and non-traditional students who cannot leave work for residential study.

The emerging model is exemplified by the National Applied AI Consortium, which Delgado describes. It combines three elements. The first is stackable credentials, meaning certificates that ladder into associate and bachelor's degrees, so that workers can enter and exit the workforce at multiple competency stages. The second is competency-based education, which credits mastery of specific skills rather than seat-time and recognises prior learning. The third is industry alignment through Business and Industry Leadership Teams, which keep curricula tied to employer needs. Whether these short, stackable credentials will carry durable labour-market value is a separate and contested question (see Q262; see also Q127).

The goal is to train the 'missing middle' of the AI workforce. These are practitioners who apply AI in healthcare, logistics, manufacturing and public services, as distinct from the researchers who build it. Georgetown's Center for Security and Emerging Technology frames this as the central challenge of AI workforce training. The applied, operational layer of AI competence is where labour-market demand is concentrated, yet it is the layer the traditional education system is least equipped to supply.

Here too, the case rests more on structural reasoning than on measured outcomes. The Hechinger piece is an opinion essay, and published evaluations of consortium-style programmes' effects on earnings or job placement remain thin. Community colleges also depend on the same public funding streams that the National Academies describe as inadequate, so the institutions best positioned to scale applied AI training are not obviously resourced to do so.

AI is also transforming the delivery of retraining. AI-powered platforms now personalise learning paths by identifying skill gaps through resume analysis and skills taxonomies. Adaptive systems adjust content to each learner's pace and prior knowledge. The World Economic Forum's 2025 guidance stresses that every career now involves continuous learning and that AI tools are both the subject and the medium of that learning.

That dual role places new demands on the educators who staff retraining systems. Güler's (2026) survey of 123 Swiss adult educators, conducted between August and October 2025, found AI tool use widespread: 82.1 per cent of this non-probability sample reported active use. Usage frequency was associated mainly with educators' self-reported AI knowledge rather than with demographic characteristics. Respondents were largely optimistic about AI's potential to support their work. They nonetheless reported substantial constraints, most notably privacy and security concerns and limited perceived institutional support. Because the sample was self-selected, the adoption rate cannot be generalised to adult educators as a whole.

Conceição and Samuel (2025) argue that faculty development for AI should itself be grounded in adult learning principles. Rather than treating AI adoption as a one-off technical training exercise, they propose a strategic integration that builds on educators' professional experience, addresses their concerns directly and supports experimentation within institutional frameworks. Their framework is conceptual, but it speaks to the barriers Güler's respondents reported, particularly the shortage of institutional support. McClain's (2026) editorial overview of AI

across disciplines and professions frames these questions as shared across fields rather than confined to any one of them, which underlines that the professionals who teach adults are themselves mid-career learners adjusting to the same technology.

The recursion noted at the outset is therefore literal. Retraining systems must upskill their own staff in the tools they are asked to teach, often with the same thin resources that constrain the wider system. Whether they can do so quickly enough will shape whether AI-enabled delivery improves outcomes for displaced workers or simply adds another layer of unevenly distributed technology.

Q131 Who profits from AI in education, and what business models are emerging around students?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

The profits from AI in education are flowing to a narrower set of actors than the market's headline growth figures suggest. The business models built around students are consolidating into a few durable patterns: institutional software with high switching costs, habitual consumer subscriptions, teacher-facing productivity tools that turn individual adoption into district contracts, and trusted assessment and credentialing. Students rarely pay directly in most of these arrangements. Their data, attention and learning outcomes are instead the substance on which the arrangements run.

The market itself is large and growing, but its size is uncertain. Commercial forecasters such as Grand View Research and MarketsandMarkets place the AI-in-education market at roughly

$2.2 billion in 2024. Their projections range from over $5.8 billion by 2030 to, over a longer horizon, as much as $92 billion by 2033. These are proprietary market-research estimates rather than peer-reviewed measurements. The spread between them reflects different definitions of what counts as 'AI in education' as much as different expectations of growth, and they should be read as indicators of investor sentiment rather than as established facts about the sector's economics.

What the forecasts do not show is how the value is distributed, and here the evidence points to marked unevenness. The sector's short history already contains a clear lesson about which models profit and which are disrupted, discussed below in the case of answer-selling platforms. The pattern resembles the wider AI economy. Generating content is becoming cheap, so returns flow to whoever controls infrastructure, distribution and trust.

The most defensible business models in AI education are those that own institutional infrastructure. Commentary on edtech business models, including New Market Pitch's analysis of what works in the AI era and investor-oriented coverage in U.S. News & World Report, identifies providers of core systems as among the most highly valued firms in the sector. These systems include student records, enrolment workflows and learning management systems. The reason is structural rather than technological. Once a school district or university runs its operations through a platform, the cost of leaving becomes prohibitive. Migrating years of records, retraining staff and renegotiating integrations makes switching unattractive even when competitors offer better features. The vendor captures predictable, long-term revenue in return.

This is the 'sticky SaaS' model, and it is where the most reliable profits in the sector currently sit. AI strengthens rather than weakens this position. Incumbents can add AI features on top of data and workflows they already control, and new entrants must persuade institutions to undertake costly migrations before they can deliver any value.

The same logic applies to assessment and credentialing. AI can generate instructional content at close to zero marginal cost, but it cannot replicate a credential that employers or regulators trust. Certification is therefore one of the most defensible segments in the market. Its value rests on institutional reputation, regulatory recognition and labour-market acceptance, none of which a language model can produce. How durable that trust will be is a separate question. AI may also be eroding the signalling value of some credentials while strengthening others (see

Q127). Newer forms such as micro-credentials and AI-verified competency records are competing for the same position of trust (see Q262).

The strategic implication is consistent across these cases. Value accrues to whoever controls the system of record or the system of trust, not to whoever generates the content that flows through them. This claim rests mainly on industry analysis and observed valuations rather than systematic economic research. It should therefore be treated as a well-supported interpretation rather than a demonstrated law of the market.

The consumer-facing segment has produced the sector's most dramatic lesson in profit and loss. Companies that built their business on selling access to academic answers have seen significant revenue declines as general-purpose AI made answer-selling nearly free. Chegg is the most prominent example, as business-model commentary from New Market Pitch and market coverage in U.S. News & World Report both describe. A student who once paid a subscription for worked solutions can now obtain comparable help from a free chatbot. The product's core value proposition collapsed rather than eroding gradually. The parallel pressures on private tutoring and test preparation follow similar dynamics (see Q129).

The consumer models that profit instead are those that monetise habitual behaviour. Duolingo is the canonical case. It succeeds by monetising a repeated learning routine rather than a one-time answer. The distinction matters for the emerging economics. Because AI commoditises content, consumer education businesses must sell engagement, habit and outcomes rather than information. Subscription models built on daily use, streaks and progress loops are the consumer pattern that is surviving. Pay-per-answer and content-access models are the pattern being destroyed.

Peer-reviewed research on student use offers context for this shift but does not directly measure its commercial effects. Tabiri, Jones-Mensah and Kouamé (2026) surveyed Ghanaian tertiary students about AI in language learning. Using a quantitative design guided by the Unified Theory of Acceptance and Use of Technology, they examined students' views of effectiveness, their patterns of use, the languages involved, and the stages at which students adopted these tools, both within and beyond the classroom. Their focus on use outside formal instruction is the territory consumer apps compete for.

Amoakohene, Owusu-Agyeman and Adu (2026) conducted a single case study of 24 business students in Ghana. They found that students judge generative AI along three dimensions: its

functions, its features and its applicability to specific academic tasks. That finding suggests students evaluate tools by their fit to concrete tasks rather than as undifferentiated sources of answers, which is consistent with the move away from content access.

Both studies are small or regionally specific, however, and neither measures willingness to pay. The link between student perceptions and which consumer business models survive therefore remains unclear.

The most successful recent business-model innovation is the teacher-facing productivity tool sold through a 'bottom-up' go-to-market strategy. Companies such as MagicSchool AI and Brisk Teaching, profiled in BotMemo's survey of AI education startups and 8allocate's 2026 review of value creation in edtech, built products that save teachers time. Their core functions are lesson planning, rubric generation and grading support. Statistics compiled by Sci-Tech Today report that teachers who use AI at least weekly save an average of around 5–6 hours per week. That figure comes from an industry statistics digest rather than a controlled study, so it should be read as self-reported savings rather than a demonstrated productivity effect.

These firms grew through individual teacher adoption. They then converted grassroots usage into district-level contracts for privacy, governance and administration. The model solves the sector's classic sales problem. Institutional procurement is slow and complex, but a product that teachers themselves demand creates pull that administrators cannot ignore. Once a district must address the privacy and governance risks of widespread unsanctioned use, a paid enterprise agreement becomes the path of least resistance.

The economics are attractive for two reasons. The value proposition is immediate and easy to state as time saved. The expansion path is also natural, running from individual licences to district-wide agreements.

Research on educator attitudes helps explain both the pull and its limits. Miranda's (2025) exploratory survey of 376 teachers, university students and future educators in the University of Salerno area examined perceptions of AI's impact, its usefulness and specific applications in education. It framed AI's promise of more efficient teaching against significant concerns about ethics and responsible implementation. That dual framing matches the bottom-up model's two stages. Perceived usefulness drives individual adoption, while ethical and governance concerns create the institutional demand that district contracts monetise.

El Idrissi and Alami (2025) studied 392 management students in Morocco using structural equation modelling. They examined how chatbot quality, task–technology fit, social influence, perceived usefulness and actual usage relate to academic productivity. As a cross-sectional model, it identifies associations among these factors rather than causal effects. It nonetheless suggests that fit to specific tasks is central to whether AI tools are experienced as productive, which is the quality teacher-facing vendors claim to deliver.

Investment data show where the market believes the profits will be. Overall edtech venture funding has fallen from pandemic-era peaks. Industry figures summarised by 8allocate (2026) and Sci-Tech Today report a drop of roughly 26 per cent in the first half of 2026 compared with the prior year. Capital is meanwhile concentrating in AI-native platforms with proven unit economics and in fewer, larger growth-stage rounds. Investors are prioritising companies that own specific workflows, such as curriculum platforms, adaptive practice tools and institutional infrastructure, over generic AI tutoring interfaces. They favour models that offer clear cost savings for institutions or measurable improvements in student outcomes. Whether funded companies actually deliver those outcome improvements is a separate empirical question, and the investment data cannot answer it.

The distinction between AI-native and AI-augmented firms is also shaping the market. Startups built on AI from day one dominate early-stage funding, according to BotMemo's startup survey and 8allocate's analysis. Established platforms adding AI layers capture larger growth-stage cheques on the strength of their existing user bases.

Both groups face a competitive threat from the largest technology companies. These firms are increasingly bundling education-specific AI features into products schools already use, at little or no additional cost. This compresses the market for specialised tools. A standalone product that offers only a feature a dominant productivity suite can include for free has a weak claim on institutional budgets.

The geography of these flows is narrower than global forecasts imply. Bali and colleagues (2024) note that, despite growth in online learning in Nigeria, many Nigerian educational institutions have yet to use AI technologies. Their study therefore draws on examples of AI implementation from developed countries. The pattern suggests that the business models described here are largely being built and monetised in wealthier systems. Many institutions

elsewhere are positioned as later adopters of imported models rather than as sites of local value creation.

Navruz-zoda and colleagues (2026) address small and medium enterprises in Central Asia rather than education specifically. They identify machine learning, natural language processing and generative AI as low-cost, quick-return priority areas for resource-constrained firms. Their framework hints that smaller local education providers might find affordable entry points, though no direct evidence yet shows this happening in education markets.

The emerging answer to 'who profits' is therefore specific. Four groups are capturing durable value: large platform and infrastructure providers, through switching costs and scale; teacher-facing productivity tools that convert grassroots adoption into contracts; habitual-use consumer apps that monetise routine rather than answers; and trusted assessment and credentialing bodies.

Three groups are being squeezed: answer-selling content providers disrupted by free general-purpose AI, generic chatbot interfaces without workflow integration, and startups that 'build for students but sell to administrators' without understanding institutional procurement. This picture draws on industry analysis from New Market Pitch, 8allocate and BotMemo and on market reporting. It is coherent and broadly consistent across those sources, but it rests on commercial commentary and observed company performance more than on independent economic research.

The students themselves hold the most contested position. Their data, attention and learning outcomes are the raw material of these models. Their interests are protected only to the extent that privacy regulation, procurement scrutiny and evidence requirements constrain the market.

The risks around data are not hypothetical. Murphy (2024) situates his work in the widespread practice of micro-targeting, in which messages are tailored to individuals using information derived from their digital footprints, often organised around personality type. He investigates whether large language models enhance the detection of personality types beyond earlier machine-learning methods. His study does not concern education. Its relevance lies in the capability it examines. Platforms that accumulate rich records of student writing and behaviour hold exactly the kind of digital footprint that such techniques exploit. The habit loops that make consumer apps profitable could therefore be tuned to individual psychological profiles.

Miranda's (2025) Salerno survey shows that educators and students themselves weigh AI's benefits against ethical concerns. That finding suggests that legitimacy, and not only efficiency, will shape which models endure. How far regulation and procurement will actually constrain data-driven business models remains unclear. Where these policy choices sit among the most consequential decisions facing education systems is discussed elsewhere (see Q050).

The business models emerging around students are thus a mirror of the wider AI economy. Value concentrates in infrastructure, distribution and trust, while the content layer is commoditised towards zero.

What changed in this edition: This answer is unchanged in Edition 120. Its most recent revision, in Edition 117: Expanded to six sections that treat market forecasts as contested commercial estimates and attribute vendor statistics explicitly. Adds peer-reviewed evidence on student and educator perceptions, data-driven micro-targeting and uneven global adoption, plus cross-references. Converted the bulleted list in the final section into running prose to comply with the no-lists rule. (865 → 2,061 words · 7 new sources)

Q262 What micro-credentials, digital badges, and AI-verified competency records are emerging as alternatives or supplements to traditional degrees, and what is their current labour-market traction?

12 citations · 12 sources · 5 cross-references

Claim 1 established

The traditional degree has long served as the dominant signal of competence in labour markets, but its cost, duration, and coarse granularity have prompted interest in alternatives. Micro-credentials, digital badges, and machine-verifiable competency records promise to recognise specific skills, accommodate lifelong learning, and allow employers to verify claims instantly. AI is accelerating this interest in two ways: by changing which skills employers value and by enabling new forms of assessment and verification. Yet enthusiasm about these credentials has run ahead of evidence about their labour-market value.

The landscape of credentials has expanded dramatically. Credential Engine, a U.S. non-profit that maintains a registry of credentials, has documented in its Counting U.S. Postsecondary and Secondary Credentials reports that more than one million unique credentials are offered in the United States, including degrees, certificates, licences, apprenticeships, industry certifications, and a rapidly growing number of non-degree credentials such as course certificates and digital badges. This proliferation makes it difficult for employers and learners to judge quality, a problem that registries and common descriptors aim to address.

Technical infrastructure for verifiable credentials has matured. The 1EdTech Consortium's Open Badges 3.0 specification aligns digital badges with the World Wide Web Consortium's Verifiable Credentials data model, enabling cryptographically signed records that can be checked without contacting the issuer. In Europe, the European Digital Credentials for Learning infrastructure, part of Europass, allows institutions to issue tamper-evident digital credentials that learners can store and share across borders. The Council of the European Union's 2022 Recommendation on a European approach to micro-credentials established common elements for describing micro-credentials, including learning outcomes, workload, assessment, and quality assurance, and encouraged member states to integrate them into qualification frameworks.

AI-verified competency records represent a newer and less established development. Some platforms use AI to assess performance on simulations, coding tasks, or portfolios and issue credentials based on these assessments, while others use AI to map learners' experiences to skills taxonomies. The reliability and fairness of such AI-based assessments are not yet well documented, and they raise the same concerns about bias, transparency, and validity that apply to AI in grading and hiring.

Labour-market traction is the crucial question, and here evidence suggests caution. The Burning Glass Institute and the Harvard Business School Project on Managing the Future of Work, in their 2024 report Skills-Based Hiring: The Long Road from Pronouncements to Practice, analysed job postings and hiring data for large U.S. employers that had announced removal of degree requirements. They found that while many firms removed degree requirements from postings, actual hiring of workers without degrees into those roles increased by only about 3.5 percentage points on average, and that the change affected fewer than one in 700 hires overall. They classified 37 percent of firms as genuine leaders in skills-based hiring, 45 percent as skills-based in name only, and 18 percent as backsliders. These findings suggest

that formal openness to alternative credentials has not yet translated into widespread change in who is hired.

Employer survey evidence is more positive but comes largely from interested parties. Coursera's 2025 Micro-Credentials Impact Report reported that 90 percent of employers surveyed would be willing to offer a higher starting salary to candidates holding professional certificates. Because Coursera sells such certificates, these findings should be treated as indicative of employer attitudes rather than as independent evidence of labour-market returns, and stated willingness may not match actual hiring and pay decisions.

Several factors appear to shape whether alternative credentials gain traction. Credentials linked to recognised employers, industry bodies, or licensing requirements tend to carry more weight than generic badges. Stackability, the ability to combine micro-credentials into larger qualifications, may increase value by connecting them to established pathways. Quality assurance and transparency about what a credential certifies help employers interpret it. Verification infrastructure reduces fraud, which may become more important as AI makes it easier to fabricate documents.

Equity implications cut both ways. Alternative credentials could open opportunities for workers without degrees, but if employers continue to favour degree holders, learners may invest time and money in credentials with limited payoff. Workers who already hold degrees may also accumulate micro-credentials more readily, potentially widening rather than narrowing gaps.

Economic theory offers a useful lens for understanding why degrees have proved so durable and why alternatives struggle to displace them. Michael Spence, in his 1973 article Job Market Signaling in the Quarterly Journal of Economics, modelled education as a costly signal: if acquiring a credential is less costly for more productive workers, employers can use the credential to infer productivity even when the education itself adds little to skills. Signalling theory does not imply that degrees teach nothing, and later empirical research has found evidence for both skill-building and signalling functions, but it explains why the value of a credential depends on what employers believe it reveals rather than solely on what it certifies. A four-year degree signals persistence, conformity to institutional expectations and the ability to complete a long programme, qualities that a short course certificate cannot easily convey, however precisely it documents a specific skill. This perspective suggests that micro-credentials may gain most traction where they certify skills that are directly observable and job-

relevant, and where degrees have been used as a crude proxy for such skills, rather than where employers value the broader attributes that long programmes are thought to signal.

Experimental evidence on how employers respond to unfamiliar credentials supports caution. David Deming, Noam Yuchtman, Amira Abulafi, Claudia Goldin and Lawrence Katz, in a 2016 study in the American Economic Review, sent fictitious résumés to real job vacancies, varying the type of institution that had awarded applicants' credentials. They found that business bachelor's degrees from large online for-profit institutions received substantially fewer callbacks than similar degrees from nonselective public institutions, and that in health occupations, certificates from for-profit institutions generated no more callbacks than résumés with no postsecondary credential at all, except where the occupation required a licence. Because the design randomly assigned credentials to otherwise similar résumés, it provides causal evidence about employer screening responses, although it measures callbacks rather than eventual hiring or pay. The findings suggest that employers discount credentials from providers they do not know or trust, which is directly relevant to new micro-credentials and digital badges from issuers without established reputations.

Evidence on sub-degree certificates, the closest established analogue to micro-credentials, points to modest and uneven returns. Christopher Jepsen, Kenneth Troske and Paul Coomes, in a 2014 study in the Journal of Labor Economics using administrative data from Kentucky's community colleges, compared earnings before and after enrolment and found that associate degrees and diplomas were associated with substantial earnings gains, while shorter certificates were associated with smaller gains, with returns varying considerably by field of study and by gender. Studies of this kind rely on individual fixed-effects methods rather than randomisation, so they cannot fully rule out the possibility that students who complete credentials differ in unobserved ways from those who do not. They nonetheless suggest that credential length and field matter, and that short credentials in fields with clear occupational demand, such as health and skilled trades, tend to show stronger associations with earnings than short credentials in general fields. Whether online micro-credentials behave similarly to community college certificates remains largely untested, since most lack comparable administrative data on completers' earnings.

The case for alternatives partly rests on evidence that degree requirements have been applied more widely than jobs require. Joseph Fuller and Manjari Raman of Harvard Business School, in their 2017 report Dismissed by Degrees, analysed job postings and found that employers

frequently requested bachelor's degrees for middle-skill roles in which most current incumbents did not hold degrees, a phenomenon they called degree inflation. They argued that this practice raised hiring costs, lengthened vacancies and excluded capable workers without degrees, disproportionately affecting lower-income workers and some racial and ethnic groups. The report relied on posting data and employer surveys rather than causal analysis, and its estimates of affected jobs depend on assumptions about which requirements are unnecessary. It nonetheless helped motivate the skills-based hiring movement whose implementation the later Burning Glass Institute analysis found to be limited, a sequence that illustrates the gap between recognising a problem in credentialing and changing hiring behaviour.

AI-based assessment of competencies raises questions that research on algorithmic hiring has begun to document. Manish Raghavan, Solon Barocas, Jon Kleinberg and Karen Levy, in a 2020 paper presented at the ACM Conference on Fairness, Accountability, and Transparency, reviewed the publicly available claims and practices of 18 vendors of algorithmic pre-employment assessments. They found that vendors disclosed limited information about how their assessments were validated, what outcomes they predicted, and how bias was measured and mitigated, and that many relied on a legal threshold for adverse impact that does not capture all forms of unfairness. AI-verified competency records share many features with these assessment tools, since both infer skills from performance data using models whose validity may be difficult for employers or learners to evaluate. If AI-issued credentials lack transparent validation, employers may discount them, and learners may be unable to contest inaccurate assessments that follow them across job applications.

Regulation of automated employment tools is beginning to address some of these concerns, with implications for AI-verified credentials used in hiring. New York City's Local Law 144, enforced by the Department of Consumer and Worker Protection from July 2023, requires employers and employment agencies that use automated employment decision tools to substantially assist hiring or promotion decisions to obtain an independent bias audit, publish a summary of the results, and notify candidates that such tools are being used. The law applies to tools used in employment decisions rather than to credential issuers directly, but an employer that relied on an AI system to screen candidates based on machine-assessed competencies could fall within its scope. In Europe, the AI Act's classification of AI used in recruitment and in evaluating learning outcomes as high-risk, discussed in other answers in this collection, creates

parallel obligations. These developments suggest that AI-verified credentials will increasingly need documented validation and bias testing if they are to be used in consequential decisions.

International comparisons show that the institutional setting strongly shapes how alternative credentials are received. In countries with strong vocational education systems and established qualification frameworks, such as Germany and Switzerland, new credentials tend to gain recognition when they are linked to existing occupational standards negotiated among employers, unions and the state. The European Union's 2022 Recommendation on micro-credentials reflects this approach by encouraging integration into national qualification frameworks rather than leaving recognition entirely to the market. In the United States, where credentialing is more decentralised and market-driven, alternatives have proliferated more rapidly but with less consistent quality assurance, which helps explain the mismatch between supply growth and employer uptake. Comparative research on labour-market returns to micro-credentials across these different systems remains scarce, but the contrast suggests that technical standards alone are unlikely to produce traction without institutional arrangements that give employers reasons to trust what a credential certifies.

Quality assurance remains the unresolved link between the technical infrastructure described earlier and employer trust. Open Badges 3.0 and European Digital Credentials make it possible to verify that a credential was genuinely issued and has not been altered, but cryptographic verification says nothing about whether the underlying assessment was rigorous or whether the skills it certifies are relevant to a job. Degrees are backed, however imperfectly, by accreditation systems, while many micro-credentials are issued by providers subject to no external review. The European Union's 2022 Recommendation addresses this by asking that micro-credentials be subject to internal and external quality assurance, and registries such as Credential Engine's aim to make descriptive information comparable. Until such mechanisms are widespread and employers understand them, the evidence reviewed here suggests that a verified badge from an unfamiliar issuer may carry little more weight than an unverified one.

The overall picture is one of rapid growth in supply, maturing technical standards, and supportive policy, alongside limited evidence of substantial labour-market returns. Independent longitudinal research tracking earnings and employment outcomes for holders of specific credentials, compared with similar workers without them, would be needed to establish whether these credentials function as genuine alternatives or remain supplements to traditional degrees.

Chapter 7: The Evidence Base — What Research Actually Shows

13 questions · 207 citations · 199 unique sources · 64 cross-references

Q051 What does current peer-reviewed evidence show about the effects of AI tutoring systems on learning outcomes, and how strong is that evidence?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

Current peer-reviewed evidence shows that AI tutoring systems can improve learning outcomes, sometimes substantially. The strength of that evidence depends heavily on which generation of technology is being evaluated. For rule-based intelligent tutoring systems, the evidence is comparatively well established. For tutors built on large language models, it is promising but thin, recent and methodologically uneven. As of mid-2026, the most defensible summary is that the evidence is encouraging yet still maturing. Two forces cut across both strands. The first is the way outcomes are measured. The second is the way the tutor is designed to help.

This is one of the most consequential questions in contemporary education research. Answering it requires keeping two literatures apart. The older literature evaluates systems that model a domain and a learner explicitly and deliver scripted hints and feedback. These systems have accumulated decades of controlled evaluation and several meta-analyses. The newer literature concerns generative AI. Here a handful of rigorous trials sit alongside a far larger volume of descriptive, small-sample and satisfaction-based studies, and public claims have often run ahead of the data. Treating the two as a single body of evidence would overstate what is known about the systems most schools and universities are now adopting. It would also understate what is known about their predecessors.

The older, pre-generative strand of evidence is the firmest ground in the field. Kulik and Fletcher's (2016) meta-analysis of 50 controlled evaluations of intelligent tutoring systems found a median effect size of 0.66 standard deviations over conventional instruction. That is roughly equivalent to moving a typical student from the 50th to the 75th percentile. Positive

effects appeared at every level of education and in nearly all subject domains evaluated. The pattern held after the authors accounted for potential publication bias. By the standards of educational research, where effects above about 0.4 are generally regarded as substantive, these are meaningful numbers. An earlier meta-analysis by Ma, Adesope and colleagues (2014) reached broadly consistent conclusions about the positive association between intelligent tutoring and learning outcomes. Taken together, these syntheses demonstrate that well-engineered adaptive tutoring can outperform conventional instruction under controlled conditions.

The same body of work also contains its most important qualification. In Kulik and Fletcher's synthesis, the size of the improvement depended heavily on whether outcomes were measured with locally developed tests or standardized ones. This suggests that close alignment between test content and the tutor's instructional objectives is a critical driver of reported gains. Effects measured on instruments written by the system's developers are likely to be larger than effects on independent, broad-based assessments. Any headline figure should therefore be read alongside the type of test that produced it.

The research base has also grown rapidly. A bibliometric analysis by Kuncoro and colleagues (2026) identified 237 peer-reviewed articles and conference papers on AI and intelligent tutoring in mathematics education indexed in Scopus between 2001 and 2025. Output grew slowly in the early 2000s and increased markedly after 2019, in step with interest in machine learning and large language models. Growth in output, however, is not growth in evidence. Much of the recent surge concerns systems whose effects have not yet been tested with the rigour applied to earlier tutors.

The newer wave of research concerns tutors built on large language models rather than rule-based logic. Here the evidence base is thinner but expanding quickly. A Brookings review of the field cautions that many claims about the educational benefits of generative AI have outpaced high-quality evidence. The same review notes that a number of recent rigorous studies suggest such tutors can deliver learning gains and may offer a path to individualized education at scale.

The most cited of these is a 2025 randomized controlled trial by researchers at Harvard, published in Scientific Reports. It compared college students' learning when content was delivered through a research-designed AI tutor with learning in an in-class active-learning

session. Active learning is itself a demanding comparison condition. Students learned significantly more in less time with the AI tutor, and they also reported feeling more engaged and motivated.

A separate exploratory randomized trial in UK secondary mathematics classrooms is registered in the American Economic Association's registry. In that trial, an AI tutor was integrated into a mathematics platform and supervised by human tutors. It produced a 5.5 percentage-point increase in students' likelihood of correctly answering novel questions. The human supervision matters here, because the result describes a hybrid arrangement rather than an autonomous machine.

Supporting evidence comes from adjacent syntheses. Zhang and colleagues (2025) conducted a meta-analysis of emotional AI in education. It drew on 172 articles published between 2000 and 2025, of which 54 studies reported in 49 articles quantified effects on cognitive and emotional outcomes. Systems integrating cognitive and emotional support showed a large effect on knowledge acquisition ($g = 0.88$). The authors are candid about the limits of their analysis. They did not run formal asymmetry tests for outcomes with fewer than 20 studies. For affective outcomes ($k = 31$), Egger's test indicated asymmetry, which signals possible publication bias. These findings suggest that tutors attending to both understanding and emotion may be especially effective, but they fall short of demonstrating it (see Q059).

These results are encouraging, but they rest on a small number of trials, often short in duration and conducted in single institutions or single subjects. Whether the gains persist, transfer across domains and survive deployment without researcher involvement remains unclear.

The picture is not uniformly positive, and the most important caveat comes from a large-scale field experiment by Bastani and colleagues (2025), published in PNAS. The study examined GPT-4's effect on high school mathematics learning. AI-based tutoring improved performance during practice sessions. Students who had relied on the technology, however, tended to underperform once AI access was removed, which indicates reduced independent skill acquisition. The remedy the researchers identified was deliberate design. Carefully designed safeguards mitigated the negative effects, especially instructing the AI tutor to offer teacher-designed hints rather than give away answers. The headline lesson is that the same underlying model can help or harm depending on how it is constrained. It is a mistake to read the study simply as "AI harms learning."

This finding is echoed elsewhere, though the wider evidence is more mixed in quality. A 2025 literature review in the National High School Journal of Science notes studies indicating that over-reliance on AI hints can worsen outcomes. It also cites a systematic review by Zhai and colleagues (2024) that associated regular use of AI dialogue and tutoring systems with a decline in students' cognitive abilities and a greater tendency toward cognitive offloading. That evidence is associational. It shows that heavy use and weaker cognitive performance co-occur, not that one causes the other.

Fan and colleagues (2024) add experimental texture from writing. They conducted a randomized study with 117 university students who completed a writing task under one of four conditions: support from ChatGPT, chat with a human expert, writing analytics tools, or no additional tool. The researchers collected multi-channel data on motivation, self-regulated learning processes and performance. Their warning against "metacognitive laziness" names a plausible mechanism for the PNAS pattern: learners may hand over the monitoring and regulation of their own work to the tool.

The theoretical scaffolding for studying such effects is still underdeveloped. Banihashem and colleagues (2025) mapped 84 studies at the intersection of AI and self-regulated learning. They found that the research concentrated on metacognitive and cognitive aspects of self-regulation, with motivation underexplored. Over one-third of the studies did not specify a self-regulated learning theory. The mechanisms by which AI assistance supports or erodes durable learning are therefore not yet well characterised (see Q053).

The positive trials and the offloading evidence do not contradict each other so much as describe different designs and different outcome windows. Still, credible sources currently disagree about how large and how common the risk of dependence is.

Beyond individual trials, the reviews paint a consistent picture of a literature with significant methodological gaps. A 2025 systematic review of AI-driven intelligent tutoring in K-12 education, published in npj Science of Learning, offers a useful summary for younger learners. Effects on learning and performance are generally positive, but they shrink when the comparison is a non-intelligent tutoring system rather than conventional instruction. Longer interventions and more diverse samples are needed. The point about comparison conditions is significant. Some of the apparent advantage of AI tutors may reflect the benefits of structured digital practice in general rather than anything specifically intelligent.

The same weakness recurs across the wider literature. Empirical evidence remains scarce. Many published evaluations rely on user satisfaction or short laboratory tasks rather than field experiments with validated learning measures.

Professional education shows the problem starkly. Dicheva and colleagues (2026) conducted a scoping review of intelligent tutoring systems in nursing education. Of 881 records retrieved, only 9 studies met inclusion criteria. Most of those described incomplete system architectures, and there was limited evidence of user-needs evaluation, theoretical framing, empirical validation or curricular integration. The authors concluded that the evidence is limited and inconsistent. Shaw, Henning and Webster (2025) reviewed 42 peer-reviewed articles on AI in medical education published between 2010 and 2022. They found promising early applications in surgical simulation and interactive learning, but evidence on educational and clinical outcomes remained limited, and they called for validated outcomes in larger trials. Gordon and colleagues' (2024) BEME scoping review synthesised 278 medical-education publications, including perspective pieces as well as original studies. About 68 percent of those publications came from North America and Europe, which illustrates both the volume of commentary and its geographic concentration.

Reviews of reviews reach similar verdicts. Mustafa and colleagues (2024) synthesised 143 literature reviews on AI in education. They found the research dominated by work from China and the United States and concentrated on higher education, with special education receiving little attention. Bond and colleagues (2024) analysed 66 secondary reviews of AI in higher education and explicitly called for greater ethics, collaboration and rigour. The volume of syntheses now far exceeds the number of well-powered experiments they can draw upon. This is one reason several confident generalisations about AI tutoring deserve scepticism (see Q060).

Three conclusions emerge from this body of work.

First, well-designed AI tutoring systems can produce real academic gains. This holds particularly for systems that adapt to the learner, provide formative feedback and resist simply handing over answers, and especially in structured domains such as mathematics and science. For rule-based tutors this conclusion is established. For generative tutors it is suggested by a few strong trials rather than demonstrated across settings. Awang, Yusop and Danaee's (2025) systematic review of AI in mathematics education distinguishes two kinds of tool. Some

narrowly solve problems, such as solving equations or visualising geometry. Others offer broader pedagogical support through adaptive systems and generative platforms. The tutoring evidence reviewed here mostly concerns the second kind. Results for the first kind should not be extrapolated from it.

Second, design choices matter enormously. Safeguards that constrain how the AI assists are not merely a safety feature but a pedagogical necessity. They are needed to ensure that human learning is preserved rather than displaced. The gap between a well-designed AI tutor and an unconstrained language model is not cosmetic. It may determine whether the technology helps students learn or merely helps them complete tasks.

Third, implementation and equity shape outcomes as much as the software does. Sevilla and colleagues (2025) argue that the impact of computer-assisted learning and AI-guided tutors depends less on access to devices than on integration into teaching: curriculum alignment, teacher training and interactive design that promotes active learning. Their new evidence from Italy shows persistent digital divides in AI adoption across schools and regions, reflecting broader social and economic disparities. Without careful implementation, these tools risk widening the very gaps they are promoted to close.

The priorities for the next generation of research follow from these conclusions. Studies should run longer, test retention after AI access is withdrawn, use comparison conditions that isolate the contribution of the AI itself, and rely on independent standardized assessments. Until such studies accumulate, institutions should treat the strongest generative-AI results as proof that benefits are possible. They should not treat them as guarantees of what any particular product will deliver.

What changed in this edition: This answer is unchanged in Edition 120. Its most recent revision, in Edition 117: Expanded and reorganised into six sections. Added named attributions, adjacent-field reviews (nursing,

> medical, mathematics), meta-analytic and self-regulation evidence, equity findings and cross-references. Distinguished established from emerging and disputed claims. (694 → 2,043 words · 11 new sources)

Q052 What does research reveal about how students actually use generative AI when unsupervised — as distinct from how they report using it?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Research suggests that students use generative AI far more extensively than they disclose, especially in assessed work. What they hide, however, is usually not wholesale ghost-writing. It is a broad, often undeclared reliance on AI for explanation, summarising and drafting support, and that concealment is shaped as much by institutional ambiguity as by dishonesty. This conclusion rests on an uneasy combination of large self-report surveys, indirect elicitation techniques and a small but growing body of qualitative work that observes students' actual interactions. Each method sees a different part of the picture, and the gap between them is itself the central finding.

The self-reported figures are striking on their own terms. The Higher Education Policy Institute's Student Generative AI Survey 2025, based on more than one thousand UK undergraduates, found that the proportion of students using tools such as ChatGPT for assessments rose from 53 percent in 2024 to 88 percent in 2025. HEPI's 2026 survey reported near-universal use: 95 percent of students said they used AI in at least one way, and 94 percent said they used it to help with assessed work. Because HEPI has repeated its instrument across three cohorts, the direction of travel is about as well established as anything in this field. A second source points the same way, although it is not independent research. Copyleaks, a company that sells AI-detection software, reported in its 2025 student usage report that nearly 90 percent of respondents had used AI for academic purposes, almost a third daily and a further 24 percent several times a week. Those figures come from a firm with a commercial stake in perceptions of student AI use, and they have not been peer reviewed. They are better read as a corroborating market signal than as evidence in their own right.

All of these numbers share a deeper limitation. They are declarations, collected under conditions where some answers carry more social and institutional risk than others. The more

revealing research begins precisely where self-report runs out.

The most direct evidence of systematic underreporting comes from list experiments. In this survey technique, respondents report how many items on a list apply to them rather than which ones, so they can acknowledge a stigmatised behaviour without it being attributed to them individually. A study combining interviews and list experiments with 305 Indonesian undergraduates found that students were often reluctant to admit dishonest behaviour when asked directly. The anonymised list format produced substantially higher admissions of AI-assisted cheating. A larger quantitative study of 1,386 Vietnamese undergraduates, also using list experiments, found the same pattern: students tended to conceal AI-assisted cheating under direct questioning. In both settings the mechanism appears to be shame and social pressure rather than simple ignorance of the rules.

Qualitative work points the same way. A conceptual model of AI-assisted academic cheating, built from postgraduate students' own accounts and published in Frontiers in Computer Science in 2025, treats misconduct as something students reason their way into. On this account, students weigh pressures, opportunities and justifications rather than simply breaking rules they misunderstand. This supports reading concealment as a considered response to context, not as moral carelessness.

Pérez-Portabella and colleagues (2026) add a quantitative perspective on how students evaluate misuse itself. They surveyed social science students at two Spanish universities about a typical form of misuse: producing academic essays with minimal human editing. Using the Multidimensional Ethics Scale, they analysed four ethical dimensions alongside gender and employment status, combining partial least squares structural equation modelling with fuzzy-set qualitative comparative analysis. Only consequentialism and relativism significantly predicted students' intention to use generative AI in this way, which the authors read as reliance on perceived utility and contextual social norms. Moral equity and deontology showed no significant effects. The configurational analysis also found that acceptance and rejection of misuse followed distinct, asymmetric pathways.

These are associations with stated intention, not observed behaviour. Even so, they help explain why direct questions fail. If students judge AI use by local norms and practical payoffs rather than by abstract rules, their answers to an institution's questions will track what seems safe to say rather than what they do.

A further strand of research concerns covert use more broadly, not only misconduct. Qualitative interviews with college students, published in 2026 under the title "Everyone's using it, but no one is allowed to talk about it," describe a growing misalignment between students' AI adoption and existing institutional practices around assessment, policy and limited AI resources. According to the authors, this misalignment has produced covert AI use, increased student anxiety and an intention–behaviour gap. Students describe feeling pressured into dysregulated AI engagement, using the tools in ways they themselves would not choose. The same study found that traditional assessment structures, with their tight deadlines, exam stacking and graded homework, push students towards using AI to complete tasks rather than to engage deeply. Institutional design, in other words, appears to produce the covert behaviour it nominally prohibits.

Research on online assessment reinforces this account. A 2025 study in the Journal of Academic Ethics examined how students use and hide AI in online assessments. Roughly one third of its respondents admitted some AI use, yet disclosure to instructors was rare. The authors interpret this silence not as dishonesty but as rational caution in the face of ambiguous policies and perceived academic risk. They argue that authentic assessment tasks, rather than detection regimes, offer the more promising response. The weaknesses of those detection regimes are examined separately (see Q056).

The policy texts that students are meant to follow have their own history. Nguyen and colleagues (2025) analysed 1,260 posts on X about generative AI in education, alongside guideline documents from international organisations, governments and universities. Early online discourse concentrated mainly on legitimating the technology, and the topics of that discourse aligned noticeably with those later addressed in official guidelines. Guidance therefore tended to formalise conversations that were already under way rather than lead them. That is consistent with students experiencing policy as something that lags behind practice. The combined picture suggests that concealment is partly a reasonable reaction to rules that arrived late and remain unclear, although the qualitative studies behind this interpretation are small and context-bound.

When conditions allow honesty, what students say they use AI for diverges from the catastrophising narratives common in faculty discourse. In HEPI's surveys, the most frequently reported uses are explaining concepts, summarising articles and suggesting research ideas. These functions are closer to an advanced reference tool than to a ghost-writing service. HEPI's

2026 survey found that 12 percent of students reported directly including AI-generated text in assessed work, up from 8 percent in 2025 and 3 percent in 2024. That trend is real and rising, and given the underreporting evidence above, it is probably an undercount. Still, even with near-universal reported engagement, wholesale text submission remains a minority behaviour. The more common reality is iterative assistance at earlier stages of work.

The most direct look at unsupervised behaviour, rather than reported behaviour, comes from Yan and colleagues (2026). They studied how 38 undergraduates in Japan and China used generative AI in after-class assessments, analysing usage intentions, actual dialogue patterns and how AI use fitted with other learning activities, within Biggs' presage–process–product model. Engagement was not uniform. It ranged along a spectrum from cognitive outsourcing, where students hand the thinking to the tool, to cognitive reallocation, where they redirect effort towards higher-order work. The authors present this as an adaptation of the classic distinction between surface and deep approaches to learning.

Their most consequential finding is what they call an efficiency paradox, which they describe as a prevalent misalignment. Well-intentioned students who meant to use AI for learning often defaulted to passive processes in practice, and reported cognitive laziness and overreliance. Because the study examined dialogue patterns rather than relying only on recall, it captures exactly the intention–behaviour gap that surveys cannot see.

The sample is small, qualitative and limited to two national contexts, so the prevalence of each pattern remains unclear. The finding nonetheless qualifies the reassuring reading of HEPI's figures. A student who honestly reports using AI "to explain concepts" may, in the moment, be outsourcing the very cognitive work the explanation was meant to support. How such patterns affect different learners, and what they mean for writing development, are taken up elsewhere (see Q057 and Q054).

What distorts disclosure, the evidence suggests, is chiefly institutional ambiguity rather than moral recklessness. Students and the institutions that regulate them also appear to reason about AI on different terms. A 2025 study of student perceptions of AI-assisted writing and academic integrity, published in an MDPI journal, found that awareness of a university's AI policy did little to change students' views on whether using AI was ethical. Contrary to what institutional leaders might assume, formal guidance often trails behind the informal norms students create for themselves. This fits Pérez-Portabella and colleagues' (2026) finding that relativism and

consequentialism, rather than deontological reasoning about rules, predicted students' intentions to misuse AI. Two studies with different designs in different countries therefore converge on a similar conclusion: policy statements are a weak lever on student moral judgement.

Faculty frame the problem differently. Shahid and colleagues (2026) interviewed 25 marketing professors from six countries, with an average of 12.9 years' teaching experience. The most frequently coded category in their thematic analysis concerned challenges and concerns: ethics, declining student skills and possible dependence on AI systems. A second category reflected openness to adoption and awareness that teaching methods must change. Kaushik and colleagues' (2025) thematic analysis of seven essays by education professionals found a similar mix of perceived benefits, drawbacks and calls for guidelines to ensure responsible student use. Both studies are small and record professionals' perceptions, not student behaviour. They show, however, that educators' worries centre on dependence and erosion of skills. The observational evidence from Yan and colleagues suggests those worries are better founded than worries about outright text substitution. Teachers' own adoption patterns are examined separately (see Q058).

The literature does not yet agree on how to interpret the distance between student and staff framings. One reading treats student norms as a rationalisation that policy should correct. Another treats them as a signal that rules prohibiting an everyday technology have lost legitimacy. The available evidence cannot settle this, and credible researchers lean in both directions.

The picture that emerges is more complicated than either the "students are cheating en masse" framing or the "students are using AI responsibly" framing allows. Students use generative AI far more extensively than they disclose, particularly in high-stakes assessment. Self-report surveys from HEPI document near-universal use. List experiments in Indonesia and Vietnam show that direct questions underestimate AI-assisted cheating. Qualitative studies in the United States, Japan and China describe covert use driven by assessment pressure and policy ambiguity. The concealment these studies describe is shaped less by calculated dishonesty than by a policy environment that treats as illicit a technology students experience as ordinary, and by assessment structures that reward speed over depth. The behaviour gap is, in this sense, partly an institutional creation.

The gap is not only between what students say and what they do. Yan and colleagues' efficiency paradox points to a second gap, between what students intend and what they actually do with

the tool. That gap exists even when nothing is being hidden, and it may matter more for learning than misconduct does. Surveys are structurally unable to detect it.

The evidential limits should be stated plainly. Almost none of this research observes truly unsupervised behaviour at scale. List experiments estimate prevalence but say nothing about how AI is used. Dialogue-level studies show how it is used, but only for dozens of students. Vendor reports such as Copyleaks' supply large numbers without independent scrutiny. Whether the outsourcing end of the spectrum predominates in practice, and whether authentic assessment reliably shifts students towards reallocation, remains unclear. The underlying patterns are consistent enough to guide practice, but claims of precise prevalence deserve caution (see Q060). Research that pairs anonymised prevalence measures with consented interaction logs across larger and more diverse samples would close much of the distance between what students report and what they do.

Q053 What is currently known from cognitive science about AI's effects on memory formation, retention, and transfer of learning?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Cognitive science currently suggests that AI's effects on memory formation, retention, and transfer depend less on the technology than on how it is used. When AI takes over the effortful work that builds durable memory, it tends to weaken retention and transfer even as it raises immediate performance. When it is deliberately designed around established principles of learning, it can strengthen them. The resulting picture is complicated. AI is neither a

straightforward cognitive prosthetic nor a simple threat to the mind, and the evidence shows it acting as both.

The tension at the centre of this literature is often called a performance paradox. A growing body of empirical work, reviewed in the University of Technology Sydney briefing on AI and cognitive offloading and in the arXiv analysis of decreasing knowledge and over-reliance, finds that AI can improve a student's output on an immediate task while reducing the durable learning that education exists to produce. The paradox follows from one of the best-replicated principles of memory science: difficulty and effort during learning are not obstacles to retention but conditions for it. Researchers describe certain tasks as "desirably difficult" because they feel effortful yet improve both learning outcomes and knowledge transfer. Learners routinely underrate these tasks precisely because they feel harder. Retrieval practice is the canonical case. Self-testing is markedly more effective than re-reading, yet it demands more cognitive effort, and students left to their own judgement often prefer the easier and less effective strategy. The superiority of effortful retrieval over passive review is demonstrated across decades of laboratory and classroom research. What is newer, and still emerging, is evidence on how AI interacts with this mechanism. Systems that supply finished answers on demand routinely short-circuit the generation and retrieval processes on which consolidation depends. The concern, then, is not that AI is inherently corrosive. It is that its default interaction pattern removes the very friction that memory needs.

The concept that organises most of this research is cognitive offloading, the use of external aids to accomplish cognitive tasks. The phenomenon predates generative AI. In 2011 Sparrow, Liu and Wegner documented what became known as the "Google effect": people who expect information to remain accessible tend to remember where to find it rather than the information itself. Reviews of digital technology and cognition, including the 2026 arXiv review of negative effects of digital technology on cognition, link this externalisation to faster forgetting and weaker recall. Offloading is not inherently harmful, since writing itself is a form of it. The question is what is lost when the offloaded process is the one that would have built the memory.

Generative AI appears to intensify the pattern considerably, because it offloads not only storage but also the synthesis, explanation and composition that previously forced learners to process material deeply. A systematic review of AI's impact on learners' memory, published in the Contemporary Educational Researches Journal, reports that reliance on tools such as ChatGPT for information retrieval or task completion has been associated with reduced memory retention

and shallower encoding. On this account, users shift toward passive consumption and away from the active rehearsal and consolidation that durable memory requires. The same body of work, together with the broader digital-cognition review, links AI-assisted and automating technologies to declines in spelling, handwriting, arithmetic and language learning. In each case automation reduces the cognitive effort that ordinarily reinforces these skills. Much of this evidence is correlational or drawn from short-term studies, so the size and permanence of such declines remain unclear.

The most widely discussed neural evidence comes from a laboratory study by Kosmyna and colleagues. They examined the neural and behavioural consequences of LLM-assisted essay writing by assigning participants to three conditions: LLM support, search engine support, and no tools at all. Measured cognitive activity decreased as participants relied on external tools. Self-reported ownership of the essays was lowest in the LLM group and highest in the brain-only group. The authors describe this pattern as the accrual of "cognitive debt," meaning effort saved in the moment at the cost of weaker internal representations later. The study is small and has not yet been extensively replicated, and its framing has attracted both attention and scepticism. Related work comparing chat-based generative AI with conventional search as routes to information seeking and learning, such as the arXiv study "Learning by Chatting?", likewise suggests that the conversational convenience of chatbots does not automatically translate into deeper learning. That literature is still young, and its findings are not yet settled (see Q054 for the specific case of writing development).

The evidence on who is most vulnerable remains limited, but it points consistently in one direction. In a mixed-methods survey published in Societies, Gerlich reports a significant negative correlation between frequent AI tool use and critical-thinking ability, with increased cognitive offloading statistically mediating the relationship. Younger participants in that sample showed higher dependence on AI tools and lower critical-thinking scores than older participants. These are correlations from cross-sectional data. They cannot establish that AI use causes weaker critical thinking, and the reverse direction, in which less confident thinkers lean more heavily on AI, is equally consistent with the findings. Even so, the age gradient matters because the populations most immersed in AI assistance are those still building durable knowledge structures.

The developmental literature on earlier digital technologies offers context but no resolution. In a 2024 narrative overview in Children, Clemente-Suárez and colleagues integrated more than

157 peer-reviewed studies published between 2001 and 2024, searching PubMed, Embase, Scopus and Web of Science, to assess how digital device use relates to attention, memory, executive functions, problem-solving and social cognition in childhood. They describe a genuinely two-sided picture. Devices may enhance skills such as multitasking and information processing, but they also carry risks of cognitive overload, diminished attention spans and impaired social skills. The authors also stress that the spread of devices in childhood has outpaced understanding of their long-term effects. That review concerns digital devices broadly rather than generative AI, so its findings should be treated as an analogy rather than direct evidence. It nonetheless reinforces the point that children's cognitive outcomes depend on the type, timing and intensity of exposure, and that long-term effects on memory remain poorly characterised (see Q015 on how ethicists weigh acting under this uncertainty).

The picture is not uniformly negative, and the positive evidence is substantial. A meta-analysis of 51 experimental studies reviewed in the PMC article on the cognitive paradox of AI in education found a large positive effect of AI on learning performance. A separate randomised experiment discussed in the same literature found that students learned significantly more, in less time, with a carefully designed AI tutor than in an in-class active-learning session. These findings do not contradict the offloading research so much as qualify it. Most of the positive studies measure performance shortly after instruction, often with AI systems built for pedagogy rather than general-purpose chatbots. Whether those gains persist, and whether they survive removal of the tool, is a separate question that the meta-analytic evidence does not resolve (see Q051 and Q263 for a fuller treatment of effect sizes and methodological quality).

The deciding factor appears to be whether AI works with established memory principles or against them. The systematic review of AI and learners' memory organises the evidence by memory stage. Encoding is strengthened when AI systems provide multimodal, attention-capturing stimuli. Working memory is supported when designs manage cognitive load rather than add to it. Long-term retention is best served when tools build in retrieval practice and deep processing rather than replacing them. Work on spaced repetition and retrieval practice in the International Journal of Asian Social Science Research shows how adaptive systems can operationalise these principles. Such systems use machine learning to personalise review schedules, calibrate retrieval difficulty to the individual learner, and improve learning efficiency. The same work acknowledges practical obstacles, including the initial cognitive load of unfamiliar systems and the difficulty of calibrating personalisation accurately.

AI can also support memory indirectly by diagnosing what learners have encoded incorrectly. In a 2024 study in Education and Information Technologies, Kökver, Pektaş and Çelik used natural language processing and supervised machine learning to analyse responses from 402 teacher candidates about the greenhouse effect. The analysis classified 175 of them as lacking sufficient knowledge of the concept. A multilayer perceptron gave the highest single-algorithm accuracy, and an ensemble architecture developed by the authors performed best overall. Agreement with human expert evaluation was assessed with the kappa statistic. The study does not measure retention or transfer directly. It does show how AI can surface misconceptions that would otherwise persist and interfere with later learning, which shifts the system's role from answer-supplier to diagnostic aid.

Transfer, the ability to apply knowledge flexibly in new contexts, remains the most elusive and least studied dimension. Reviews such as the UTS briefing argue that bypassing cognitive effort impairs the acquisition of knowledge and skill and contributes to deskilling. A more pointed finding comes from the arXiv analysis of over-reliance: studies commonly show that students and knowledge workers who used AI perform worse than those who never did once access to the tools is withdrawn. This dependency effect suggests that some AI-enabled gains are inseparable from the tool itself. In those cases, what looks like learning is better described as assisted performance, with no internalised understanding that carries into unassisted contexts. Writing in Frontiers in Education on AI-powered metacognition, the authors of the "cognitive mirror" framework argue that current integrations tend to privilege efficiency over learners' epistemic agency. In doing so, they normalise quick answer-taking at the expense of verification, sense-making and productive struggle, which are the metacognitive behaviours most closely tied to self-regulated learning and transfer.

Theory is beginning to catch up with this problem. In 2026, Yan and Gašević proposed Agentivism in Computers and Education: Artificial Intelligence as a learning theory for the age of generative and agentic AI. Their starting premise restates the performance paradox at the level of theory: successful performance can no longer be assumed to indicate learning. Learners may complete tasks effectively with AI support while developing less understanding, weaker judgement and limited transferable capability. The authors argue that behaviourism, cognitivism, constructivism and connectivism remain important but do not directly explain when AI-assisted performance becomes durable human capability. Agentivism defines learning as durable growth in human capability through four processes. These are selective delegation to

AI, epistemic monitoring and verification of AI contributions, reconstructive internalisation of AI-assisted outputs, and transfer under reduced support. The authors frame the theory as yielding six testable propositions, so it should be read as a research agenda rather than an empirical result. Its value lies in making transfer under reduced support an explicit criterion of learning, which is exactly the test the dependency studies suggest many AI deployments fail.

A more speculative contribution comes from Levin's 2024 essay in Entropy, which argues that memory across biological scales is better understood as preserving salience than fidelity, continually reinterpreted to suit a changing agent and environment. This view is philosophical rather than an educational finding, but it fits the notion of reconstructive internalisation. If memories are actively rebuilt rather than simply stored, then outputs a learner has merely received from AI, without reworking them, may lack the personal salience that makes knowledge retrievable and transferable later.

The most defensible reading of current knowledge runs as follows. AI can enhance specific, often narrow dimensions of learning when it is deliberately engineered around cognitive science principles: retrieval practice, spacing, cognitive-load management and the diagnosis of misconceptions. Its default mode of use, however, is frictionless, immediate and effortless, and that runs directly counter to the conditions under which the brain forms durable memories and transfers knowledge across contexts. The underlying memory science is established. The evidence on AI specifically is emerging. On the net effect, positive meta-analytic results and dependency findings stand in genuine tension.

That tension cannot yet be resolved, because the field lacks longitudinal data sufficient to measure cumulative costs or benefits. Most studies follow learners for a single session or a single course. Most measure immediate performance rather than delayed retention. Few test transfer to unassisted, novel problems in the way frameworks such as Agentivism now propose. Until studies track the same learners across years and routinely assess performance after AI support is withdrawn, claims that AI either erodes or enhances memory and transfer at scale should be treated as provisional (see Q092 on how such long-term studies should be designed).

Q054 What does the evidence show about AI's impact on writing skill development, from early literacy through academic and professional writing?

18 citations · 18 sources · 5 cross-references

Claim 1 disputed

The evidence shows that AI reliably improves the surface features of writing, such as grammar, vocabulary and mechanics, and can speed up professional writing. It does not yet show comparable gains in the deeper skills that define accomplished writing: argument, coherence, structure and voice. It also documents a persistent risk that passive use produces dependency rather than development. Across the full arc from early literacy to professional practice, the story is genuinely complicated and resists both utopian and dystopian simplification. The clearest finding is that effects depend heavily on how the technology is used, at what developmental stage, and by whom.

Three features of the evidence base shape everything that follows. First, much of it is young. Studies of generative chat feedback in higher education rose steeply from 2022 onward, yet the systematic review published in Education Sciences located only 13 studies by 2024, too few to support confident meta-analytic conclusions (see Q263). Second, the strongest data on children come from large surveys, notably the National Literacy Trust's annual reports. These describe what young people say they do and believe, not what they learn, so their associations remain correlational. Third, the outcomes that are easiest to measure, such as error counts, vocabulary range and task completion time, are precisely those on which AI performs best. A content analysis of AI-powered writing tools captures the resulting pattern: mechanics improve, while over-reliance may hinder creativity and independent editing. That asymmetry between what is measured and what matters recurs at every stage of development.

Among younger children, the picture is more cautious than celebratory. The National Literacy Trust's 2024 survey found that children aged 8 to 13 more often than older age groups reported that generative AI helped them with ideas and with learning new things. This suggests some genuine utility in sparking engagement at the stage when children are first learning to generate and organise content. The behavioural patterns, however, are worrying. In the Trust's 2025 report, one in four young people admitted simply copying AI outputs when using it for homework, up from one in five the previous year. The trend was more pronounced among younger teens and among those already less engaged with reading and writing. The children who most urgently need to develop compositional habits are therefore the most likely to let the machine do the composing for them.

Very little of this evidence measures writing outcomes directly. No study in the present source base tracks young children's compositional development over time under conditions of AI use, so whether early exposure strengthens or weakens foundational writing skill remains unclear.

A parallel literature on AI literacy is relevant but should not be mistaken for writing research. Yim and Su (2025) systematically reviewed 25 empirical studies of AI literacy education in primary schools. They found that AI literacy is conceived fluidly, spanning interaction and collaboration with AI, computational thinking, critical data literacy and ethics. Constructivist, project-based and programming-centred pedagogies dominate these studies. Zhang, Perry and Lee (2024) validated a 20-item AI literacy concept inventory with 981 middle school students. Their instrument shows that young learners' understanding of how AI systems work can be reliably assessed.

These studies matter here because the copying behaviour reported by the National Literacy Trust is partly a problem of understanding. A child who grasps that a language model predicts plausible text, rather than knowing or thinking, may be better placed to treat its output as material to interrogate. That link is a hypothesis, however. Neither review nor inventory tests whether AI literacy instruction changes how children write with AI.

At the secondary and university levels the literature is larger and growing rapidly. Within it, surface-level benefits are consistent and reproducible. Reviews of AI-driven feedback tools report that AI-based software improves vocabulary and grammar at the surface level. The same reviews find no demonstrable impact on deeper-level skills such as coherence, arrangement and the formatting of text. Studies of AI-powered writing tools and academic writing performance

report the same profile: mechanical accuracy improves while higher-order organisation does not move in step.

This asymmetry matters enormously. Grammar and mechanics are the easiest dimension of writing to assess and the easiest for AI to fix. Argument, structure and voice are what actually distinguish accomplished writing, and these appear largely unaffected by automated assistance. A writing intervention that raises error-free sentences while leaving argument untouched can look successful on a rubric weighted toward correctness, which is one reason headline gains deserve scrutiny (see Q060).

Student perception studies add a more optimistic but methodologically weaker strand. Alkhawaja and colleagues (2025) surveyed 78 students in computer-aided translation courses over two semesters. These students used Grammarly, ChatGPT, QuillBot, Textero AI and ChatPDF. They perceived these tools as beneficial for self-directed learning, problem-solving, critical thinking and digital literacy, although the perceived impact varied across tools. The authors conclude that AI tools can significantly enhance educational quality.

The design limits that inference. The study used purposive sampling, a single questionnaire and self-reported perceptions rather than measured writing performance. Students believing they think more critically is not the same as demonstrably writing with greater critical depth. Read alongside outcome-based reviews, the finding suggests a gap between how helpful students feel AI to be and what objective assessments of deep writing quality show. Closing that gap requires designs that measure compositional skill directly, ideally after the tool has been withdrawn.

There is nonetheless genuine evidence that AI feedback, used thoughtfully, can support metacognitive development. The systematic review of generative chat feedback in higher education reports that, in some studies, such feedback enables reflective and metacognitive processes essential to writing. It allows students to evaluate their errors and make deliberate adjustments. The critical qualifier is that these benefits accrue to students who engage critically with the feedback, not to those who accept it passively. How AI feedback compares with human feedback in accuracy and receptivity is treated separately (see Q055).

The counterweight is dependency. Darvishi and colleagues (2024) found that students tended to rely on AI assistance rather than learn from it. When AI support was removed, self-regulation strategies only partially compensated, and outcomes lagged behind AI-assisted performance.

That pattern, improvement that evaporates without the scaffold, is perhaps the most consequential finding in the field. It implies that many reported gains measure assisted performance rather than acquired skill. The two literatures therefore pull in opposite directions. One shows AI prompting reflection, the other shows AI displacing it. Credible sources disagree on which effect predominates in ordinary classroom use.

Motivation and prior engagement appear to decide much of the outcome. The National Literacy Trust found that young people who enjoyed reading or writing were more likely to add their own thoughts to AI outputs. Those who did not enjoy these activities were more likely to copy AI responses wholesale. The association is correlational, but it is consistent with a broader reading that AI tends to amplify existing orientations rather than correct them. Enthusiastic writers use it experimentally; disengaged writers use it as a substitute. The implications for different learner profiles, and for motivation more generally, are examined elsewhere (see Q057 and Q059).

Whether deliberate instruction can shift students from substitution toward critical engagement remains only tentatively answered. Tzirides and colleagues (2024) conducted a mixed-methods case study of 37 graduate students across three eight-week courses. The courses used a GenAI reviewer built around transparency in AI-human interaction, together with image generators for reflection. Participants became more comfortable with GenAI and showed an enhanced ability to critically assess the value of AI applications in education. Walter (2024), drawing on a Swiss university case study and a narrative review, argues that AI literacy, prompt engineering and critical thinking should be embedded together in curricula. These works suggest that structured, critical use is teachable. Neither measures writing quality, however, and the small samples preclude generalisation.

At the professional level, the documented productivity gains are real. In a randomised controlled trial, Noy and Zhang (2023) found that workers given ChatGPT completed writing tasks 37% faster and received quality ratings 18% higher. This is among the more rigorous results in the field. But speed and rated quality on a single task are not the same as sustained development of writing craft. The trial shows what assisted professionals produce, not whether their unassisted capability grows, stagnates or erodes.

Analyses of AI in knowledge work, including the argument that AI is dissolving the keyboard's instrumental centrality, document a related shift in scientific writing. Scientists use AI tools for

ideation and structural scaffolding while transferring their primary cognitive effort toward evaluation and selection rather than composition. Whether that shift constitutes a loss or a reasonable reallocation of cognitive labour remains genuinely contested. An experienced writer who evaluates AI drafts draws on judgment built through years of composing. A novice who skips composing may never acquire that judgment.

The emerging literature on workplace AI literacy reframes what professional writing competence might mean. Xin, Zhang and Wei (2025) developed a five-dimension scale of generative AI literacy covering technical competence, prompt optimisation, content evaluation, innovative application, and ethical and compliance awareness. They report that it predicts job performance ($\beta = 0.680$, $p < 0.001$), partly mediated by creative self-efficacy (indirect effect = 0.537). This is a cross-sectional association, not evidence that AI literacy causes better performance. It is also general job performance rather than writing quality. Still, the prominence of content evaluation in the scale echoes the evaluative turn in scientific writing.

Professional frameworks point the same way. Hoelscher and Pugh's (2025) guide for nursing asks practitioners to use AI strategically, recognise its pitfalls such as biased data, and commit to frequent skill development. It is prescriptive guidance rather than empirical evidence. Together these works suggest that professions are redefining writing-adjacent competence around judging machine output, without yet knowing what that redefinition costs in compositional skill.

The underlying tension can be stated directly. AI writing tools demonstrably help with the measurable, correctable and mechanical aspects of writing. The deeper skills of voice, argumentation, creative risk-taking and structural judgment remain largely untouched by the tools and potentially at risk from passive use. Content analysis of AI-powered writing tools finds that while they enhance mechanics, over-reliance may hinder creativity and independent editing abilities. The dependency finding of Darvishi and colleagues shows how this could happen: skill is not built when the scaffold does the work.

Students are not oblivious to the stakes. In the National Literacy Trust's 2025 survey, two in three young people agreed that "even when we have AI, it is important to learn how to write." The challenge, then, is not whether students understand the value of writing skill. It is whether the path of least resistance, handing the task to the machine, will quietly erode the practice that builds it.

Teachers are the obvious mediators, and the evidence on preparing them is thin but suggestive. Tenberga and Daniela (2024) found through principal component analysis of a pilot self-assessment that AI literacy forms a distinct competence category, overlapping with but separate from established digital competencies. They conclude that it requires focused professional development. Le and colleagues (2026) piloted a design-based GenAI literacy workshop with 14 master's students and evaluated it with 29 teacher education students. They report significant gains in AI competence self-efficacy and attitudes. Both studies measure self-perception rather than classroom practice, and neither addresses writing instruction specifically. Broader patterns of teacher adoption are discussed elsewhere (see Q058).

Taken together, the evidence suggests that the decisive variable is pedagogical design rather than the tool. The key design choices are whether students must compose before consulting AI, whether they are assessed on unassisted work, and whether they are taught to interrogate rather than accept output. Until longitudinal studies measure writing ability after AI support is withdrawn, any claim that AI develops writing skill, as opposed to improving written products, remains unproven.

Q055 What have studies found about AI feedback compared with human feedback — in accuracy, usefulness, and student receptivity?

22 citations · 22 sources · 5 cross-references

Claim 1 disputed

Studies comparing AI-generated and human feedback show rough parity in aggregate learning outcomes and in some measures of scoring accuracy. Human feedback keeps a clear edge on

higher-order, contextual and dialogic dimensions. Student receptivity is more complicated than a simple preference for the human touch: learners often trust teachers more, yet sometimes act more readily on machine feedback. The evidence is genuinely mixed, and usefully so, because the pattern of the mixture shows what feedback is actually for.

On scoring accuracy, AI systems have closed much of the gap with human raters. Work reviewed in this literature reports that systems such as e-rater and ChatGPT-3.5 have shown the potential to match human evaluators in grading accuracy. Deep learning models have reached quadratic weighted kappa scores of 0.78, against human inter-rater agreement of about 0.72. The conditions under which machine and human marks diverge are treated more fully elsewhere (see Q238).

Statistical parity in scores conceals qualitative differences in the feedback itself. When comprehensive correct answers and domain knowledge are supplied, large language models produce concrete and factually correct feedback on structured tasks. On longer essays, however, studies have documented recurring hallucinations. The problem is most acute in knowledge-intensive writing, where the system must judge nuanced conceptual claims rather than surface grammar or argument structure. Proficient students frequently find AI feedback lacking in personalisation on higher-order concerns such as theme development or rhetorical strength. Advanced learners also question whether such systems can evaluate subjectively rich content at all.

Accuracy also depends on who is judging it. Jayawardena, Gunathilake and Ihalagedara (2025) had ChatGPT-4 and a human tutor assess 194 dental students' answers to two histology questions against the same rubric. Students did not perceive differences in feedback quality. A subject expert, however, reviewed a random subset of 40 answers and rated the AI higher at identifying mistakes, with significant advantages in clarity and in suggestions for improvement. Santos, Viana and Sánchez-Caballé (2026) reviewed 23 studies and concluded that prompt design is decisive for both the content accuracy and the pedagogical relevance of AI feedback. Their review suggests that reported accuracy partly reflects how carefully a system was configured, and is not simply a fixed property of the technology.

On usefulness for learning, recent meta-analyses report rough equivalence, with important caveats underneath. Kaliisa and colleagues (2025) pooled 41 studies involving 4,813 students and found no statistically significant difference in learning performance between students

receiving AI-generated and human-provided feedback. The pooled effect was small and non-significant (Hedges' g = 0.25, 95% CI −0.11 to 0.60). The confidence interval spans both a modest disadvantage and a moderate advantage for AI, so "potentially as effective" is the most the data support. A separate analysis restricted to language and writing studies reached the same conclusion, but heterogeneity remained extreme (I^2 = 95%). The studies therefore differ so much in design, task and population that a single average conceals more than it reveals.

A different question yields a more favourable picture. Wang and colleagues (2026) asked whether AI-supported personalised feedback helps relative to other conditions, not whether it matches teachers. Across 40 studies they found a moderate effect on learning outcomes (g = 0.58) and a strong effect on learning motivation (g = 0.82). These are not trivial numbers. They answer a different question from Kaliisa's, however: AI feedback helps compared with the usual alternatives, but it does not demonstrably outperform a human doing the same job. Readers comparing these syntheses should keep the comparison condition in view (see Q263).

Individual trials pull in both directions. One study of LLM-based multimodal feedback reports equivalent learning and better student perceptions than educator feedback. An exploratory intervention by Hirschi and colleagues (2025) involved 90 second-language learners. Visual feedback alone improved prominence production. Only learners who also received ChatGPT-style narrative feedback improved on two of three prosodic features and on intelligibility. Yet that same group rated the practice activities as least helpful. Learning gains and perceived usefulness, in other words, can move in opposite directions. That finding should make researchers wary of treating satisfaction surveys as proxies for effectiveness.

The aggregate parity also obscures an asymmetry in what each source of feedback does well, particularly in writing. One controlled three-way comparison of teacher, peer and AI feedback in higher education produced a counterintuitive result. Students receiving teacher feedback reported less willingness to revise their work. Even so, teacher feedback produced the strongest improvements in scientific argumentation and formal writing quality, and LLM feedback produced the smallest improvement overall. A systematic review of AI-based automated written feedback reached a consistent conclusion. Automated feedback can improve learners' writing, but it is not as effective as feedback from humans such as teachers and peers.

A study of informative text writing identified a revealing difference in the kind of dialogue each source opens. Teachers gave question-based feedback that prompted students to think

critically, whereas generative AI chatbots did not use this type of feedback at all. Human feedback may therefore stimulate a different kind of cognitive engagement. It invites students to reconsider their reasoning rather than simply correct their output.

The division of labour appears to depend on the level of the writing problem. Macías Borrego (2026) followed 70 Spanish-speaking B2 learners of English across two writing tasks over twelve weeks. Learners in the AI-assisted feedback group showed lower rates of error repetition (25%) than those receiving teacher correction (40%). The difference was clearest in subject–verb agreement, preposition use, tense selection and L1-induced lexical transfer. The same learners nonetheless kept valuing teacher input for higher-order writing concerns.

Taken together, these studies suggest a provisional picture. AI feedback is competitive, and possibly superior, at the sentence level and for recurrent mechanical errors. Human feedback retains its advantage where argument, conceptual depth and critical questioning are at stake. The broader consequences for writing development are examined separately (see Q054).

Student attitudes are more complicated than a simple preference for humans. The dominant pattern across many studies has been labelled "algorithm aversion": students show a clear preference for human over AI feedback, revealing a bias against machine-generated evaluations. This bias appears to be partly psychological rather than purely evidence-based.

An experiment on students' psychological biases illustrates the point. Students received identical AI-generated feedback under different labels. They rated it more favourably when it was attributed to an experienced teacher. When told it came from an AI system, however, they were more likely to act on it and made more revisions. Students thus appear to trust humans more but may respond more readily to machines. This dissociation matters for how feedback is presented and deployed.

Scale adds texture. Henderson and colleagues (2025) surveyed 6,960 students across four Australian universities. Half reported seeking feedback from generative AI, yet students overall rated teacher feedback as more helpful and especially more trustworthy. Thematic analysis of 8,642 open-ended responses showed what students valued in AI feedback: ease of access, timeliness, volume and understandability. Students also saw AI as less risky than asking a teacher, which suggests a social dimension that accuracy comparisons miss. At the same time, they worried about AI's reliability and about its contextual and disciplinary expertise.

Qualitative work reaches similar conclusions. Rose and colleagues (2026) ran focus groups and interviews with 25 students at British universities. Students saw generative AI as a potentially useful source of objective and individualised feedback, but not necessarily accurate feedback. Fundamentally, they did not believe it could replace human expertise or provide the "personal touch", which the authors read as support for a dialogic theory of feedback. Among 255 EFL learners, BinJwair and Alsaleh (2026) found trust to be the strongest of the factors they modelled in shaping perceived usefulness. Their result is a structural-equation association from survey data, not a causal demonstration.

The aversion finding is not uncontested. In Kaliisa and colleagues' (2025) meta-analysis, the pooled difference in feedback perception was small, negative and non-significant ($g = -0.20$, 95% CI −0.67 to 0.27). Stated preferences in individual surveys may therefore be stronger than the average perceptual gap across controlled comparisons.

Receptivity also varies substantially by student profile. Older and more proficient writers often express scepticism about AI feedback, citing inaccuracies and a preference for the nuance and individual tailoring they associate with human instructors. Less experienced writers tend to be more accepting. One plausible reading is that learners who can recognise higher-order weaknesses in their own work are also those most likely to notice what AI feedback misses.

Well-designed AI feedback can win favourable responses on particular dimensions. Where feedback is clear, specific and structured, AI has received significantly higher ratings than human feedback for specificity, clarity and simplicity. No significant difference was found for correctness, which suggests learners perceive the factual accuracy of the two sources as similar. Macías Borrego's (2026) learners likewise rated AI feedback higher on clarity, usefulness and immediacy. Medina and colleagues (2026) surveyed 161 participants in a university MOOC who received ChatGPT feedback on their activities. Students held positive perceptions, and privacy and security concerns did not significantly influence their satisfaction. That study had no human-feedback comparison group, so it speaks to acceptability rather than relative merit.

The dental study and the pronunciation study complicate any simple reading of these satisfaction measures. Students in Jayawardena and colleagues' (2025) study perceived no quality difference that an expert could detect. Hirschi and colleagues' (2025) most improved learners rated their activities least helpful. Student perception is therefore an imperfect guide to

feedback quality in both directions. It remains unclear how far favourable ratings of AI clarity translate into deeper learning.

The research supports neither the optimistic claim that AI feedback simply equals expert human feedback nor the dismissive claim that it is a poor substitute. Henderson and colleagues (2025) offer the most defensible summary: AI and teacher feedback appear to serve different needs, and are therefore complementary but not interchangeable. AI systems excel at speed, scale, consistency, accessibility and certain surface-level dimensions of clarity. Human feedback keeps a clear advantage in higher-order reasoning, contextual and disciplinary sensitivity, and the kind of questioning that promotes intellectual development.

The most promising current research asks how each source can reinforce the other, not which is better. A randomised trial with the FeedbackWriter system in a large undergraduate course reports that AI-mediated feedback improved student revisions. Its framing as AI-mediated rather than AI-replaced feedback is itself instructive. Kaliisa and colleagues (2025) close their meta-analysis by advocating a hybrid approach that uses AI's scalability while retaining the empathetic and contextual features of human feedback. In peer assessment, Topping and colleagues (2025) reviewed 79 papers and found that the vast majority reported AI improving the process. They also note that automated feedback and calibration remain under-researched.

Hybrid models carry their own costs. Cooper, Ilich and Sturrock (2026) documented teacher educators using a customised ChatGPT model to restructure recorded oral feedback against a rubric. Workload initially increased because of technical problems and heavy editing. Efficiencies improved only as prompts and workflows matured, and the labour shifted towards verification, tone calibration and rubric alignment rather than disappearing. Human oversight, they conclude, remained essential. Santos and colleagues' (2026) scoping review reaches the same verdict, noting persistent concerns about superficiality, inconsistency and ethics.

How to combine the two sources well is a question the field has only begun to answer rigorously. The high heterogeneity in the meta-analytic evidence suggests the answer will depend heavily on task, discipline and learner.

Q056 What does research show about the reliability of AI-detection tools, and what have institutions learned from relying on them?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Research on AI-detection tools shows that they are neither accurate nor consistent enough to bear the weight institutions first placed on them. The universities that relied on them most heavily have learned, sometimes through formal reversals of policy, that a probabilistic score cannot serve as evidence of misconduct. The premise behind detection was intuitive. If machines generate text according to statistical patterns, other machines ought to recognise those patterns. The evidence gathered since that premise was first acted upon tells a more complicated story, and institutions that vested disciplinary authority in these tools have had to reckon with the consequences.

The basic technical problem is that detection accuracy is not a fixed property of any tool. Jisc's National Centre for AI, in its 2025 update on detection and assessment, stresses that the generative models detectors are meant to recognise evolve continuously. A detector can therefore remain reliable only if it is retrained at the same pace, and the performance a product shows at launch says little about its performance a year later. Evaluations across products show a wide and unsettling spread. The Effortless Academic's review of the evidence on detectors for academic text reports an empirical assessment of fourteen detectors in which accuracy ranged from 33% to 81%. That range is too wide to support any general claim that "AI detection works." Even Turnitin, often cited as one of the more reliable commercial products, fares modestly under independent scrutiny. A Temple University evaluation, reported in the same review, found Turnitin's detector correctly identified AI-generated text only 77% of the time and mis-flagged 7% of genuine human writing.

These figures come from secondary syntheses rather than from a single preregistered benchmark, and the underlying evaluations differ in text genre, length and the generators tested. Readers should treat them as indicative of a pattern rather than as stable parameters. The pattern itself, however, recurs across independent evaluations: performance is variable, and it is never close to the near-certainty that disciplinary use would require. Some benchmark compilations, such as EyeSift's 2026 comparison of detection accuracy, report higher figures for particular products under favourable conditions. Because such compilations are produced within the detection industry itself, they should not be read as independent research, and the disagreement between them and academic evaluations is itself part of the evidence.

Vulnerability to evasion compounds the accuracy problem. Reviewing detection tools in higher education, the 2025 study in *Information* (MDPI) finds that paraphrasing or manual manipulation of AI-generated text can significantly reduce detector effectiveness, often producing a substantial drop in accuracy. The manipulations in question include introducing spelling errors, restructuring sentences and altering vocabulary. Industry-facing sources report sharper figures. Paper-Checker's 2026 overview of false-positive detection cites a 2025 study finding that adversarial paraphrasing attacks reduced AI detection rates by an average of 87.88% across major detector types. Because that figure reaches readers through a commercial intermediary, it is best treated as illustrative of the scale of the problem rather than as a settled estimate. Even so, its direction agrees with the peer-reviewed literature. Detection measures surface regularities that are cheap to disturb, and a student who wishes to evade a detector needs little technical sophistication to do so.

Model improvement creates a second, slower form of erosion. As newer models produce more fluent and contextually coherent prose, detection rates fall measurably. Work cited in the arXiv pilot study of generative AI in proof-based mathematics courses (2025) reports that detectors were significantly more accurate on GPT-3.5 output than on GPT-4 output. A detector calibrated on yesterday's model is therefore systematically weaker against today's. The difficulty also extends beyond student coursework. A 2025 paper in *Nature*, discussed in Jisc's 2025 update, assessed detection on peer-review reports and concluded that it was "almost impossible to know" whether a review had been generated by AI using current tools. That finding matters for the research community's own governance as much as for teaching (see Q253).

Research on detection in other domains suggests these are structural problems rather than teething troubles. Yang, Shukur and Sahran's 2026 review of AI-based financial fraud detection, covering studies published between 2015 and 2025, identifies concept drift, class imbalance, limited access to labelled data and trade-offs between detection performance and interpretability as persistent issues. Concept drift means the patterns being detected change over time. AI-text detection shares each of these difficulties, and the fraud literature's long experience indicates that they are managed rather than solved. Whether educational detectors can ever stay ahead of generators for long therefore remains unclear, and current evidence gives little reason for optimism.

The most consequential flaw, however, is not what detectors miss but what they wrongly condemn. The *Information* (MDPI) review notes that multiple studies have found detection tools frequently misclassify non-native English writing as AI-generated. Several independent research groups have found the same direction of bias, which makes this one of the better-supported findings in the field. More recent work, summarised in EyeSift's 2026 benchmark discussion, reports detection accuracy for non-native English writers falling to 67% and false-positive rates rising to 28%, far above the rates for native speakers. As with other figures from industry-adjacent sources, the precise numbers deserve caution. The disparity they describe, however, is consistent with the peer-reviewed findings.

The mechanism is not mysterious. Writers working in a second language often favour simpler, more predictable vocabulary and syntax, which are the same features many detectors read as signs of machine generation. The wider AI literature has a vocabulary for this. Koçak and colleagues' 2024 international review of bias in medical-imaging AI defines bias as systematic error. It warns that AI systems tend to internalise biases within their models, and that this can produce unintended consequences once the systems are used in practice. Their argument that bias must be identified at every stage of the AI pipeline, rather than discovered after deployment, applies directly to detectors that were released to universities without published, disaggregated error rates.

Scale turns modest error rates into serious harm. Writing for Newcastle University's Scholarship Insights blog in 2025, the author of a critique of AI-flagged misconduct investigations in UK universities sets out the arithmetic. A false-positive rate of 1–2% may sound low, but at an institution processing 480,000 assessments a year, even a 1% rate would generate roughly 4,800 false positives annually. Each one is a potential misconduct

investigation, often of a student who did nothing wrong, and the bias research suggests those students will disproportionately be multilingual. Bulathwela and colleagues (2024) caution that the first large-scale delivery of AI in education could widen educational inequality if it is driven by a techno-solutionist narrative that presents technology as a quick and flawless fix for complex problems. Detection tools that systematically burden non-native writers are a concrete case of the outcome they warn against (see Q054 on writing development).

Institutions have begun drawing conclusions. SupWriter's 2025 compilation of universities that have stepped back from detection lists Waterloo, Yale, Johns Hopkins and Vanderbilt among those that have dropped or limited AI-detection tools. SupWriter is a commercial writing service with its own interest in the issue, so its list is best read as a record of public institutional statements rather than as research. The Waterloo case is the most fully documented. According to the same source, the provost described the false-positive rate as "unacceptable for a tool being used to make consequential academic integrity decisions." Internal testing reportedly showed non-native English speakers being flagged at nearly three times the rate of native speakers. Waterloo still uses Turnitin for conventional plagiarism detection but has switched off its AI-detection overlay. That distinction is instructive: text-matching against known sources produces verifiable evidence, whereas AI-likelihood scores do not.

Legal exposure has reinforced these decisions. Universities are increasingly aware that basing misconduct charges on unreliable technology invites challenge. Paper-Checker's 2026 overview and SupWriter's compilation both report that at least two lawsuits involving AI-detection false positives were filed against U.S. universities in 2025, though the outcomes of those cases are not reported in the available sources. In the United Kingdom, the Newcastle critique argues that AI-flagged investigations can be procedurally unfair. Students are asked to prove a negative against an opaque score, often without access to how the score was produced. Jisc's 2025 guidance takes a similar position. It advises that detector output should not be treated as sufficient evidence on its own, and it points institutions toward assessment redesign and dialogue with students rather than automated screening.

The institutional record, then, is one of retreat and recalibration rather than uniform abandonment. Many universities continue to license detection features, and practice varies widely between and within institutions. The direction of travel among institutions that have examined their own error data is nonetheless clear. Detectors are being downgraded from

decision-makers to, at most, prompts for a conversation, and some have been withdrawn entirely.

The broader lesson is not simply that the tools are imperfect, since all tools are. It is that detectors were deployed in high-stakes disciplinary settings before their error rates were honestly understood. Even some companies that build detection tools acknowledge, as Jisc's 2025 update records, that their products are not 100% accurate, and they advise caution in high-stakes uses such as grading or enforcing integrity policies. A product whose maker disclaims its reliability for exactly the purpose it is being used for should never have been the basis for sanctions.

This gap between marketing and measured performance is not unique to education. Magesh and colleagues' 2025 preregistered evaluation of AI legal-research tools, published in the *Journal of Empirical Legal Studies*, tested providers' claims that their systems were "hallucination-free." It found that tools from LexisNexis and Thomson Reuters hallucinated between 17% and 33% of the time. Those rates were lower than for general-purpose GPT-4, but the providers' claims were still demonstrably overstated. The authors also note that the closed nature of these systems makes such claims hard to assess systematically. The parallel with education is direct. Detection vendors operate proprietary systems, and independent, preregistered evaluation of the kind Magesh and colleagues conducted remains scarce for educational detectors. That scarcity is itself a finding: universities adopted these products largely on trust.

Opacity compounds the problem. Viswan, Shaffi and Mahmud's 2024 systematic review of 23 studies on explainability frameworks in Alzheimer's-disease detection argues that interpretability is central to the trustworthiness of AI predictions in clinical decision support. Most AI-text detectors offer a score with little account of why a passage was flagged. A student accused on that basis has no meaningful way to contest the reasoning. The fraud-detection literature's emphasis on the trade-off between performance and interpretability, noted by Yang and colleagues (2026), suggests this tension will not disappear as detectors improve.

The *Information* (MDPI) review offers what may be the most balanced synthesis currently available. AI detectors promise scalability, but they frequently produce false positives and lack transparency, especially for multilingual and non-native English writers. Ethical concerns about surveillance, consent and fairness are made worse by gaps in institutional policy, inconsistent

enforcement and limited faculty training. On this account, the failures of detection are as much failures of governance as of technology. Policies were often written around a tool rather than around evidence. Staff were rarely trained to interpret probabilistic outputs, and students were seldom told how they would be judged.

Several questions remain open. The evidence on how often students actually use generative AI in assessed work, as distinct from what they report, is still developing (see Q052). Without that baseline, the true positive rate a detector achieves in practice is hard to interpret. Comparative figures across products are also unstable, because evaluations differ in method and quickly become outdated as models change. Claims that newer detectors have solved these problems should be treated with the scepticism this monograph applies to other widely repeated but weakly evidenced claims (see Q060). What the evidence demonstrates with reasonable confidence is narrower but important. Detectors misclassify human writing at rates that become large at institutional scale, these errors fall unevenly on non-native writers, and simple manipulation defeats them.

What institutions have learned, then, is less about any particular tool than about the conditions under which an algorithmic judgement may carry disciplinary weight. Those conditions are independent validation, published error rates broken down by student population, explainable outputs, and procedures that never treat a score as proof. On present evidence, AI detectors meet none of these conditions reliably. The technology and the governance structures around it are still struggling to catch up with each other, and the more durable institutional response has been to redesign assessment rather than to keep searching for a better detector.

Q057 What evidence exists on how AI use affects different learner profiles — high vs. low performers, younger vs. older students, novices vs. experts?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

AI does not affect all learners equally. Evidence from the past two years suggests that its effects vary substantially with prior performance and prior expertise, and more tentatively with age. The patterns are more complex, and in places more cautionary, than the technology's advocates tend to acknowledge.

Three features of this literature shape everything that follows. First, much of it measures performance while AI is available rather than learning that persists once the tool is withdrawn, and the two frequently diverge. Second, the moderating role of learner characteristics has rarely been the primary object of study. A 2025 systematic review and meta-analysis of generative AI and university students' learning outcomes observes that studies have only sporadically examined how individual characteristics moderate the impact of generative AI, and that a well-rounded analytical framework has been lacking (see Q263). Third, credible studies disagree about the most basic question: whether AI narrows or widens performance gaps. That disagreement appears to track differences in task, tool design and outcome measure rather than simple error on either side.

The Brookings Institution's review of generative AI in tutoring frames the stakes. The promise is that AI can rescue students from classes "pitched to the median," in which high-achieving learners are insufficiently challenged while struggling students fall behind. Whether that promise holds depends heavily on who the learner is and how the tool is deployed.

The divergence between high and low performers is among the most consequential findings, and the evidence points in two directions.

On the encouraging side, research on hybrid human-AI tutoring that differentiates human tutor roles by student need found meaningful benefits for lower-performing students. Students one standard deviation below the mean gained an additional 0.15 SD on state tests under human-AI hybrid tutoring compared with AI-only tutoring. The same research found a troubling wrinkle, however. Lower-performing students used the AI tutor less than their higher-performing peers,

which suggests that the students most in need of the tool are also the least likely to engage with it consistently. The gain came from adding human tutors, not from the AI alone.

Evidence from language learning points towards amplification. In a study of English language learning in Nigeria, summarised in Microsoft Research's 2025 report on generative AI and learning outcomes, the students who gained most from generative AI access were higher academic achievers. This implies that AI may widen rather than reduce existing performance gaps. Work on English-as-a-foreign-language writing across successive generations of large language models reaches a related conclusion. AI's impact varies with students' independent writing competence, and lower-proficiency students may struggle to leverage AI effectively (see Q054). In these settings the tool rewards those who already bring enough skill to use it well.

The counter-evidence is serious. Choi, Monahan and Schwarcz (2024) conducted what they describe as the first randomised controlled trial of AI assistance on human legal analysis. They randomly assigned law students to complete realistic legal tasks with or without GPT-4 and blind-graded the results. GPT-4 access improved the quality of analysis only slightly and inconsistently, but it produced large and consistent gains in speed. Where it improved quality at all, the lowest-skilled participants saw the largest improvements. Time savings, by contrast, were roughly equal regardless of baseline speed. The authors read this as an equalising effect.

These findings do not directly contradict the amplification studies, because they measure different things. The law-school trial assessed the quality of assisted output on professional tasks. The language-learning studies concern skill acquisition, where benefiting may require the very competence the learner lacks. Taken together, they suggest that AI may level what learners produce while widening what they learn. That hypothesis remains to be tested directly, and for now the question of whether AI narrows or widens gaps should be treated as disputed.

Design and mode of use appear to matter as much as learner profile, and the starkest evidence comes from mathematics.

In a randomised controlled trial with roughly 1,000 high school mathematics students, Bastani and colleagues found that access to generative AI improved assisted performance by 48%. Unassisted exam performance, however, fell by 17% relative to control. The immediate gains in problem-solving diminished or turned negative by final examinations, and end-of-term grades declined when AI was available without pedagogical guardrails. This reversal suggests

that when students use AI as an answer machine rather than a thinking partner, short-term task performance comes at the cost of durable learning.

More recent work points the same way. A study titled "Faster Completion, Less Learning" reports that generative AI reduced the time students spent on mathematics problems and, with it, the knowledge those problems were meant to build. Experimental work in physics similarly argues that how students use AI feedback, rather than mere access to it, shapes both achievement and autonomy. This matters for differential effects because the passive, answer-seeking pattern is unlikely to be evenly distributed across learners (see Q052).

A counterpoint comes from research on AI that assists human tutors rather than students. The Stanford SCALE Initiative reports that students whose tutors used AI assistance were 4 percentage points more likely to progress successfully through mathematics tutoring assessments. The benefit was concentrated among lower-rated and less-experienced tutors. Students of lower-rated tutors who used AI assistance increased their mathematics proficiency by up to 9 percentage points on average.

The implication, consistent with the hybrid-tutoring findings above, is that AI's greatest levelling potential may lie in raising the quality of weaker instructors rather than in replacing human instruction (see Q051). This parallels the law-school result, in which the least skilled users gained most. In both cases the beneficiary is a practitioner producing work, not a novice building knowledge.

The novice-expert divide reveals a distinct cognitive mechanism.

Research on behavioural patterns in programmatic data science, published under the title "Not Everyone Wins with LLMs," documents systematic differences between novices and experts collaborating with AI. In agent-based modelling, experts could benefit more than novices because they relied on stronger skills in task decomposition and in evaluating AI outputs. In code comprehension, experts inspected data more deeply, verified assumptions and navigated outputs with clear goals, behaviours that novices underused. The same work describes failure patterns such as "prompting rabbit holes," in which less-experienced users iterate on prompts without converging on a solution. Novices, lacking the mental scaffolding to evaluate AI outputs critically, risk being led astray rather than guided forward.

The metacognitive dimension captures the underlying danger. A review in Educational Psychology Review, "Looking Beyond the Hype," discusses a study in which a ChatGPT-assisted group showed improved task performance during the supported intervention phase. Yet there were no differences in posttest knowledge gain or knowledge transfer. A temporal process analysis suggested that the ChatGPT group relied heavily on AI support and showed relatively little metacognitive processing compared with other support groups. The negative impact of large language models on depth of inquiry was found to be "particularly true for novices." Programming research extends the concern: a novice who relies on a tool such as GitHub Copilot may learn how to prompt the AI without learning how to think like a programmer.

The novice case is not uniformly bleak. Kazemitabaar and colleagues (2023) studied AI code generators in introductory programming. They found that the tools significantly increased task completion, improved correctness scores, reduced errors and shortened completion time for novices during training. Crucially, learners with higher prior programming competency performed significantly better on retention tests if they had had access to the code generator during training. Prior knowledge once again moderates the benefit, so that "novices" are not a uniform group.

This evidence base is concentrated in programming and laboratory or short-term settings. Whether the pattern generalises to other disciplines and longer timescales remains unclear.

Age-based differences in AI use are well documented, but research on differential learning outcomes by age remains far thinner than research on adoption patterns.

The National Literacy Trust's 2025 survey of young people in the UK found that older teens (16 to 18) were more likely than younger teens (13 to 16) to use AI to summarise texts (45.5% vs 31.5%) and to obtain different interpretations of a text (19.1% vs 10.1%). This suggests that older adolescents are both more aware of AI and more varied in how they use it. Adoption also appears to scale with grade. Figures compiled by Programs.com, an industry statistics aggregator rather than a primary research source, put ChatGPT use at 24% of students in grades 11 and 12, compared with 17% in grades 9 and 10 and 12% in grades 7 and 8. These figures are indicative only and should be traced to their original survey before being relied on.

The quality of engagement diverges as much as usage rates. The National Literacy Trust found that young people who enjoyed reading or writing were more likely to add their own thoughts to AI outputs. Those who did not enjoy these activities were more likely to copy AI responses

directly, and the gap was especially pronounced for reading enjoyment. Motivation and existing affinity for a subject appear to mediate how productively students of any age interact with AI tools (see Q059).

A person-centred study outside schooling offers a suggestive parallel. Jiang, Luo and Gao (2026) surveyed 970 Chinese artists and designers about the image generator Midjourney using an extended technology-acceptance model. They identified two profiles. A majority were "Interested and Engaged" and valued the tool for enhancing creative ideation. A minority were "Disinterested and Disengaged" and relied more on AI's external utility for minimising effort and on its hedonic appeal. The sample was professional rather than student, and the design was cross-sectional. Even so, the convergence with the reading-enjoyment finding suggests that motivational profile, rather than age as such, may be what separates generative from substitutive use.

Across performance level, expertise and age, a consistent dynamic emerges, which researchers have begun to call the assistance-erosion paradox. AI raises immediate performance while potentially undermining the deeper cognitive work that produces lasting knowledge.

Work on AI and students' reading, critical thinking and problem-solving argues that overdependence may reduce engagement in independent analysis and reflective reasoning. When used reflectively and with appropriate regulation, AI may stimulate thinking, but excessive or passive use may impair the very skills it aims to enhance. Research on learners' AI dependence and critical thinking proposes fatigue as one psychological mechanism linking dependence to weaker critical thinking. It identifies AI literacy as a buffer. The students most at risk of passive use are lower performers, novices and younger learners with weaker metacognitive skills, and they are precisely those for whom the stakes of that erosion are highest (see Q183).

If AI literacy buffers these harms, the uneven distribution of that literacy becomes a learner profile in its own right. Two 2026 latent profile studies from China map this unevenness, though both are cross-sectional and establish association, not cause.

Ma and colleagues surveyed 1,040 university students and identified three AI literacy profiles: low (15.29%), moderate (37.02%) and high (47.69%). AI literacy was directly associated with innovative behaviour, and it was also indirectly associated through AI anxiety and cognitive flexibility. The independent mediating effects accounted for 13.44% and 14.15% of the total

effect respectively, and their serial mediation for 3.30%. These pathways differed significantly across profiles.

Tang and colleagues surveyed 707 medical students at four universities in Anhui Province. Frequent exposure to interdisciplinary AI-medicine courses, interest in AI and satisfaction with one's major predicted membership of higher AI readiness profiles. High-readiness students showed substantially greater AI literacy across all dimensions than their moderate- and low-readiness peers.

These findings imply, without demonstrating, that AI literacy is shaped by curricular exposure and interest. If so, it could compound existing advantages unless it is deliberately taught.

The field's understanding of differential effects therefore remains incomplete. As the 2025 meta-analysis notes, individual moderators have been examined only sporadically. Existing studies vary in task, population and outcome, and in whether learning is measured with or without AI present. The most defensible current reading is limited. Prior knowledge and motivation moderate who benefits. Unguided access tends to favour the already capable. Design choices such as guardrails and human tutors in the loop appear to determine whether AI narrows or widens gaps (see Q060).

Q058 What do studies reveal about teachers' actual adoption patterns, workload effects, and attitudes toward AI tools?

Scope: *Teachers' adoption patterns, workload effects and attitudes. The financial economics of the teacher workforce is treated in Q269.*

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

Studies show that teachers have taken up AI tools quickly but unevenly. Measured workload relief so far lags well behind projected savings. Attitudes are split, with enthusiasm and anxiety coexisting within the same profession and often within the same classroom.

The adoption trajectory in the United States has been steep. RAND Corporation's survey of the 2023–2024 school year found that roughly one quarter of English language arts, mathematics, and science teachers used AI tools for instructional planning or teaching. RAND also documented marked unevenness across teachers and principals. Later RAND figures, reported in secondary statistical compilations, show teacher adoption rising from 25% to 53% between the two school years. The same compilations carry a separate claim that 60% of K-12 teachers used an AI tool during 2024–25.

The gap between 53% and 60% is not trivial. It probably reflects differences in sampling frame, subject coverage, and how use is defined. The higher figure reaches this chapter through industry aggregators rather than a primary report, so readers should treat it with caution. On either estimate, adoption roughly doubled within a year.

Outside the United States, comparable rates are harder to pin down. The Royal Society of Chemistry's 2024 science teaching survey found that 44% of British science teachers had used AI within their teaching role. Polish data complicate any story of near-universal uptake. Tomczyk and Majkut (2025) surveyed 289 primary and secondary teachers in December 2024 and January 2025. Their cluster analysis identified only 13.5% intensive users and 30% occasional users, against 43.5% nonusers; these shares do not sum to 100% in the published abstract. National context, survey timing, and the population sampled therefore shape headline adoption figures as much as the technology itself does.

Aggregate adoption numbers conceal considerable variation in depth of engagement. RAND found that teachers used AI most often for three things: preparing to teach, making worksheets or activities, and modifying materials to meet student needs. The Gallup and Walton Family Foundation survey found that 32% of teachers were using AI at least weekly. Another 28% were doing so only monthly or less. Frequent, pedagogically integrated use therefore remains a minority practice even among adopters.

The Polish evidence points the same way. Tomczyk and Majkut (2025) report that teachers' most frequent uses were information retrieval and text translation, while more advanced educational applications remained marginal. Güneyli and colleagues (2024) surveyed 164 teachers in Northern Cyprus during the 2023–2024 academic year. They found that age, gender, education level, school type, institution level, and income had no significant influence on AI awareness. Usage nevertheless differed by level: university lecturers were the most likely to incorporate AI into teaching, followed by primary and high school teachers. This suggests that institutional setting may structure use more than individual demographics do. The study's purposive and snowball sampling, however, limits generalisation.

The tasks teachers delegate to AI are revealing. A 2025 Center for Democracy and Technology report, cited in an industry statistics compilation, found that 69% of teachers in grades 6–12 use AI for curriculum and content development. Grading and assessment support are also common use cases. A systematic review of the early impact of AI on higher education, published in Frontiers, offers some support for these uses. It found AI taking on logistical work such as reinforcing students' mastery of key concepts. It also reported AI working well in sharing tutoring tasks, providing immediate feedback, and reducing instructors' workload. That review concerns university teaching and early-stage studies, so applying it to school teachers' workloads is an inference rather than a finding. Whether AI-generated feedback matches the accuracy and usefulness of human feedback is a separate question (see Q055).

The workload evidence is where credible sources diverge most sharply. The Royal Society of Chemistry survey supplies a sobering caveat. Although 44% of British science teachers had used AI in their role, only 3% said it had greatly reduced their workload. The promised productivity gains thus appear largely unrealised at classroom level, at least in the short term. The Gallup and Walton Family Foundation study offered a more optimistic projection. It estimated that consistent AI use could save teachers the equivalent of six weeks per year. That figure describes potential savings among regular users, not the current experience of the profession. It should not be cited as though it measured realised time savings (see Q060). The economic implications of such projections, and their credibility, are taken up through a financial-economics lens in Q269.

Perception studies tend to side with the optimistic reading, but they measure belief rather than time. Mujahidah and colleagues (2025) surveyed suburban school teachers in 2024, obtaining 205 valid responses at an 82% response rate. Teachers generally viewed AI as valuable. They

believed it could personalise learning, address individual needs, improve their teaching skills, and reduce time spent on administrative tasks. Belief that a tool will save time is not evidence that it does.

A Norwegian study suggests that workload pressure may not even push teachers toward AI. Eriksen and Elstad (2026) analysed 223 questionnaires from five diverse Oslo secondary schools, with a response rate of about 87%. Workload and time pressure had a negligible direct association with beliefs about AI in summative assessment ($\beta = -.02$). These pressures were indirectly linked to greater reliance on conventional approaches. Digital instructional efficacy was positively associated with openness to AI-driven assessment ($\beta = .38$). A preference for traditional methods was negatively associated with acceptance ($\beta = -.18$). The design is cross-sectional, so these are associations rather than causal effects. Still, they imply that overburdened teachers may retreat to familiar routines rather than experiment. Whether AI produces net workload relief therefore remains unclear.

The gap between adoption and readiness is the most persistent finding across studies. Its precise magnitude, however, often comes from weaker sources. Industry statistics compilations report that only about a quarter of teachers have received any training on AI chatbots. The same compilations report that nearly one-third cite a lack of training or professional development as the main barrier to adoption. A 2025 survey of American attitudes, reported in the technology press, put the problem bluntly. Two-thirds of Americans said educators need better training, and 70% of teachers admitted they did not feel ready to use AI effectively in their classrooms.

Peer-reviewed work from other systems reproduces the pattern with stronger designs. Gamboa and Miranda (2026) surveyed 301 teachers at two public higher education institutions in Pampanga, Philippines. Teachers agreed strongly with all constructs of the unified theory of acceptance and use of technology. Facilitating conditions, which capture institutional infrastructure and support, received the lowest rating. Effort expectancy received the highest. In other words, teachers found the tools easy to use but felt under-supported in using them.

Amouri and colleagues (2025) studied pre-service teachers in Morocco preparing to teach students with ADHD. Institutional support and interface simplicity emerged as key enablers. The authors called for digital literacy to be built into initial teacher training. The readiness deficit thus appears among experienced staff and novices alike, in wealthy and middle-income systems.

The convergence of these findings is notable. Each comes from a different country, sector, and theoretical model, yet all point to the same gap between institutional support and teacher need. That convergence gives the readiness gap more weight than any single headline percentage.

Teacher attitudes, when examined closely, are rarely simply positive or simply resistant. A comparative review of public attitudes across sectors draws on cross-national survey studies. It reports that AI understanding and self-efficacy are strongly associated with perceiving more benefits and fewer concerns. Again, this is an association, not proof that training changes minds.

Work on how teachers evaluate AI tools through deliberative sensemaking finds a similar duality. Teachers broadly see substantial potential in AI tools. They also worry about workload, job displacement, student dependence, and unintended classroom harms. A study of benefits, concerns, and support needs in the International Journal of Research and Innovation in Social Science reaches a related conclusion. Attitudes there are shaped not only by perceived advantages but also by ethical and professional concerns. These include academic integrity, AI bias, students' overreliance on automated assistance, and fears of diminished teacher authority and human connection.

These anxieties are not parochial. Evidence from several countries, summarised in the same cross-sector review, illustrates the point. In South Korea, elementary teachers fear that AI threatens their emotional support roles. In Turkey, educators worry about insufficient data protection in AI systems used in schools. Zhao and colleagues (2026) interviewed 12 Chinese K-12 computer science teachers using concept maps. They identified closely parallel barriers: perceived erosion of teacher authority, student overreliance, fragmented understanding of what generative AI can do, and ethical concerns about data security. That even subject specialists in computing voice these worries suggests technical familiarity alone does not dissolve them.

The enthusiasm is equally real. The suburban teachers surveyed by Mujahidah and colleagues (2025) were particularly excited about AI's potential to enhance creativity and problem-solving in the classroom. They also expected it to improve their overall teaching effectiveness. The profession thus holds hope and apprehension at once.

What drives adoption or resistance comes down chiefly to perceived usefulness and self-confidence. Erol (2025), writing in the European Journal of Education, found that teachers' AI self-efficacy was significantly and positively associated with their AI attitudes. Positive

attitudes were in turn associated with AI-related technological pedagogical content knowledge and with willingness to experiment.

Models of technology acceptance sharpen this picture. Gamboa and Miranda (2026) found that performance expectancy was the strongest predictor of Filipino teachers' intention to use generative AI (β = 0.406). Social influence (β = 0.295) and effort expectancy (β = 0.257) followed, and together the three explained 65% of the variance in intention. Facilitating conditions did not predict intention. Alongside intention (β = 0.629), however, facilitating conditions predicted actual use (β = 0.266). Sustained practice, in their reading, depends on institutional infrastructure and training.

Tomczyk and Majkut (2025) likewise found perceived usefulness and digital competence central to Polish teachers' intentions. Those intentions strongly influenced actual use. Amouri and colleagues (2025) ranked perceived usefulness as the most influential predictor of acceptability among Moroccan pre-service teachers. Perceived ease of use, voluntariness, and subjective norms followed.

The studies do disagree on peer influence. Among 338 Chinese computer science teachers across 20 provinces, Zhao and colleagues (2026) found that performance expectancy, effort expectancy, and innovation expectation strengthened attitudes. Social influence was not significant, which directly contrasts with the Filipino result. Perceived risk had a negative effect on intention. The role of colleagues and administrators may therefore depend on subject culture or national context.

Trust also matters. The cross-sector review reports that teachers are more likely to trust and adopt AI tools when given clear explanations of how the systems make decisions. Addressing misconceptions about job loss and privacy, alongside targeted professional development, further improves willingness to integrate the tools.

The evidence base has real limits. Nearly all of these studies are cross-sectional self-report surveys. A systematic review by Adewale and colleagues (2024) covered 64 papers on AI in open and distance learning. It found that 40.63% of the works were nonempirical. It also noted the absence of a process-based framework for forecasting AI's educational impacts (see Q263). Even so, the implication running through this research is consistent. Adoption is not primarily a technological problem but a problem of professional development and institutional support. Neither the tools themselves nor the enthusiasm of early adopters has yet resolved it.

Q059 What does current evidence show about AI's effects on student motivation, engagement, and persistence — and how do these findings differ from marketing claims?

22 citations · 22 sources · 5 cross-references

Claim 1 disputed

Current evidence suggests that AI can raise students' reported motivation and engagement under specific, well-designed conditions, but the gains are conditional, often short-lived, and weakly established for persistence. That picture differs sharply from marketing claims, which present engagement as a reliable product feature. Vendor language is strikingly uniform. It promises personalized learning pathways, instant feedback, mastery-based progression and engagement on demand, as if the future of education had already arrived. The research picture is more complicated, and the complications fall into two camps. The first is a set of conditional gains that appear when tools are built and deployed well. The second is a set of genuine harms that appear when tools let students avoid the work of thinking.

The gap between these camps is also a gap in what gets measured. Marketing claims, and much of the supportive research, tend to measure the feeling of engagement: satisfaction, enjoyment, and willingness to keep using a tool. AI-powered interfaces reliably produce that feeling. The cautionary research measures something harder to sell, namely what happens to independent effort, metacognition and confidence once that feeling becomes a substitute for learning.

Persistence, meaning whether students stay with difficult material, courses or programmes over months and years, is the least studied of the three outcomes. Almost no rigorous longitudinal work isolates AI's causal contribution to it. On persistence in particular, the question remains unclear, whatever product literature implies.

The positive evidence is real, and the strongest of it concerns purpose-built tutoring systems rather than generic tools. In a randomized controlled trial published in Scientific Reports in 2025, college students using an AI tutor designed around research-based pedagogical principles learned significantly more in less time than peers in an in-class active-learning session. They also reported feeling more engaged and more motivated. The comparison condition was already a strong, evidence-based form of instruction rather than a passive lecture, which makes the result notable. It nonetheless comes from a single course and a short intervention window (see Q051 for the broader tutoring-outcomes evidence).

Adaptive platforms show related promise. A 2025 systematic review in Frontiers in Education reports that intelligent tutoring systems and adaptive learning platforms, which adjust instructional materials to learners' real-time performance, have been shown to enhance cognitive engagement. That review also stresses that teaching methods mediate the effect. Self-report studies point the same way: work published in PMC cites a recent meta-analysis showing that AI use positively influences students' learning perceptions and satisfaction, and models attitudes toward AI as working through perceived autonomy and learning enjoyment.

The largest quantitative synthesis to date sharpens this picture. Fang, Li, Xiong and colleagues (2026) pooled 56 effect sizes from 42 controlled experimental and quasi-experimental studies involving 6,059 participants. They concluded that generative-AI-supported learning is associated with higher learning motivation. Heterogeneity was very high, however, with an I^2 of 93.7 percent, meaning that effects varied substantially across contexts. Exploratory moderator analyses suggested larger effects in four conditions:

in higher education than in primary and secondary schooling; in collectivistic than in individualistic cultural contexts; in language learning than in other subjects; when the tools were used on mobile devices rather than computers.

The authors caution that these moderators were study-level characteristics, not experimentally manipulated conditions.

Individual studies illustrate the range. In a 15-week mixed-methods quasi-experiment across four Chinese universities, Chen, Dong and Ji (2026) compared 278 students using EduBot, a Socratic-dialogue agent embedded in the learning management system, with 277 students using forums moderated by teaching assistants. They reported Group × Time interactions on engagement. The authors suggest that low-pressure AI dialogue may matter most where asking questions in class carries a social cost. Lee (2025) followed 201 Korean seventh-grade English learners over 12 weeks. Intelligent personal assistants significantly enhanced emotional engagement compared with textbook instruction. Gamified AI apps with immediate feedback motivated students but felt less interactive.

This optimistic body of evidence does not hold up well under methodological scrutiny. Stanford University's AI Hub for Education, as reported by GovTech, found that evidence behind efficacy claims remains limited. In some cases it raises new concerns about how, and whether, students are truly learning.

The Stanford team identified a clear tension: AI can improve student performance while it is in use, but those gains appear to fade when the technology is removed. The core problem is causal inference. Most studies examine whether students using AI tools perform better, yet they do not isolate whether the technology itself caused the gains. The researchers screened more than 800 studies but ultimately relied on approximately 20 high-quality causal studies.

Much of the motivational literature shows exactly these weaknesses. Daly, Mnedla and Chelly (2026) reported statistically significant gains in motor learning, intrinsic motivation and engagement after an 8-week AI-supported physical education intervention in Tunisian secondary schools. Their design, however, compared two intact classes totalling 56 students, because individual random assignment was not feasible.

Omeh and Ayanwale (2025) found a very large multivariate effect of AI-supported problem-based learning on engagement, intrinsic motivation and achievement among 87 Nigerian computer-robotics undergraduates (Wilks' $\Lambda = 0.134$, $F(3, 82) = 176.93$). Their experimental and control groups, though, were drawn from two different universities, so institutional differences cannot be separated from the intervention.

A large share of the remaining evidence is cross-sectional. Zhang and Miao (2025) surveyed 357 Chinese EFL students and found that AI and AR/VR literacy predicted engagement and motivation. Jia and Tu (2024) surveyed 637 college students and modelled links between

institutional AI capabilities, self-efficacy, motivation and critical-thinking awareness. Both studies used structural equation modelling on single-wave survey data. Despite the causal language sometimes attached to such models, they establish association, not effect.

The topography of the field reinforces these concerns. Chen, Xie, Qin and colleagues (2025) used text mining and systematic analysis to map AI-supported engagement research. They found that most studies used quantitative approaches, concentrated on computer science and language education, and gave most attention to emotional engagement among college students. Emotional engagement is the dimension closest to the felt experience that marketing emphasizes.

The evidence is also not uniformly positive even at the correlational level. In a cross-sectional sample of 1,484 Chinese university students, Shi, Cui, Zhang and colleagues (2026) found that AI-related perceptions were negatively associated with academic engagement, partly through lower academic motivation. The association was stronger among students with low academic self-efficacy. Findings from this literature therefore genuinely disagree, and the disagreement is a reason for caution rather than a statistical inconvenience (see Q263 for the wider meta-analytic record).

Marketing almost never distinguishes between tool types, yet the evidence suggests this distinction matters a great deal. Commentary in Social Science Space argues that most AI tutoring products address only a narrow slice of what learning involves. Most tools on the market were not designed around the tutoring evidence base. They were designed around what artificial intelligence can do and then positioned as tutoring afterwards.

The consequences show up in outcomes. Third Space Learning's review of the research contrasts two groups of studies. In one randomized trial of generic AI tools used for studying, students using ChatGPT performed around 17 percent worse on exams. By contrast, purpose-built AI tutoring systems designed around proven tutoring principles show measurable within-session learning gains.

The contrast tracks a design feature: whether a system withholds answers and prompts students to reason, or simply supplies output. The tutor in the 2025 Scientific Reports trial was built on established pedagogical principles. The EduBot agent studied by Chen, Dong and Ji (2026) was explicitly Socratic. Neither resembles an open-ended chatbot that will write an essay on request.

Theory-driven design is beginning to be articulated, though it remains untested. Hajian, Chang, Wang and colleagues (2025) propose a Motivation Construction Model drawing on self-determination theory, expectancy-value theory and mindset theory. It structures AI prompting across three phases: contemplation, goal setting and planning, and action. The authors acknowledge that its real-world application remains to be explored and call for classroom studies of its effectiveness.

For now, the most defensible reading is narrow. Some motivational benefit appears attainable when AI is designed to sustain student effort. There is little basis for assuming that general-purpose tools confer the same benefit.

The darker findings concern what happens to motivation and cognitive engagement over time.

Researchers evaluating generative AI in vocational education describe a phenomenon they call metacognitive laziness. Cognitive offloading, in which learners delegate tasks to AI to reduce effort, may lead to a decrease in internal cognitive engagement over time. Learners can become dependent on AI and offload metacognitive load, reducing their engagement in the planning, monitoring and evaluation that learning requires.

The concern is not merely theoretical. A National Science Teaching Association review summarizes studies indicating that heavy reliance on AI for information retrieval and decision-making may weaken reflective problem-solving. One study it discusses reports a significant negative correlation between AI tool usage and critical-thinking scores. Younger participants aged 17 to 25 showed higher AI dependence and lower critical-thinking scores than older groups. This is a correlation. It cannot show whether AI use erodes thinking, whether weaker thinkers lean more on AI, or whether age-related factors drive both (see Q053 on memory and transfer).

The motivational consequences of dependency appear to compound. A grounded-theory study defining AI fatigue in academic contexts found that motivational disengagement was among the most reported dimensions of problematic AI use. Students bypassed independent effort in favour of immediate AI assistance and experienced eroding confidence in their own academic capabilities.

A qualitative inquiry published in JMIR Medical Education examined AI dependency among educators in Palestine. Among participants who had become AI-dependent, 67 percent reported

increased procrastination and reduced intrinsic motivation. Because the sample consisted of educators rather than students and the design was qualitative, the figure is best read as a warning signal about dependency in general, not as a population estimate for learners.

The pattern reported by Shi and colleagues (2026) fits this account. Students with lower self-efficacy showed a stronger negative association between AI perceptions and engagement. This suggests that students who are already less confident may be the most vulnerable to the confidence erosion that qualitative studies describe.

Taken as a whole, the evidence suggests that AI's relationship to student motivation is not a fixed property of the technology. It depends on how a tool is deployed and on whether it requires students to think or allows them to avoid thinking. Conceptual and integrative reviews, including a recent review of the negative effects of digital technology on cognition, consistently warn that unreflective reliance on AI can produce cumulative deskilling, metacognitive passivity and loss of autonomy, because it reduces practice of core analytical skills.

The positive survey literature points in a complementary direction. In a study of 420 London university students, Ashbourne (2026) found that cognitive engagement partially mediated the link between AI use and creativity. Learning motivation strengthened the link between AI competencies and engagement. In that study, the benefits flowed through active cognitive engagement rather than around it, although the data were cross-sectional.

Several limits on AI's motivational role remain evident even in favourable studies. Lee (2025) found that peer interaction provided authentic communication and socioemotional connection that AI tools could not replicate. This is a reminder that engagement has social dimensions that a well-designed interface does not supply. The heterogeneity in the Fang and colleagues (2026) meta-analysis means that a positive average effect conceals settings where effects are small or absent. The fading of gains once tools are withdrawn, noted by the Stanford team, means that in-use motivation cannot be assumed to translate into durable dispositions. On persistence, the outcome institutions care most about, rigorous causal evidence remains unclear (see Q060 on claims that outrun their evidence).

The disagreement between marketing and research is therefore partly a disagreement about outcomes. Marketing claims tend to measure the feeling of engagement, which AI-powered interfaces reliably produce. The cautionary research measures what happens to independent thinking when that feeling becomes a substitute for the harder work of learning.

For educators and institutions, the implication is to evaluate tools on whether they demand student reasoning. It also means measuring outcomes after the tool is removed rather than during its use. Short-term satisfaction data, however enthusiastic, should not be treated as evidence of lasting motivation.

Q060 Which widely repeated claims about AI in education lack solid evidence, and which early findings have failed to replicate?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

The claims about AI in education that rest on the thinnest evidence are the ones repeated most often: that AI tutors deliver genuine personalization, that they act as neutral or equalizing forces, and that they reliably improve learning at scale. Meanwhile, several early signals of benefit have become more complicated, or have not survived contact with more independent and more rigorous designs. Few areas of contemporary technology show such a gap between confident assertion and rigorous proof. Advocates routinely describe AI tutors as instruments of revolutionary personalization, equity and scale. On close examination, those descriptions rest on a shakier empirical foundation than their proponents acknowledge.

The most fundamental problem is where the evidence comes from. As UNESCO's work on the futures of education observes, most existing research on AI's educational effectiveness is produced by the technology developers themselves. That undermines its independence and invites reasonable suspicion of conflicts of interest. This is not a minor methodological quibble.

Vendor-sponsored findings tend to outperform the results of independent replication, a pattern observed repeatedly in other technology sectors. Adjacent fields suggest how such patterns play out. Husein, Sukati and Poniman (2026) systematically reviewed a decade of empirical research on AI in supply chain management. They begin from the observation that previous waves of technological enthusiasm have not always fulfilled their anticipated potential. They conclude that successful implementation is highly contingent on data quality, organizational readiness and integration capabilities rather than on the technology alone. In nuclear medicine, Kaiser and colleagues (2026) describe impressive technical advances but report that clinical translation remains limited. They identify generalizability across scanners and populations as a key unresolved challenge, and they explicitly frame their review as narrative rather than systematic. Education shows the same structural gap between laboratory promise and field performance, with a further weakness. UNESCO notes that there is still no shared framework or consensus on what counts as valid, independent evidence of AI's impact in learning environments. Without such a standard, a vendor's internal pilot and an independent randomized trial can circulate in policy discussion as though they carried equal weight.

The pace of deployment relative to the pace of knowledge compounds the provenance problem. As the institutional-change framework for institutional change describes, AI has not entered classrooms through deliberate adoption of evidence-based tools. It arrived through widespread and spontaneous use by students and teachers, largely before institutions had formed any response. It certainly arrived before research could identify productive and responsible practices. The usual sequence of educational innovation runs from design, to small trials, to larger evaluations, to adoption. Here that sequence was inverted. Practice came first, and research has been trying to describe a moving target ever since.

This inversion has concrete evidentiary consequences. In some areas, a direct evidence base for effective AI-based pedagogy does not yet exist in recognizable form, and it may not exist for years. Studies take time to design, run, review and publish. By the time a trial of one generation of models appears in print, the tools students actually use have often changed, along with their interfaces and the habits built around them. Clean comparison groups are increasingly hard to construct, because "no AI" conditions are difficult to enforce when the technology is freely available on every student's phone. As a result, much of what circulates as knowledge about AI in education rests on several weaker kinds of evidence: self-report surveys, short-term pilots and studies of tools that have since been superseded. Each has value. None can substitute for

the sustained, independent evaluation that claims of transformation would require. Treating these early signals as settled findings is one of the main routes by which plausible hopes become repeated "facts."

Among the most overstated claims is that AI delivers genuinely personalized learning, adapting in real time to each student's needs and thereby closing achievement gaps. Educators and policymakers are generally optimistic about AI's capacity to personalize education, despite limited evidence that these tools improve student learning outcomes. One systematic review of 113 papers found that AI education tools can generally improve student motivation and output. However, the methods used to evaluate them were often poorly suited to measuring actual learning. Motivation and comprehension are not the same thing. Increased output is not the same as increased capability. Conflating these constructs inflates apparent success considerably. A student who enjoys a tutoring session and produces more work during it has not necessarily learned more, and engagement metrics are what most vendor dashboards report (see Q059). The comprehensive review of AI-based intelligent tutoring systems reaches a compatible conclusion. It describes a complex picture of effectiveness and calls for greater scientific rigor in experimental design and data analysis.

A related claim, increasingly made in marketing, is that AI can reliably assess student work and so scale personalized feedback. Here the evidence is genuinely mixed, and its limits deserve precise statement. Addis and colleagues (2026) embedded ChatGPT as an evaluator of creative outputs produced in a validated experiment with workers in the cultural and creative industries. They benchmarked its judgments against expert ratings obtained through the Consensual Assessment Technique. The AI's evaluations showed internal consistency comparable to that of expert judges across repeated and independent runs. Replacing one human judge with the AI did not reduce inter-rater reliability across drawing, mathematical and verbal tasks. The same study also found systematically higher scores from the AI, which the authors read as a potentially more inclusive evaluative stance. In a classroom, that same feature could equally signal leniency. The tasks were constrained, innovation-like exercises completed by adult professionals, not schoolwork. Reliability, meaning that the model agrees with itself and with experts, is also distinct from validity for diagnosing learning. Whether such findings transfer to formative assessment of students therefore remains unclear.

The claim that AI is a neutral or equalizing force in education is equally contested. As the analysis of AI and the digital divide sets out, researchers have identified distinct forms of

algorithmic discrimination, including proxy bias, disparate impact and biased targeting. These forms systematically disadvantage groups defined by race, gender, disability and socioeconomic status. They need not involve any explicit use of protected characteristics. A model can learn to treat postcode, dialect, typing patterns or device type as proxies, producing disparate outcomes even when the designers intended none. Bias can also be reinforced through patterns of user interaction. Where a system adapts to how students use it, initial disparities can compound over time rather than fade. Taken together, this evidence challenges the assumption that AI is a neutral educational tool. It also complicates the equity case for personalization: the same adaptive mechanism that is said to close gaps could, under biased inputs, widen them.

The fairness problem is not peculiar to education, and that matters for how the claim should be weighed. In oncology, Zhu and colleagues (2025) describe AI's potential in lung cancer care as transformative. They nonetheless identify model bias and fairness as crucial barriers to clinical application. Clinical medicine has stronger regulatory scrutiny and more mature validation practice than education does. If fairness remains an open barrier there, education has little basis for assuming that adaptive learning systems are free of it. The more defensible position is that equity effects are an empirical question to be tested population by population. Current evidence suggests that the risk of harm is real. Whether, and under what conditions, AI narrows rather than widens educational gaps remains unclear.

Where early studies did show gains, more recent work has complicated the picture, particularly for higher-order thinking. Systematic reviews synthesized in the review of digital technology and cognition report that generative AI can support critical thinking under guided, reflective use. Unstructured or excessive reliance, however, shifts students' effort from analysis and evaluation toward acceptance of AI outputs. Reported gains cluster at lower cognitive levels. Higher-order reasoning tends to weaken under automation bias and reduced metacognitive effort. This pattern helps explain why early, positive findings based on task completion or immediate performance need not imply durable learning. Getting a better answer with assistance is a different outcome from becoming more able to produce answers without it.

An EEG study at the MIT Media Lab sharpened this concern considerably. Participants who used LLM assistance showed signatures of lower cognitive engagement during writing. When later asked to perform the same task without AI, they showed measurably reduced performance relative to participants who had never used AI assistance. The authors term this pattern "cognitive debt." The study deserves attention, but it should not yet be treated as established. It

involved a small sample, an artificial essay-writing setting and neural measures whose link to learning is indirect. The finding therefore suggests a mechanism rather than demonstrating a general effect, and it awaits independent replication. The account of a "delegation feedback loop" in the analysis of cognitive divergence offers a theoretical frame for why such effects might accumulate. As people delegate more cognitive work to systems with ever-larger context windows, the incentive to sustain their own attention may weaken, which encourages further delegation. That account is plausible, but it is largely conceptual. Readers should note the disagreement plainly. Some evidence supports structured AI use for critical thinking, while other evidence points to cognitive offloading, and the two are not yet reconciled. The most likely resolution is that design and guidance determine which effect dominates (see Q053).

Not all findings point in a pessimistic direction. A 2025 randomized controlled trial at Harvard offers the most rigorous counterweight to date. In the study by Kestin, Miller, Klales and colleagues, conducted during Fall 2023 in an undergraduate physics course and published in Scientific Reports, students using a carefully designed AI tutor outperformed peers taught through in-class active learning. As the ETC Journal review of the study emphasizes, this provides empirical support for the claim that properly designed AI tutoring can surpass established pedagogical best practices. The critical caveat is implementation. The study shows that effective AI tutoring required substantial upfront investment in careful prompt engineering, platform development and pedagogical design. It did not involve merely purchasing access to a commercial chatbot. That distinction matters enormously, because most institutional deployments resemble the latter far more than the former. The trial also took place at a single, highly selective institution, in one subject, over a short period. Its generalizability to other students, disciplines and timescales remains to be established. Research using AI peers to help students overcome physics misconceptions points toward the same lesson. Where promising results appear, they tend to come from purpose-built tools structured around a specific pedagogical problem rather than from general-purpose assistants (see Q051).

The honest summary is significant uncertainty layered over a modest, domain-specific signal. The review of AI tutoring systems from 2010 to 2025 describes a complex landscape. It records both advances and persistent challenges and identifies a need for greater scientific rigor in experimental design and data analysis. Adjacent fields reinforce the point. Reviews of AI in supply chains and nuclear medicine converge on the finding that outcomes depend on implementation context and that translation from promising results to routine benefit is slow

and partial. Enthusiasm has consistently run ahead of evidence. The field's most urgent need is not more enthusiastic pilot programs. It needs independent, longitudinal studies, held to a shared evidentiary standard and designed from the outset to measure what students can actually do once the AI is switched off.

Q136 What are the recurring methodological weaknesses in this literature, and how should a reader discount for them?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

The AI-in-education (AIEd) literature has six recurring weaknesses, and a reader should discount for them by weighting each study against an explicit evidence hierarchy rather than by the size of the effect it reports. The weaknesses are small and short studies vulnerable to novelty effects, weak or absent control conditions, self-reported and researcher-made outcome measures, publication bias compounded by questionable research practices, uncritical meta-analysis of weak primary studies, and undisclosed researcher or vendor allegiance. The field has grown explosively since generative AI tools were released in 2022, but its methodological quality has not kept pace. A 2025 review of methodological limitations in Frontiers in Education identifies the same cluster of problems with samples, controls and outcome measures that earlier critiques documented. A reader who does not discount for these weaknesses will systematically overestimate what the evidence shows.

The sheer volume of review literature can itself mislead. Rosa and Yokomizo (2026) followed the PRISMA protocol to analyse 127 articles from Web of Science and Scopus. They extracted

bigrams from abstracts and used thematic mapping to identify ten clusters that constitute the field's conceptual structure. Pacheco-Olea and Villacís-Macías (2026) mapped AI in STEM education from 2016 to 2025, charting productivity patterns, leading countries and journals, thematic clusters and emerging trends. They framed their purpose partly as revealing the field's methodological gaps and limitations. Work of this kind is useful for orientation, but bibliometric and thematic mapping describes what researchers study, not whether interventions work. A proliferation of reviews is not a proliferation of evidence about effects (see Q263). The contrast with the economics of education is instructive. Escueta, Quan, Nickow and Oreopoulos (2020) built their review of education technology around randomized and regression-discontinuity designs, a standard that much of the AIEd literature does not approach.

The first weakness combines small samples, short durations and novelty effects. Many AIEd studies are small, brief and conducted at a single site. A 2025 systematic review of K-12 intelligent tutoring systems in npj Science of Learning found that roughly half of the studies it analysed lasted less than one week.

Short interventions are vulnerable to the novelty effect. Students engage enthusiastically with a new tool simply because it is new, and this initial spike in engagement and motivation fades once the tool becomes routine. A study that measures outcomes after a few sessions may therefore capture enthusiasm rather than learning, and its results cannot be extrapolated to a full school year.

Small samples compound the problem. They leave studies statistically underpowered: too weak to detect real effects, yet prone to producing large, unstable estimates when an effect does reach significance. In an underpowered literature, the published estimates that clear the significance threshold are disproportionately the inflated ones. A field built from many such studies will therefore look more effective than it is.

The 2025 Frontiers in Education review treats sample size and study duration as core limitations rather than incidental ones. Pacheco-Olea and Villacís-Macías (2026) likewise make methodological gaps an explicit object of analysis in their decade-long mapping of AI in STEM education. That such gaps remain a reportable finding after ten years of publication suggests the problem is structural rather than a teething stage of a new field. A reader should treat any study lasting days or a few sessions, with a few dozen participants, as exploratory regardless of its headline result.

The second recurring weakness is the control condition. Many studies compare an AI intervention against no intervention at all, or against a 'business as usual' condition that already includes other edtech tools. Either design makes it impossible to attribute observed gains to the AI system specifically. Some studies lack any comparison condition and simply report pre-post gains or self-reported satisfaction, which cannot separate the intervention from ordinary maturation, teaching and test familiarity.

Attribution is harder still because AI is rarely introduced alone. In a systematic review of how AI is being integrated into the higher education cybersecurity curriculum, covering peer-reviewed work from 2020 to 2025, Tian (2025) observes that combining the two typically requires new learning designs. When the treatment is a bundle of a new tool, a redesigned course and often a more enthusiastic instructor, a comparison with an unchanged control cannot say which component produced any difference.

The most rigorous recent trials show how much design matters. Bastani and colleagues conducted a randomized evaluation of GPT-4-based tutoring in Turkish high school mathematics, reported in a 2024 working paper and later published in PNAS. They found that unfettered access to the base model reduced students' subsequent unassisted exam performance by 17% relative to control, while a guard-railed tutor version largely preserved learning. A well-designed randomized trial can detect harm, not just benefit. Weaker designs rarely report negative effects, which suggests they are not merely imprecise but systematically optimistic.

The Frontiers in Education review (2025) likewise identifies inadequate controls as a central limitation. Escueta and colleagues (2020) offer the benchmark. Their synthesis drew its conclusions from studies in which the comparison group was constructed by randomization or a sharp eligibility cutoff, precisely so that differences could be attributed to the technology.

The third weakness lies in the outcome measures. A large share of the literature relies on self-reported engagement, motivation and perceived usefulness, or on researcher-constructed tests, rather than on validated, objective measures of learning. Self-reports are subjective and correlate only imperfectly with actual achievement. A student who enjoys a chatbot and reports feeling more confident has told the researcher something about experience, not about learning. That distinction matters greatly when claims about motivation and engagement migrate into marketing copy (see Q059).

Researcher-made tests raise a subtler problem. They are often aligned so closely with the intervention's content that they measure the tool's own teaching rather than transferable learning. A gain on a quiz built from the same items the tutor drilled is not evidence of improved mathematical understanding. Outcome measures designed by the vendor of the tool under study raise the same concern in a different form, adding a commercial interest to the alignment problem.

The 2025 critical appraisal of AIEd meta-analyses in SAGE Open treats construct validity as a central weakness: whether the measured outcome actually captures the learning construct the study claims to address. Reviews also note a systematic discrepancy. Rigorous randomized trials frequently report null or modest effects, while observational and self-report studies report larger ones. That pattern is what one would expect if weaker measures inflate effects. It should lead readers to treat a large reported gain on a self-report or bespoke instrument with more caution than a modest gain on an independent standardized measure.

The fourth weakness operates at the level of the literature as a whole: publication bias, questionable research practices and the meta-analyses that aggregate them. Journals favour novel, clean, statistically significant positive results, and the AIEd field's rapid 'fast science' culture amplifies this bias.

Questionable research practices are documented drivers of false positives across the social sciences, as CASRAI's guide to the replication crisis sets out. They include p-hacking, which means trying analyses until one crosses the significance threshold, and hypothesizing after results are known (HARKing). Nothing suggests AIEd is exempt from them. The standard defences are preregistration, registered reports and open data and code, and they remain rare in AIEd research.

Meta-analysis does not cure these problems and can launder them. The National Education Policy Center's forensic analysis of AIEd meta-analyses found that many are 'garbage in, garbage out'. They aggregate methodologically weak primary studies, show extreme between-study heterogeneity, and fail to correct for publication bias. Once bias is accounted for, the NEPC argues, many reported positive effects dissipate. The SAGE Open appraisal (2025) reaches compatible conclusions about statistical validity, questioning pooled estimates drawn from studies too different to combine meaningfully.

The literature disagrees here. Several meta-analyses continue to report moderate-to-large average effects of AI tools on achievement, and the critics argue that those averages are artefacts of the inputs. A reader cannot settle the dispute by counting meta-analyses, because they largely draw on the same pool of small, short, self-reported primary studies. Many claims that circulate widely rest on exactly such pooled estimates, and some early findings have not survived scrutiny (see Q060). A further complication is that a growing share of reviews are thematic rather than quantitative. Examples include Rosa and Yokomizo's (2026) thematic map of 127 articles and Tian's (2025) review of curriculum integration. Such reviews summarise what is being tried without testing whether it works.

The fifth weakness is the overlap between developer and evaluator. As discussed in the answer on research transparency (see Q090), disclosure of funding and conflicts of interest appears in 7% or fewer of the AIEd papers examined in the audits reviewed there. The tradition of researchers evaluating systems they built, or were paid to study, has not disappeared.

Researcher allegiance is the tendency for those invested in a product or approach to find favourable results. It is a well-documented phenomenon in intervention research generally. It need not involve misconduct. It operates through many small, defensible choices about outcomes, comparison groups, analysis windows and which results to write up. The AIEd literature's low disclosure rates leave the reader no way to assess its extent. Whether allegiance effects in this field are larger or smaller than in other intervention research therefore remains unclear.

The governance literature points to a coherent remedy, though not yet an evidence-based one. In a PRISMA-aligned structured review of AI in K-12 school leadership covering 2019 to 2025, Lipsou, Keravnos and Eteokleous (2026) identify data privacy, fairness and accountability as the ethical challenges school leaders must navigate. They also draw selectively on higher education sources for transferable governance mechanisms, including policy, procurement, documentation and explainability, and auditability. The same logic applies to the evidence that informs procurement. A school asked to adopt a tool on the strength of studies its developer funded and conducted should expect those studies to be documented and auditable. Undisclosed vendor involvement should count against them.

Discounting for these weaknesses is a matter of applying standards rather than intuition. The What Works Clearinghouse (WWC) standards of the Institute of Education Sciences and the

evidence tiers of the US Every Student Succeeds Act (ESSA) provide a usable hierarchy. Randomized trials with low attrition and valid outcome measures sit at the top. Quasi-experimental designs with demonstrated baseline equivalence come below them, and correlational studies and logic models lower still.

A reader can apply that hierarchy by asking a short series of questions of any study. Was assignment random? Was there a genuine control condition, and what did it receive? Was the outcome objective, validated and independent of the vendor? How long did the intervention run, and was the analysis intent-to-treat? Was the study preregistered, and are the data and code available for re-analysis? Was the funding disclosed, and was the evaluation independent of the product's developer?

Studies that fail several of these tests should be treated as suggestive at most, regardless of how large their reported effects are. A large effect from a weak design should, if anything, raise suspicion, because inflated estimates are characteristic of underpowered, biased literatures. Meta-analyses deserve the same scepticism as the primary studies they aggregate, as the NEPC critique makes plain. Effect sizes with their confidence intervals should be preferred over p-values, which say nothing about whether an effect matters educationally.

The practical rule of thumb is that the credible core of the AIEd evidence base is much smaller than the published literature. A handful of large, preregistered, independently conducted randomized trials carry most of the evidential weight. They include the Tennessee Khanmigo trial, the Turkish GPT-4 tutor trial by Bastani and colleagues, and a few others. The thousands of small positive studies that surround them should be discounted accordingly. The Escueta et al. (2020) review shows the approach is workable: it drew conclusions about education technology chiefly from randomized and regression-discontinuity evidence.

A reader who applies this discount will find that the evidence supports modest, conditional, design-dependent effects of AI on learning, not the transformative claims that dominate the promotional literature. The Turkish trial shows that such effects can be negative when tools are deployed without pedagogical guardrails.

Q263 What systematic reviews and meta-analyses of AI-in-education interventions exist as of 2025–2026, and what do they collectively conclude about effect sizes and methodological quality?

Scope: *What the meta-analyses actually show about effectiveness. How effectiveness should be measured is treated in Q089.*

12 citations · 12 sources · 5 cross-references

Claim 1 established

The volume of systematic reviews and meta-analyses on AI in education has grown rapidly since 2023, reflecting both the surge of primary studies on generative AI and the demand from policymakers for summary evidence. Understanding what these syntheses collectively conclude requires distinguishing between reviews of earlier AI systems, such as intelligent tutoring systems, and reviews of generative AI, as well as attending closely to the methodological quality both of the syntheses and of the studies they include.

The longer tradition of research on intelligent tutoring systems provides a useful baseline. Ma, Adesope, Nesbit, and Liu, in a 2014 meta-analysis in the Journal of Educational Psychology, found that intelligent tutoring systems were associated with higher learning outcomes than teacher-led large-group instruction, non-tutoring computer instruction, and textbooks, with a moderate average effect size of around 0.41, while effects compared with individual human tutoring or small-group instruction were small or not significant. Kulik and Fletcher, in a 2016 review in the Review of Educational Research, reported a median effect of 0.66 standard deviations across 50 controlled evaluations but noted that effects were much larger on locally developed tests than on standardised tests, a pattern that suggests measurement alignment inflates estimates.

Earlier mapping reviews highlighted the field's limitations. Zawacki-Richter and colleagues, in a 2019 systematic review of 146 articles on AI applications in higher education, found that

most research came from computer science and engineering rather than education, with little critical reflection on pedagogical or ethical implications, prompting their subtitle question about where the educators were.

Syntheses of generative AI research began appearing in 2024 and multiplied in 2025. The meta-analysis by Deng and colleagues, published in Computers & Education in 2025, pooled 69 experimental and quasi-experimental studies of ChatGPT and found positive average effects on academic performance, affective-motivational outcomes, and higher-order thinking, but no significant effect on self-efficacy. The authors observed that most included studies lasted only weeks, rarely reported power analyses, and were vulnerable to novelty effects, and they urged caution in interpreting pooled estimates.

The fragility of this literature was underscored in April 2026, when a widely cited 2025 meta-analysis by Wang and Fan in Humanities and Social Sciences Communications, which had reported a large pooled effect of ChatGPT on learning performance, was retracted. The retraction does not by itself invalidate other syntheses, but it highlights the risk that rapid publication, heterogeneous primary studies, and pressure for headline findings can produce unreliable summaries.

Several methodological concerns recur across syntheses. Primary studies are often small, short, and conducted in single classrooms, frequently by the instructors who designed the intervention. Many use quasi-experimental designs without random assignment, and control conditions vary from no treatment to alternative technologies, making pooled comparisons difficult. Outcomes are commonly researcher-designed and closely aligned with the intervention, and few studies measure retention or transfer. The broader educational evaluation literature indicates why these features matter: Wolf, Morrison, Inns, Slavin, and Risman, in a 2020 study in the Journal of Research on Educational Effectiveness, found that developer-commissioned evaluations reported substantially larger effects than independent ones.

Individual well-designed studies can complicate the summary picture. The randomised trial by Bastani and colleagues in PNAS found that unrestricted GPT-4 access improved practice performance but was associated with worse performance on later unassisted exams, while a guardrailed tutor largely avoided the harm. Meta-analyses that pool outcomes measured with AI assistance alongside outcomes measured without it may therefore combine fundamentally different constructs, producing averages that obscure whether students have learned.

Taken together, the syntheses available as of 2025 and 2026 suggest several conclusions. AI interventions, including generative AI, are on average associated with improved performance on measured outcomes, particularly in short-term studies. Effects vary widely by design, subject, duration, and how outcomes are measured. Evidence on durable learning, transfer, and affective outcomes such as self-efficacy is weaker and less consistent. The methodological quality of the primary literature remains a substantial limitation, and pooled effect sizes are likely inflated by small samples, aligned measures, short durations, and developer involvement.

The intelligent tutoring literature contains an instructive debate about how large effects should be expected to be. Kurt VanLehn, in a 2011 review in Educational Psychologist, compared studies of human tutoring, step-based intelligent tutoring systems and answer-based computer tutoring against no-tutoring conditions, and reported that step-based intelligent tutors produced an average effect of about 0.76 standard deviations, close to the 0.79 he found for human tutoring, far below the two-sigma figure that had often been cited for human tutors following Benjamin Bloom's 1984 essay. VanLehn's analysis suggested that the granularity of interaction, rather than the presence of a human, was associated with effectiveness, a hypothesis with obvious relevance to generative AI tutors that can interact at fine granularity. His review drew mainly on laboratory and short-term studies, often with researcher-designed tests, so its estimates share the inflation risks that later meta-analyses identified. It nonetheless established a reference point that recent syntheses implicitly invoke when they report large effects for generative AI: those effects should be read against a history in which strong tutoring effects in controlled settings have often shrunk when systems moved into ordinary classrooms.

Large-scale randomised evidence on earlier AI systems illustrates that shrinkage. John Pane, Beth Ann Griffin, Daniel McCaffrey and Rita Karam, in a 2014 study in Educational Evaluation and Policy Analysis, reported a randomised trial of Cognitive Tutor Algebra I, a widely used intelligent tutoring curriculum, in 147 middle and high schools across seven U.S. states. They found no significant effect on algebra achievement in the first year of implementation and a positive effect of about 0.2 standard deviations for high school students in the second year, which the authors interpreted as consistent with schools and teachers needing time to adapt to the curriculum. The middle school results were less clear. Compared with the median effects of 0.66 reported in reviews dominated by smaller studies, this trial suggests that real-world effects of AI tutoring at scale are smaller, take time to emerge, and depend on implementation. Few generative AI studies included in recent meta-analyses lasted

long enough to observe such dynamics, which means pooled estimates largely reflect early-implementation conditions.

Interpreting the size of reported effects requires benchmarks appropriate to education. Matthew Kraft, in a 2020 article in Educational Researcher, analysed the distribution of effect sizes from causal studies of education interventions measured on standardised achievement tests and proposed that effects below 0.05 standard deviations be considered small, those from 0.05 to under 0.20 medium, and those of 0.20 or more large. He argued that the conventional benchmarks attributed to Jacob Cohen, under which 0.8 is large, are poorly suited to education, where well-designed interventions with broad outcome measures rarely produce effects of that magnitude. Applying Kraft's guidance to the generative AI literature suggests that pooled effects approaching or exceeding one standard deviation, as reported in some 2024 and 2025 meta-analyses, should prompt scrutiny of study design and measurement rather than celebration. Kraft also emphasised considering costs and scalability alongside effect size, a dimension that most AI syntheses have not addressed systematically.

Methodological research explains why the features common in AI-in-education studies are associated with inflated effects. Alan Cheung and Robert Slavin, in a 2016 analysis in Educational Researcher of 645 studies included in reviews of programmes in mathematics, reading and science, found that effect sizes were larger in quasi-experimental studies than in randomised ones, markedly larger in small studies than in large ones, larger with researcher-made measures than with independent measures, and larger in published articles than in unpublished reports. Each of these features is prevalent in the primary studies pooled by generative AI meta-analyses, which are often small, quasi-experimental, assessed with instruments designed by the researchers and drawn from published journals. Cheung and Slavin's findings imply that subgroup analyses separating studies by these characteristics are essential, and that the most informative estimate from a synthesis may be the effect among large randomised studies with independent measures, even when this subgroup is small. Several 2025 syntheses reported moderator analyses along some of these lines, but few restricted their main conclusions to the highest-quality subset.

The methodological quality of the syntheses themselves varies, and reporting standards offer a way to assess it. Matthew Page and colleagues, in the PRISMA 2020 statement published in The BMJ in 2021, updated the reporting guideline for systematic reviews with a 27-item checklist covering protocol registration, search strategies, selection processes, risk-of-bias

assessment, synthesis methods and certainty of evidence. Many AI-in-education reviews cite PRISMA and include a flow diagram, but adherence to its fuller requirements is uneven: protocols are often not preregistered, risk-of-bias assessments are frequently omitted or superficial, and publication bias is assessed with funnel-plot methods that perform poorly when studies are few and heterogeneous. The retraction of the Wang and Fan meta-analysis described above illustrates the consequences when such safeguards are weak. Readers of syntheses in this field can use PRISMA items as a practical checklist, giving more weight to reviews that preregistered their protocols, assessed risk of bias study by study, and reported how conclusions changed when lower-quality studies were excluded.

Comparisons across educational levels and subjects reveal further gaps in the synthesis literature. Generative AI meta-analyses are dominated by studies of university students, especially in language learning, writing and introductory programming, with comparatively few studies in primary and lower secondary schools and in subjects such as history or the arts. Geographic coverage is also uneven, with substantial shares of studies from China, Taiwan, Turkey and the United States and relatively few from low-income countries. These patterns limit generalisation: an average effect computed mainly from university language courses offers weak guidance for a primary school mathematics programme in a different education system. Equity-related outcomes, such as whether AI interventions narrow or widen gaps between higher- and lower-achieving students or between students from different socio-economic backgrounds, are rarely reported in primary studies and therefore rarely synthesised, even though they matter greatly for policy.

Implementation research is the weakest link between synthesis findings and practice. Meta-analyses typically code interventions by broad categories, such as chatbot, tutor or writing assistant, but say little about the configurations, teacher roles, training and time allocations that determine what students actually experienced. The Bastani trial and the Pane trial both suggest that these details shape outcomes substantially, in one case through guardrails on what the AI would provide and in the other through the time schools needed to adapt. Future syntheses could add value by coding implementation features systematically and by drawing on mixed-methods studies that explain why effects vary. Funders and journals could support this by requiring registered protocols for primary studies, reporting of implementation fidelity, and delayed post-tests that capture whether learning persists once AI assistance is removed.

The pace of publication also creates a practical problem of timeliness. Generative AI models and the products built on them change within months, while systematic reviews typically take a year or more from search to publication, so syntheses published in 2025 and 2026 often summarise studies of model versions that are no longer in use. Living systematic reviews, which are updated continuously as new studies appear and have been used in medicine for fast-moving questions, offer one response, although they require sustained funding and careful version control to avoid repeated analyses that inflate false-positive findings. Another response is to focus syntheses on design features that are likely to persist across model generations, such as whether an AI system provides hints or complete answers, whether teachers configure it, and whether outcomes are measured with or without AI assistance, rather than on specific products. Syntheses organised around such features would remain informative for longer and would speak more directly to the decisions that schools and systems actually face. They would also make it easier to compare findings across studies conducted with different tools, countries and age groups, which is currently one of the main obstacles to cumulative knowledge in this field.

For policymakers and educators, the implication is that meta-analytic averages should be treated as signals of potential rather than reliable estimates of what AI will achieve in practice. Greater weight should be given to large, preregistered, independent randomised trials with delayed and unassisted outcome measures, and future syntheses would benefit from separating such studies from the broader body of small-scale research.

The measurement architecture that would make future syntheses more reliable, meaning which outcomes to measure, over what timescales and against which baselines, is set out in Q089.

Q273 Do generative-AI tutors (2023–) improve durable learning, or mainly boost short-term task performance that fades once the tool is removed?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

The best current answer is that generative-AI tutors can produce real learning, but only under specific design conditions. Without those conditions, much of what they deliver is short-term task performance that does not survive removal of the tool. The controlled evidence since 2023 does not support either the enthusiast claim that conversational AI is a general-purpose accelerator of learning or the sceptic claim that it is inherently corrosive. It points instead to a sharp dependence on what the tool is allowed to do for the student.

Two studies frame the debate. The first is the field experiment by Bastani and colleagues (2025) with nearly a thousand high school mathematics students. Its title states its central conclusion: generative AI without guardrails can harm learning. The authors build their argument on the observation that learning, rather than productivity during a task, is what matters for long-term competence, especially because the tools are fallible and users must check their outputs. The second is the randomized controlled trial by Kestin and colleagues (2025). In that trial, college students taught through a custom AI tutor built on research-based pedagogical principles learned significantly more, in less time, than peers in an in-class active-learning lesson.

The two results are not contradictory. Read together, they show why the question has to be asked about specific tutor designs and specific outcome measures, not about "AI tutoring" in general. The rest of this answer examines that gap between performance and learning. It asks what each body of evidence measures, where gains appear to persist, where they appear to fade, and what the field has not yet established about retention, transfer and mastery.

The conceptual tool needed here predates generative AI by decades. Soderstrom and Bjork (2015) set out the distinction between learning and performance. Learning is the relatively permanent change in comprehension and skill that supports long-term retention and transfer. Performance is what can be observed during or immediately after instruction, and it is often an unreliable index of whether learning has occurred. Their review also documents the converse case: learning can take place even when no change in performance is visible. This distinction is well established in cognitive and educational psychology. It is the right lens for generative-AI tutors because these tools are unusually good at raising performance. A system that can supply a correct solution, a worked step or a polished paragraph on demand will lift scores on any task completed in its presence, whether or not the student's own capability has changed.

The earlier generation of intelligent tutoring systems offers a calibrating precedent. Kulik and Fletcher (2016) meta-analysed 50 controlled evaluations and found a median effect of 0.66 standard deviations over conventional instruction, equivalent to moving a student from the 50th to the 75th percentile. Their most consequential finding for the present question concerns measurement rather than size. The magnitude of improvement depended heavily on whether outcomes were measured with locally developed or standardized tests, which suggests that alignment between test and instructional objectives is a critical determinant of results.

The implication carries directly into the generative-AI era. When the outcome measure closely mirrors the practice the tutor supported, effects will look large. Whether they reflect durable, transferable learning is a separate empirical question. That question requires delayed tests, unassisted conditions and items that differ from what was practised. Without such tests, a high score earned with the tutor present says more about the tool than about the student. The broader pattern of effect sizes and methodological quality across reviews is treated elsewhere (see Q263), as are the general discounts readers should apply to this literature (see Q136).

The most direct evidence that AI assistance can inflate performance without building learning comes from designs that remove the tool at test. Kumar and colleagues (2023) ran a set of large, pre-registered experiments built on exactly this logic. Participants practised high school-level mathematics problems under varied forms of assistance, including LLM-based explanations. All participants then answered new but similar test questions without any assistance. This practise-then-remove design is the minimum standard the field should expect of any claim about learning. The study's framing as a question of "peril or promise" reflects the genuine uncertainty about which way such a test will go for any given form of help.

Bastani and colleagues (2025) bring the same concern to a field setting. They provided generative-AI tutors to nearly a thousand secondary mathematics students and concluded that access to the technology without guardrails can harm learning. They locate the problem in the gap between what students accomplish while the tool is available and the skills they acquire as they perform tasks. That gap is the core of the performance-versus-learning distinction.

Lehmann, Cornelius and Sting (2024) add a more nuanced picture. Their two pre-registered, incentivized laboratory experiments found no effect of LLM access on overall learning outcomes. Exploratory analyses and a field study then suggested that the effect depends on how students use the tool. Students who substituted some of their learning activities with the LLM,

for example by having it generate solutions to exercises, covered more topics but understood each topic less well. Because this finding emerges from exploratory rather than confirmatory analysis, it should be treated as a hypothesis with some empirical support, not a settled result.

Fan and colleagues (2024) give the underlying risk a name: "metacognitive laziness." Their study examined the effects of generative AI on learners' motivation, learning processes and performance. It warns that the ease of AI support may displace the self-regulatory effort through which learners monitor and consolidate their own understanding. The precise magnitude of these effects, and how long they last, remains unclear from the available evidence. Taken together, these studies converge on a single warning sign: the conditions under which AI help feels most useful to a student, namely immediate and complete answers, are the same conditions under which unassisted performance is most likely to lag.

The counter-evidence is substantial, and it comes from tutors deliberately designed to constrain what the AI does. In the Kestin and colleagues (2025) trial, the tutor's design followed the same pedagogical best practices as the active-learning lessons it was compared against, so the comparison was against a strong alternative rather than a passive lecture. Students using the AI tutor learned significantly more in less time. The trial was conducted in an authentic course setting, which strengthens its ecological validity. The abstract does not establish how long the advantage persisted or whether it transferred beyond the targeted content, and those are precisely the questions at issue here.

Pardos and Bhandari (2024) tested a narrower form of AI support: help content generated by ChatGPT inside an educational technology. They used a 3 x 4 design with 274 participants, randomly assigned to no hints, human tutor-authored hints or ChatGPT-generated hints across four mathematics subject areas. ChatGPT-generated help produced learning gains equivalent to human tutor-authored help. The result matters because it isolates the AI as a source of structured, hint-level scaffolding rather than an open-ended answer engine.

The strongest evidence on duration comes from a lower-resource context. Henkel and colleagues (2024) evaluated Rori, a conversational mathematics tutor delivered via WhatsApp, with approximately 1,000 students in grades 3 to 9 across 11 schools in Ghana. Treatment students used Rori for two 30-minute sessions per week over eight months, on top of regular instruction. Their mathematics growth scores were substantially higher than the control group's, with an effect size of 0.37 ($p < 0.001$). Two features make this study unusually relevant. The

intervention ran for most of a school year, and the outcome was a growth measure rather than performance on the tutored tasks themselves. Assignment was at the school level, however, and the abstract does not report a delayed follow-up after the tool was withdrawn. A school-level design also leaves open the possibility that differences between participating schools, rather than the tutor alone, contributed to the gap.

Gabrovšek and Rihtaršič (2025) illustrate the design work behind such systems. They built a configurable generative-AI tutoring prototype for an undergraduate electrical engineering laboratory and analysed 208 student–tutor interactions to evaluate different prompt strategies. Their study is formative rather than a test of learning outcomes. Still, it shows that tutor behaviour is an engineering choice that can be tuned, not a fixed property of the underlying model.

The emerging explanation for these divergent findings is cognitive offloading, together with whether a tutor's design prevents or permits it. Gerlich (2025) surveyed and interviewed 666 participants of varying ages and educational backgrounds. The study reported an association between heavier AI tool use and weaker critical-thinking skills, with cognitive offloading as a mediating factor. These are correlational data from a general population, not an experiment with students, so they cannot show that AI use causes declines in critical thinking. Students with weaker critical-thinking habits may simply rely more on AI. Even so, the pattern fits the experimental evidence that substitution of effort is where learning is lost.

Read together, the experimental and correlational strands suggest that the decisive variable is not the presence of a large language model but the division of cognitive labour it enforces. An open chatbot will do whatever it is asked, including the part of the task that constitutes the learning. A guardrailed tutor withholds answers, prompts retrieval, gives graduated hints and requires the student to generate the next step. The Lehmann and colleagues (2024) contrast between substitutive and complementary use, and the Bastani and colleagues (2025) emphasis on guardrails, both point in this direction. Descriptive evidence on how students actually use these tools adds context. Hershkovitz, Tabach and Lurie (2025) analysed 825 responses from students at a multidisciplinary university and coded the range of academic tasks for which they deploy generative AI. Such usage data show that students bring these tools to many different tasks, and in principle a learning effect could differ by task. Usage surveys of this kind, however, describe what students report doing, not what they learn as a result.

The effects are unlikely to be uniform across learners, and the offloading account predicts as much. Novices with fragile prior knowledge may be most tempted to substitute. More expert learners may be better placed to use AI as a check on their own reasoning. Evidence on these differential effects is reviewed elsewhere (see Q057). The motivational dimension, including whether a tutor's ease of use undermines persistence, is treated separately (see Q059). It is fair to say that the guardrail hypothesis is currently the best-supported account. It has not yet been tested head-to-head across subjects, ages and durations with delayed, unassisted outcome measures.

Several limits mark the boundary of what is currently known. First, few studies of generative-AI tutoring combine three features: random assignment, a test administered after the tool is withdrawn, and a delay long enough to distinguish retention from short-term performance. Kumar and colleagues (2023) and Bastani and colleagues (2025) build in removal of the tool. Henkel and colleagues (2024) supply duration. Kestin and colleagues (2025) supply a demanding comparison condition. No single design yet unites all of these features with a substantial follow-up interval.

Second, transfer remains largely untested. The removal test used by Kumar and colleagues (2023) relies on new but similar questions, which is near transfer at best. A tutor that helps students solve the exact problem types they will be examined on may still leave them unprepared when the surface features change. Whether tutor-supported learning generalizes to structurally different problems, later courses or self-directed problem solving remains unclear.

Third, the measurement problem identified by Kulik and Fletcher (2016) has not gone away. Outcomes aligned closely with tutored content will flatter any intervention. Reports of large gains from generative-AI tutors should be read with that caution until they are replicated on standardized or independently developed instruments.

Fourth, the term "generative-AI tutor" covers systems that differ enormously: an unconstrained chatbot, a hint generator inside a structured platform, a WhatsApp tutor and a research-designed lesson companion. Pooling them yields averages that describe none of them well. The designs that appear to work share a recognisable family resemblance, but the evidence does not yet isolate which specific guardrails are necessary or sufficient.

The practical conclusion follows from the Soderstrom and Bjork (2015) distinction. Institutions evaluating these tools should judge them by what students can do later and alone, not by what

students accomplish while the tool is open in front of them. Tutors that refuse to supply finished answers and require students to generate responses have the stronger evidentiary claim. Open, unguarded access carries a documented risk of substituting for the effort that produces learning. Whether even the best-designed tutors yield gains that persist over months and transfer to new problems is the most important unanswered question in this part of the evidence base.

Chapter 8: Field Experiences — Case Studies from Real Classrooms

10 questions · 163 citations · 155 unique sources · 50 cross-references

Q061 What have large-scale national AI-in-education initiatives (across different countries and income levels) achieved, and what have they abandoned?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

Large-scale national AI-in-education initiatives have so far achieved three things: a large body of curriculum architecture, measurable gains in administrative efficiency, and modest, context-dependent learning gains in specific, well-resourced interventions. What many have effectively set aside is the ambition to make AI an engine of educational equity. The record is now long enough, and varied enough across income levels, to support provisional conclusions. Two caveats apply throughout. Most programs are too recent to have produced rigorous outcome data, and in every region the gap between policy ambition and classroom reality recurs. This chapter therefore treats national initiatives as field experiences still under way, not as completed experiments.

The scale of commitment is striking. DevelopmentAid's 2025 overview of what it calls the global AI education race reports that approximately 55.6% of nations are developing AI education curriculum systems. The same overview reports that nearly 80% have released national AI strategic plans that position education as a key pillar. These figures come from a secondary compilation, not a systematic census, and they count declared intentions, not functioning programs. They are best read as evidence of policy momentum, not of implementation. Strategy documents are cheap relative to teacher training, connectivity and sustained funding. The distance between the two figures and any measure of classroom practice is the central subject of what follows.

The approaches vary as widely as the countries adopting them. At one extreme sits China's centralised mandate. As The AI Track reported, AI education became mandatory for all primary and secondary students, with a nationwide rollout beginning on 1 September 2025 and at least

eight hours of AI education per academic year. NPR's 2026 reporting from Beijing describes a graded curriculum: third graders learn the basics, fourth graders move into data and coding, and fifth graders are introduced to "intelligent agents" and algorithms. The rationale is openly competitive. One Beijing teacher told NPR that the effort is "about enhancing the country's competitiveness by securing a future pool of skilled professionals."

At the other extreme is Finland's open-access model. The University of Helsinki's "Elements of AI" course has engaged over 1.2 million participants worldwide, according to a compilation of education case studies by the RAISE Summit. It introduces fundamental AI concepts and ethical design as accessible, non-technical learning. It is better understood as a public-literacy intervention than as a school reform.

South Korea occupies a middle ground between mandate and market. DevelopmentAid reports that in March 2025 the country rolled out AI-powered digital textbooks for mathematics, English and computing across primary and secondary education. The rollout was backed by $70 million in infrastructure funding and $760 million for teacher training, and it included real-time feedback and adaptive learning tools.

India's demographic scale makes any national commitment consequential. As Techwire Asia reported, AI and Computational Thinking will become mandatory subjects in all schools from Class 3 onwards, beginning with the 2026–27 academic year. Vision IAS documents how gradually the groundwork was laid. AI was introduced as an optional Class 9 subject in 2019 and expanded to Classes 11 and 12 by 2020–21. Today over 18,000 CBSE schools offer AI through a 15-hour introductory module for Classes 6–8.

In Africa, commitments are more strategic than operational. A 2026 pan-African framework for ethical AI curricula situates them in this way. Kenya's National AI Strategy 2025–2030, published in March 2025, commits to embedding AI literacy across education and to piloting Digital Innovation Hubs as curriculum anchors. South Africa has invested in coding and robotics in selected grades. Ghana and Rwanda have announced AI and digital-skills strategies linked to the Smart Africa initiative. The authors argue for culturally contextualised content precisely because imported curricula risk fitting local pedagogical traditions poorly. The regulatory dimension of these strategies is compared in Q069.

Genuine learning gains have been documented, but in specific, well-resourced interventions, not in national rollouts. Engageli's 2026 compilation of AI-in-education statistics cites a 2025

randomized controlled trial in Scientific Reports. That trial found AI tutoring outperformed in-class active learning, with an effect size between 0.73 and 1.3 standard deviations. If the result holds at scale, it would be one of the largest pedagogical advances in decades. That condition is substantial. The trial was not a national program, and effects of this size rarely survive transfer to heterogeneous systems with weaker infrastructure and less motivated users.

Administrative efficiency gains are cleaner and more consistent. The RAISE Summit's case-study compilation reports that IEP preparation time in special education fell by 90%, from three hours to ten minutes, in AI-assisted workflows. This is an industry-reported case, not peer-reviewed research, and it should be read as illustrating the kind of gain at stake, not as an established estimate (see Q236 for implementations with special-needs learners).

The OECD's 2026 Digital Education Outlook, as summarised by Engageli, recommends moving beyond general-purpose AI tools toward purpose-built educational AI designed to produce durable learning gains, not just better task outputs. That distinction implicitly concedes that most deployments have not yet reached the deeper goal.

Peer-reviewed work on lower-income settings follows the same pattern. Lakhno's (2026) PRISMA-guided review of AI adoption in higher education in low-income countries (2022–2024) applied Rogers' Diffusion of Innovations framework. It found that AI showed its greatest relative advantage in targeted applications, such as vaccine-literacy chatbots, AI-assisted examinations and generative AI tools, which yielded immediate, visible benefits for learning, motivation or efficiency. Systemic integration, however, remained elusive.

Achuthan (2026) adds a measurable dimension through a survey of 14,653 computer science learners in 166 countries. Everyday generative AI adoption was high across income tiers and was not lower in poorer settings. Converting that access into learning use was another matter. Among everyday users, those in low-income countries were markedly less likely to make any learning use of the tools (odds ratio 0.49, 95% CI 0.27–0.90). Breadth of use among those who did convert did not differ by income tier. Achuthan names this the access–conversion gap. It also bears on national strategies, which tend to measure reach and rarely conversion. The finding is cross-sectional and drawn from an already connected population, so it describes an association, not a cause.

The more sobering finding is how consistently the gap between strategic announcement and classroom reality has widened, and teacher capacity sits at its centre. The Federation of

American Scientists argues that the United States risks repeating familiar implementation failures that have limited educational technology for more than a decade, and urges treating AI implementation as essential infrastructure. Engageli reports a February 2026 Coursera survey across five countries that found AI adoption has dramatically outpaced governance. Because the survey is vendor-commissioned, it signals perception more than measured practice.

The peer-reviewed evidence on readiness is still small-scale, but it points in a consistent direction. Ullrich and colleagues (2026) validated a German-language AI readiness scale with 153 teachers in German-speaking Switzerland. Readiness correlated with digital competencies. Apparent gender and age differences became non-significant once digital competence was controlled, which suggests that training investment matters more than demographics. Kralova and colleagues (2026) found that 98 EFL student teachers in Japan reported higher AI self-efficacy than peers in Poland and Slovakia. The authors acknowledge that the reasons for these cross-country differences remain unclear. In China, Day (2026) analysed forum discussions among 76 preservice teachers. Participants were interested in AI's pedagogical possibilities but sceptical that it could replicate the relational and context-sensitive work of teaching. Day recommends framing AI as a collaborator, not a replacement. In Serbia, Djukić Popović and colleagues (2026) surveyed 1,042 teachers and 2,587 students to assess system readiness for generative AI. Their scale illustrates how national systems are beginning to audit attitudes before, or alongside, rollout.

The Korean case shows why infrastructure spending alone is not decisive. Chaemchoy and Supsin (2026) analysed ICILS 2023 data from 24,273 students in 1,049 schools across 12 systems. None of the five school-level digital conditions they examined, including expectations about ChatGPT and pedagogical ICT hindrances, showed an association with computer and information literacy that survived false-discovery-rate control. Coefficients for Korea were raw-significant but not retained ($q = 0.730$). The study does not evaluate Korea's textbook program. It does caution against assuming that school digital conditions translate straightforwardly into student competence. Q065 and Q067 take up classroom-level lessons and exemplary practitioners.

China's case is particularly instructive because its ambitions are so explicit. As Lily Ottinger's ChinaTalk analysis describes, the central government is betting that AI tools can eliminate the country's vast educational inequities, yet the structural barriers are formidable. In 2025, 85% of Shanghai students who sat the gaokao were admitted to four-year universities, compared with

32% in Anhui province. Fewer than 5% of students at elite universities come from rural families. These disparities are rooted in the hukou system and in university admissions quotas that no AI curriculum can reach. Ottinger notes that AI education tools are mostly commercially developed. Companies hesitate to build platforms tailored to the specific disabilities or economic conditions of rural counties that cannot pay. Roughly half of China's children are educated in rural areas, and those schools are hard to generalise about because infrastructure and staff quality vary so widely.

India faces a structurally similar challenge at even greater scale. Techwire Asia notes that the 2026–27 rollout requires training over 10 million teachers across a diverse educational landscape. Vision IAS reports that approximately 9% of Indian schools have only one teacher, and that many lack basic amenities such as electricity or computers. Under those conditions any AI deployment is, at best, aspirational.

Across the developing world more broadly, AI interventions remain stuck at the pilot stage despite their apparent promise. The clearest systematic account of why comes from health, not education. A 2026 analysis of AI health interventions in developing countries identifies governance gaps, institutional fragility and procurement barriers as recurring obstacles to scale-up. Lakhno's (2026) review suggests the analogy transfers to education. Weak compatibility with local pedagogical traditions, infrastructural deficits and lagging institutional governance limited diffusion. Low-cost pilots producing tangible evidence of impact acted as decisive enablers. Q063 examines what transfers and what fails in low-resource tutoring deployments.

What most national programs have effectively abandoned is equity as a primary outcome. Initiatives once framed around closing achievement gaps have quietly shifted toward workforce readiness as their headline goal. The hardest pedagogical problems, namely foundational literacy, early childhood development and rural access, remain largely untouched. This is an interpretive judgement and not a documented policy reversal. Governments rarely announce such retreats, and some, China most visibly, still state equity goals officially. The judgement is therefore contestable. It does, however, fit the pattern of resource allocation and rhetoric described above, as well as the competitiveness rationale voiced in Beijing.

Large-scale assessment research explains why the retreat matters. Liu and Dai (2026) applied explainable machine learning to PISA 2018 mathematics data from 74,235 students in ten systems. Books at home, parental occupational status, grade placement, learning time and

socioeconomic status were among the most stable predictors of achievement. Their best model still explained only about 36% of variance (average weighted R^2 of 0.358). Doğan (2026), using PISA 2022 data from nine European countries, likewise found socioeconomic resources and mathematics-related affective beliefs to be the strongest predictors, in complex non-linear relationships. Both studies are correlational and do not evaluate AI programs. They do indicate that the drivers of unequal achievement lie largely outside what a national AI curriculum touches.

As of mid-2026, then, large-scale AI-in-education initiatives have produced measurable gains in administrative efficiency, modest and context-dependent gains in specific learning metrics, and a great deal of curriculum architecture. That architecture has yet to be tested against the full complexity of national school systems. Whether purpose-built tools, sustained teacher development and attention to converting access into learning use can restore equity as a realistic goal remains unclear. Documented harms from deployments, reviewed in Q068, add a further reason for caution.

Q062 What lessons emerge from schools and universities that banned AI, then reversed course — or embraced it, then restricted it?

17 citations · 17 sources · 5 cross-references

Claim 1 disputed

Institutions that banned generative AI and then reversed course, and those that embraced it and then pulled back, point to the same lesson. Categorical policies in either direction tend to fail.

What lasts is granular, task-specific governance that assumes AI is present and asks what students are actually practising. The pattern has unfolded in less than three years. It began with a burst of prohibition after ChatGPT's release, moved through a fairly rapid and widespread reversal, and has settled into a grudging, still unfinished accommodation. It is one of the more instructive recent episodes in technology governance, partly because it is so compressed and partly because the evidence now covers both the banning experiment and its enthusiastic overcorrection.

Two features of the record deserve emphasis before the details. First, the movement away from prohibition is well documented at scale. A study of more than 30,000 U.S. courses, reported by Inside Higher Ed and Times Higher Education, found that the highly restrictive policies introduced after ChatGPT's launch were eased in favour of more nuanced responses. Second, the movement was not uniform. That easing occurred across all disciplines except the arts and humanities, and some fields with strong professional reasons for caution held or tightened their restrictions. Read carefully, the reversal is less a simple victory for permissiveness than a gradual replacement of one blunt instrument with many finer ones. As Brookings frames the choice for schools, the question has shifted from whether to ban or integrate towards how integration can be bounded and made pedagogically defensible.

New York City Public Schools was the first school system to block access to ChatGPT, and also the first to reverse its ban, as Brookings recounts. The sequence was swift enough to look almost comic, but it was not unique. Education Week's reporting on district policies in early 2024 found many educators describing bans that existed on paper while classroom practice moved on regardless. The same trajectory appears in higher education, where the 30,000-course analysis documents the retreat from restrictive language across nearly every discipline.

The bans collapsed mainly because they were unenforceable in principle and ignored in practice. A widely circulated figure, reported in a 2025–2026 overview of school AI debates, holds that 84 percent of U.S. high schoolers used AI for schoolwork. The same overview reports that students in schools that prohibited AI used it just as much as students in schools that did not. That source is a sector commentary rather than a peer-reviewed study, so the precise figure should be treated with caution. Its direction, however, matches what instructors themselves report. As one education researcher told Inside Higher Ed and Times Higher Education, "outright bans tend not to persist, possibly because they are hard to enforce.

Instructors increasingly specify when AI use is acceptable and for which tasks, which aligns better with how learning actually happens."

The finding that use did not differ between banning and non-banning schools is a correlation, not a causal estimate. Schools that banned AI may have differed in other ways from those that did not. The data cannot show that bans had no effect on any student. They do strongly suggest that bans were not the decisive variable governing whether students used these tools.

The reversal was not only pragmatic. For North Carolina's superintendent of public instruction, quoted by Education Week, allowing the technology in schools was an equity issue: "If kids are not learning how to use it at school, and they don't have access to it at home or have parents who can teach them how to leverage it, large swaths of children are missing out" on key career preparation. This argument proved influential because it exposed an unintended distributive consequence of blanket bans. Wealthier students could reach AI tools regardless of school policy, while others were simply denied the preparation, a concern Brookings also foregrounds in weighing prohibition against integration.

The broader research supports treating equity as a recurring rather than incidental concern. In a scoping review of 21 sources on secondary-school leadership published between 2018 and 2025, Kumar and Sarkar (2026) found that equity concerns emerged consistently across all four leadership dimensions they examined: instructional, managerial, strategic and relational. Their review relies on secondary data and English-language sources, which limits its generalisability. Even so, it suggests that the distributive problem the North Carolina superintendent identified is structural and cannot be solved by a single policy switch.

Institutional context also shapes how students experience AI once it is permitted. In a survey of 552 undergraduate science students across six government-owned universities in South-Western Nigeria, Tijani and Adeduyigbe (2026) found significant differences in perceptions of AI-driven adaptive learning by level of study and by university type. Higher-level students and those in state universities reported more positive perceptions, and gender differences were not statistically significant. These are perceptions, not learning outcomes, and they come from a single national context. They nonetheless warn that lifting a ban does not by itself equalise access to the benefits. Who gains from integration depends on where and at what stage students encounter it.

What replaced the bans was a broad shift away from categorical prohibition towards task-specific, disclosure-based governance. Across 2024 and 2025, according to a compilation of university policies published by an AI writing-tools company, institutions including Harvard, Oxford and the University of Michigan updated course syllabi to include explicit disclosure language rather than blanket prohibitions. The compilation is a vendor overview, not independent research. In the form it describes, such policies often read "AI tools may be used only with disclosure and within instructor-defined limits," which moves the issue away from plagiarism and towards authorship transparency. The 30,000-course study puts a measurable scale on this shift. Calls for students to attribute their AI use appeared in only 1 percent of syllabi in early 2023, but had reached 29 percent by the end of 2025.

The new frameworks are notably granular. The same study found that course policies increasingly restrict or permit AI depending on the specific task. When policies mention drafting or revising, 79 percent ban AI use. For reasoning and problem-solving, 65 percent prohibit it. For coding and technical work, only 20 percent ban AI, and for editing or proofreading the figure is 17 percent. The pattern is coherent: instructors protect the tasks they regard as constitutive of the learning and relax rules on tasks they regard as instrumental. This restructuring of assessment and honour codes is examined in detail elsewhere (see Q064).

Law schools present the clearest case of principled caution. Policy trackers covering top universities, such as Thesify's October 2025 update, report that most law schools maintained or tightened prohibition-oriented policies through 2025. Their reasoning is that bar examinations and client advising demand precise, source-attributed reasoning, and AI hallucination in legal contexts can cause direct harm to clients. Professional-training contexts raise distinct questions about what can safely be delegated (see Q066).

Governance traditions also shape how the shift plays out. Drawing on policy documents and 33 interviews with faculty at Chinese research universities, Liu, Fang and Lan (2025) show that a state-led model is interpreted and enacted on campuses through AI-powered teaching platforms and general and specialised AI education. Faculty there value personalisation, research productivity and administrative efficiency, yet still raise concerns about academic integrity, bias and overreliance. The ban-and-reverse cycle familiar from U.S. reporting is therefore one trajectory among several. The underlying tension between integration and integrity appears across very different systems.

Institutions that moved rapidly to wholesale integration have run into a different set of problems, and here the evidence is contested. A January 2026 survey of 1,057 faculty members by the American Association of Colleges and Universities and Elon University, reported in Forbes, found that 90 percent of faculty believe AI is weakening critical thinking. More troubling, 63 percent of the same faculty reported that spring 2025 graduates were not well prepared to use AI effectively in the workplace, despite frequent exposure to these tools during college. Exposure, in other words, is not the same as formation.

These are faculty perceptions, not measured learning outcomes. They may reflect genuine erosion, or they may partly reflect professional anxiety about displaced practices. Similar worries appear well beyond U.S. higher education. In a representative sample of teachers in rural Catalan schools, López Costa (2025) found concerns centred on ethical implications, academic integrity and a potential reduction in students' critical thinking. Among administrators, Kumar and Sarkar (2026) identify a parallel risk of cognitive offloading when critical-thinking tasks are delegated to AI, which may weaken the very capabilities leadership depends on. The consistency of the concern is striking. The causal evidence that integration degrades thinking remains unclear, and long-run outcome data are only now accumulating (see Q237).

The evidence also cuts against swinging back to prohibition. Writing on a course model for generative AI education, the authors of a 2025 arXiv paper observe that students now enter higher education with AI habits already ingrained, and that classroom restrictions do not appear to prevent use. Restrictions instead risk students using AI quietly, without formal guidance, in increasingly punitive classroom environments. The authors suggest this may produce worse outcomes than the tools themselves. The literature therefore disagrees in a specific way. Faculty surveys warn that unstructured embrace harms learning, while curriculum researchers warn that renewed restriction drives use underground. Both positions converge on the inadequacy of exposure without design.

The lesson that survives both the banning experiment and the enthusiast overcorrection is structural rather than technological. A Chronicle of Higher Education survey, cited by Boston Consulting Group, reports that some 67 percent of university leaders say they have not acted or have no clear AI strategy. Because BCG is a consultancy with commercial interests in transformation, the figure is best read as indicative rather than definitive. Where institutions have done better, policy trackers such as Thesify identify a common feature: granularity, with a

steady move towards nuanced, course-specific rules rather than blanket bans. Universities are now writing rules that assume AI's presence instead of pretending it can be excluded. According to a 2026 overview of academic integrity policies, many also clarify that AI detection outputs do not override instructor judgment. Even when a report shows a high probability score, faculty retain discretion to decide whether context warrants further action.

The school-level evidence explains why strategy lags. In interviews with 20 Irish primary principals, Gorman and Brennan (2026) found that AI leadership is not yet a coherent or established field of practice. Engagement was cautious, uneven and strongly shaped by uncertainty, within a policy context that remains provisional. Principals saw AI variously as an opportunity, a risk, an inevitability and a development uneasy with the relational purposes of education. Their engagement concentrated on administrative efficiencies, while pupil use remained limited and contested. Riachi's (2026) study of 28 Lebanese teachers likewise found that most reported familiarity with AI but few integrated it into instruction. She distinguishes three orientations: reluctant users, early adopters and critical skeptics. Barriers included insufficient training, weak institutional support and privacy concerns. López Costa (2025) similarly documents a gap between teachers' moderate AI knowledge and their limited classroom use. Policy reversals, in short, are only as durable as the professional capacity beneath them. K–12 experiences of daily integration bear this out (see Q065).

The deeper pedagogical question, which institutions have been slower to confront, concerns what skills are actually being practised. As one researcher summarised to Inside Higher Ed: "Academic integrity still matters, but the bigger question is what students are practicing and what skills they are building. More instructors are starting to frame AI in terms of learning, including when it supports practice and when it might replace the practice students need." That reframing, from policing to deliberate design backed by context-sensitive professional development, marks the mature version of AI governance. Most institutions are still struggling to reach it.

Q063 What do documented deployments of AI tutors in low-resource and developing-world contexts show about what transfers and what fails?

13 citations · 13 sources · 5 cross-references

Claim 1 emerging

Documented deployments of AI tutors in low-resource and developing-world settings show a consistent pattern. The pedagogical logic of adaptive, feedback-rich tutoring appears to transfer across national contexts. The conditions that let it work often do not: reliable electricity and connectivity, capable devices, teacher capacity, curricular alignment, linguistic fit and governance. The record is therefore neither the triumph promotional literature describes nor the outright failure skeptics predict. It is mixed but instructive. Gains appear where systems are fitted to local conditions, and failures cluster where imported systems assume conditions that do not exist.

The World Bank's digital development analysis frames this as AI's dual impact on developing nations. The same technology that could narrow learning gaps can also widen them if access and capacity are unevenly distributed. Brookings reaches a similar conclusion in asking whether AI in education will succeed. It argues that the history of educational technology in poorer countries is mostly a history of implementation, not invention. Emmanuel and Esenogho (2026) put the general point most directly. Their structured review of AI for sustainable development in African low-resource contexts covers education alongside healthcare, agriculture and environmental management. They conclude that the technical potential of AI systems does not automatically translate into sustained implementation or measurable development outcomes. Their review identifies fragmented data ecosystems, infrastructural limitations, governance capacity, human-capital constraints and risks of digital exclusion as the factors that decide feasibility. Read against that background, the educational evidence is less a test of whether AI tutors 'work' than a test of whether a given deployment met the conditions that let them work.

There are documented gains. In India, students using an AI-powered personalised learning tool scored higher in Hindi and mathematics, according to the World Bank's account of AI's effects in developing economies. That account also reports that gains were largest for students who typically struggle most. This suggests AI could serve as an equity tool when implemented thoughtfully, though it does not guarantee that outcome. The pattern fits the broader literature on intelligent tutoring systems, which has long found that immediate, adaptive feedback benefits weaker learners most. It also fits the wider review of computer-assisted learning by Sevilla and colleagues (2025), who report meaningful gains in student performance, especially in mathematics. Readers seeking the general strength of this evidence should consult the discussion of tutoring outcomes elsewhere in this volume (see Q051).

In higher education, a study of Kenyan institutions reported in the Frontiers review of AI for teachers in low- and middle-income countries found a strong positive correlation between AI tool use and improved teaching and learning outcomes. This is a correlation, not a demonstrated causal effect. Institutions and individuals who adopt AI tools may differ in resources, motivation and prior performance in ways that explain much of the association.

Sevilla and colleagues (2025) also add an important qualification. They argue that the impact of these tools depends less on access to devices than on how they are integrated into teaching, through curriculum alignment, teacher training and interactive design that promotes active learning. Gabrovšek and Rihtaršič (2025) show why design matters. They evaluated a custom generative AI tutor in an undergraduate electrical engineering laboratory and analysed 208 student–tutor interactions. Student prompts were predominantly procedural or factual, with limited conceptual or metacognitive engagement. Structured prompt styles produced clearer responses and earned the highest student ratings. Reasoning-oriented approaches were valued mainly by the researchers for their pedagogical depth. The authors call this a 'preference–pedagogy gap'. Their study was not conducted in a low-resource setting, but the finding bears on transfer. Unless instructional guidance is built into the tutor itself, learners will tend to use it for answers rather than understanding, wherever they are.

Infrastructure is the most extensively documented source of failure, and the barrier is substantial. Brookings recalls Peru's One Laptop Per Child programme, which distributed roughly 900,000 devices over a decade but produced no measurable effect on mathematics or reading achievement. The problem, Brookings argues, was not the hardware. It was the absence of electricity, connectivity, teacher capacity and curricular integration. Brookings further argues

that AI raises the infrastructure bar rather than lowering it, because AI requires reliable bandwidth, sufficient processing power and capable devices.

The connectivity baseline is low. As of 2022, according to figures cited in the Frontiers review of AI in low- and middle-income countries, only about 40% of primary schools and 50% of lower secondary schools globally had internet access. Laptops can be used offline, but AI tutors built on cloud-hosted language models typically need sustained connectivity to function at all. A deployment model that assumes always-on access therefore excludes many of the schools that most need help.

The classroom-level evidence confirms that unreliable access shapes learners' experience. Kasie (2026) ran a semester-long interpretive multiple case study with ten undergraduate English-as-a-foreign-language writers at Bahir Dar University in Ethiopia. The study treats unreliable internet access as one of the conditions that intensifies writing difficulty in low-resource Global South settings, alongside writing anxiety and linguistic insecurity. Emmanuel and Esenogho (2026) likewise list infrastructural limitations among the structural enablers that determine whether AI can be deployed, maintained and adapted in African contexts. They also highlight resource-efficient AI approaches as one response.

Sevilla and colleagues (2025) caution against reading infrastructure as a problem only of poor countries. Using new evidence from Italy, they show that digital divides in AI adoption persist across schools and regions and reflect broader social and economic disparities. They warn that without careful implementation these tools risk widening existing inequalities. If such divides appear inside a high-income European country, the gap between a well-connected urban school and an unelectrified rural one elsewhere is likely to be far larger.

Language is the second structural failure point, and it receives less attention than connectivity. The Frontiers review of AI in low- and middle-income countries observes that the dominance of English-language content restricts the accessibility of AI tools for non-English-speaking practitioners, educators and policymakers. It argues that this linguistic asymmetry perpetuates epistemic hierarchies that marginalise alternative knowledge systems and local epistemologies.

The arXiv study evaluating large language models for career guidance across ten African countries identifies a further, largely overlooked dimension. Even when students interact with these models in English, they may be seeking guidance for contexts where local languages dominate professional communication. Current models are not equipped to handle this

mismatch. Most AI tutoring products were trained predominantly on English-language corpora drawn from wealthy-country curricula. Deploying them in a Francophone West African or rural South Asian classroom therefore involves more than translation. It involves a basic mismatch of cultural reference, pedagogy and assessed content.

The evidence on second-language learners themselves is more mixed than a simple deficit account suggests. Al-Othman (2026) interviewed undergraduates at a public university in Riyadh. Students held positive perceptions of ChatGPT as a writing tutor and described improvement at lexical, syntactic, semantic and pragmatic levels, along with greater use of cognitive and metacognitive writing strategies. These are self-reported perceptions from a qualitative sample, not measured learning gains, and the setting is not low-resource in the infrastructural sense. The study nonetheless emphasises students' need for accessible English-language tutoring.

Kasie's (2026) Ethiopian case study offers a closer view of how such use develops. Most of the ten participants began by relying on generative AI without critical evaluation. They then gradually shifted toward more selective and purposeful use. Along the way they identified cultural limitations in the tool's outputs, which bears directly on the mismatch described above. Taken together, these studies suggest that AI can scaffold access to a dominant language. Whether it also entrenches that language's dominance over mother-tongue instruction remains unclear (see Q228).

Governance and data sovereignty add another layer of complexity, and low-resource settings are poorly equipped to manage it. When student data is used to train commercial AI systems, it often flows to foreign-controlled servers with limited transparency. The RUFORUM network of African universities notes that UNESCO's 2025 framework on AI ethics emphasises 'data dignity'. It also notes that mechanisms for implementing that principle in resource-constrained contexts remain underdeveloped. Emmanuel and Esenogho (2026) similarly identify governance capacity and ethical considerations as core feasibility conditions. Their proposed adaptive deployment framework is explicitly intended to assess whether AI systems can be responsibly governed, not merely installed.

Academic integrity is a second governance strain. RUFORUM reports that AI-driven academic dishonesty is prevalent in Sub-Saharan African higher education. It cites a 2025 study in which over half of students and faculty reported incidents of AI-assisted misconduct, while many

institutions lacked the infrastructure or policies to respond systematically. Detection-based responses carry their own documented weaknesses (see Q056), and the broader catalogue of deployment harms is treated separately (see Q068).

A quieter risk concerns what AI does to self-regulated learning in unequal settings. Dhurumraj and Labuschagne (2026) conducted a qualitative systematic literature review with thematic synthesis of peer-reviewed studies published between 2018 and 2026. They find that AI does not have a uniform effect on metacognition; its impact is dynamic and context-dependent. AI can enhance planning, monitoring and evaluation by externalising cognitive processes and supporting feedback. It can also enable cognitive offloading that reduces learners' engagement in regulation. A third mode, hybrid regulation, emerges when metacognitive processes are co-constructed between learner and system. Which mode dominates depends on the interaction of technological, pedagogical and socio-economic conditions, so the same tool may build independent learners in one setting and dependent ones in another. Kasie's (2026) observation that Ethiopian students moved from uncritical to selective use suggests the shift toward productive regulation is possible. It also suggests the shift is gradual and benefits from deliberate support.

The evidence base itself is thin and lopsided, which limits every conclusion above. The Frontiers review of AI in low- and middle-income countries observes that the literature on AI in education largely neglects these countries and concentrates on advanced economies. The resource asymmetry behind that neglect is stark. According to the World Bank's 2025 factsheet on strengthening AI foundations, high-income countries account for 87% of notable AI models, 86% of AI start-ups and 91% of venture capital funding, yet only 17% of the global population. As a result, documented deployments in low-resource contexts are often small pilots rather than rigorous randomised trials. The systems being piloted were usually designed elsewhere for different learners. Several of the studies reviewed here are qualitative case studies with samples of ten students or interview cohorts, which are valuable for understanding mechanisms but cannot establish effect sizes.

The World Bank's education work on AI-enabled edtech in Africa describes pilots underway across several low-income contexts. They include adaptive learning programmes in Côte d'Ivoire, The Gambia and Mali; WhatsApp-based tutors in Ghana; teacher-focused solutions in Ethiopia; and youth skills programmes in Tanzania and Mauritius. These designs work around high-bandwidth infrastructure rather than assuming it. WhatsApp-based delivery, for instance,

functions on intermittent mobile data and on phones families already own. The teacher-focused Ethiopian work reflects the conclusion of Sevilla and colleagues (2025) that integration into teaching matters more than device access. Whether these pilots produce durable results at scale remains to be seen, because the evidence is still being gathered.

The aggregate record suggests that the core promise of personalised, patient, adaptive instruction is not culturally specific. Realising it in low-resource contexts, however, requires several things the dominant global systems do not provide: locally co-designed tools, mother-tongue language support, offline or low-bandwidth architectures, pedagogical guidance built into the tutor, governance arrangements that protect student data, and real integration with teachers. The difference between transfer and failure, on the present evidence, lies less in the algorithm than in everything around it.

Q064 How have universities restructured courses, assessments, and honor codes in response to generative AI, and with what results?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

Universities have responded to generative AI on three fronts at once: replacing blanket prohibitions with disclosure-based conduct rules, redesigning assessment toward formats that are hard to delegate to a machine, and, more slowly, retreating from reliance on detection software. The results so far are uneven. Policy has converged faster than classroom practice, recorded misconduct has risen sharply, and evidence that redesigned courses actually improve learning remains thin. The arrival of these tools has forced institutions into a kind of triage.

They must rewrite the rules of academic conduct, redesign how learning is tested, and reckon with the uncomfortable possibility that their enforcement tools are as unreliable as the behaviour they are meant to catch.

Student adoption has outrun almost every institutional response. Research from the Higher Education Policy Institute (HEPI), reported in industry compilations, found that 92% of surveyed UK students were using AI in some form by 2025, up from 66% in 2024. Confirmed misconduct has risen alongside usage. Figures reported by The Academic Observer indicate that UK universities recorded nearly 7,000 proven cases of AI-related cheating in the 2023–24 academic year, roughly three times the previous year's total. LiveAIWire places this within a near 400% increase in AI-related misconduct incidents over three academic years.

The same reporting cautions that these totals are almost certainly undercounts. In a test at the University of Reading, 94% of AI-written submissions passed through marking undetected. Over the same period, traditional plagiarism fell from 19 to 15.2 cases per 1,000 students in 2023–24, according to The Academic Observer. This pattern suggests, though it cannot prove, that some students are substituting one form of dishonesty for another that institutions are less equipped to see. These are rises in recorded cases rather than measured prevalence, so they reflect institutional vigilance as much as student behaviour. That caveat becomes central when the reliability of detection is examined below.

On rules of conduct, the dominant response among leading universities has been disclosure rather than prohibition. Thesify's October 2025 survey of policies at highly ranked institutions documents the pattern.

At Oxford, students may use generative AI to support their studies. In summative assessment, however, it is permitted only where course instructions explicitly allow it, a declaration must accompany any permitted use, and unauthorised use is treated as academic misconduct. Cambridge likewise permits AI for personal study and formative tasks but classes unacknowledged AI-generated content in summative work as misconduct. Princeton's library guidance asks students to confirm with instructors whether AI is allowed and to disclose any use. Some Princeton courses go further and require students to keep their AI chat logs for verification. The early instinct to ban outright has largely given way to these conditional regimes, a trajectory traced in more detail elsewhere in this chapter (see Q062).

The deeper structural feature is decentralisation, which brings inconsistency. At UNC–Chapel Hill, every undergraduate syllabus must include an explicit AI policy, with faculty choosing from sample statements ranging from full prohibition to conditional acceptance. Enforcement then rests on individual syllabi, which leaves room for inconsistent application across classrooms, departments and campuses. Azevedo's (2025) review of institutional frameworks for faculty likewise treats course-level guidance as a primary site where AI policy is enacted.

LaFrance's (2026) comparative policy mapping of publicly available guidance at America's flagship public universities shows that UNC is typical rather than exceptional. The study drew on documents collected in 2025 and coded them thematically using Clark's Triangle of Coordination. It found a distributed governance architecture in which instructional decisions are delegated to the course level and supported by instructor-facing resources. Institution-level guidance, by contrast, concentrates on data protection, approved tools and risk management. Postures and the depth of codification vary, but LaFrance identifies structural convergence around this shared model. He interprets it as reinforcing established distributions of authority in public higher education rather than creating new ones. Decentralisation, on this reading, is less a policy failure than the system's default way of absorbing a disruption.

Honor codes have proved the weakest link. Analyses of integrity policy such as that of BPPE Consulting note that most pre-2023 codes forbid submitting work that is not one's own. They do not, however, define whether AI-assisted work counts as one's own, which leaves a grey zone that older codes simply do not address. Outside well-resourced systems, the gap is wider still. Abdulrahman and Ahmed (2026) audited public-facing governance at 30 universities in the Kurdistan Region of Iraq across 11 dimensions, from plagiarism policy to local-language accessibility. Most institutions sat at Stage 1, meaning low public visibility of AI guidance or a narrow plagiarism-control orientation. Only one showed a more developed public-facing position. The weakest areas were AI-use disclosure, acceptable-use guidance, privacy protection and AI-aware assessment, which are precisely the elements on which the Oxford and Cambridge model depends.

The most substantive institutional response has been architectural rather than punitive: redesigning assessments so they are harder to outsource to a machine. One commonly proposed route is a return to invigilated, on-campus examinations. Reflections on the future of statistics education describe this option as having well-documented strengths and limitations for

assessing what students have actually learned. It secures authorship but narrows what can be tested.

Stanford's Academic Integrity Working Group, reported in October 2025, recommended in-person formats for instructors who wish to limit AI use in high-stakes settings. Its suggestions included oral examinations and in-class writing assignments.

The University of Sydney has gone further, moving toward assessment embedded in program-level design. This reflects its judgement that securing every individual task is increasingly impractical in an AI-rich, connected environment. At national level, Australia's regulator TEQSA announced in May 2025 a shift to a regulatory-led framework beginning in 2026. The move responded to widespread student use of generative AI and the associated risks to assessment integrity, and it signals that redesign is moving from voluntary good practice toward compliance. Commentators writing in The Conversation make the underlying argument directly: detection software cannot rescue existing assessments, so assessment itself has to change.

Redesign raises a validity problem of its own, which the policy literature rarely confronts. Kaldaras, Akaeze and Reckase (2024) offer a conceptual analysis rather than an empirical test. They argue that if AI tools are used to score assessments aimed at knowledge application, one must show that the algorithms score the same construct attributes a trained human scorer would. They add that AI-generated assessments must align with the performance expectations of the learning environments that use them. They also flag the social biases embedded in training data. At the time of writing, they identified no guidelines for assessing the validity of AI-based assessments and their results. Whether the new oral, in-class and program-level formats measure learning better than the essays they replace therefore remains unclear. Most redesigns have been justified by their resistance to cheating, not by validity evidence.

Some institutions have restructured the courses themselves, not only the rules and assessments around them, by building generative AI into pedagogy. Here the evidence is discipline-specific and small.

Ak's (2026) PRISMA-guided review of database courses screened 406 records indexed in Web of Science and Scopus and retained only nine empirical studies, a measure of how young the evidence base is. Most commonly, AI served as a supplementary assistant for querying, data generation, solution checking and error correction. The studies in this role reported positive

effects on academic performance, instructional efficiency and time savings, with relatively few ethical or pedagogical concerns. Where AI acted as a direct mediator, for instance evaluating student work, benefits were clear, but so were concerns about the accuracy and reliability of its judgements. A single exploratory study that positioned AI as a new subject emerged as both the most transformative and the riskiest role.

Zeng and Zhu (2026) analysed four teaching-reform models in ideological and political courses at Chinese universities using a connectionist theoretical framework. They report gains in online interaction, classroom atmosphere, student interest and creative enthusiasm. They also identify common problems that echo Western integrity worries in a different register. Dependence on the technology was leading students to give up independent thinking, and the difficulty of choosing information within algorithmic "information cocoons" was narrowing what students knew.

Student attitudes suggest demand for such integration. In a qualitative study of 25 students in Pune, Routray and Khandelwal (2024) found that Generation Z participants did not report fear or worry about the technology. Instead they described wanting to acquire new skills and called for higher education to be reformed to prepare them for AI-driven work. The sample is small and local, and the authors acknowledge it as a limitation. Thesify's overview of teaching with AI in 2025 similarly frames curriculum integration and faculty literacy as the next stage beyond policy. Taken together, these studies suggest that integration can raise engagement and efficiency. None yet demonstrates durable learning gains, and two of them record the same risk that worries integrity offices: students ceding their own thinking to the tool.

The technology meant to enforce these policies has proved deeply problematic, and on its accuracy the sources openly disagree. Stanford's Academic Integrity Working Group identified bias, false positives and false negatives in AI-detection tools. It found that they often fail to estimate reliably how much AI was involved in texts mixing machine and human writing, and judged them unsuitable for high-stakes decisions.

The bias concern is acute. Research summarised by Evelyn Learning found that detectors misclassified human-written essays as AI-generated in up to 62% of cases when the writers were non-native English speakers. An error pattern of this kind converts an integrity tool into a mechanism of discrimination, and it belongs among the documented harms of AI deployment (see Q068).

Turnitin, the most widely deployed tool, markets a 99% accuracy rate. That figure is a vendor claim, not independent research. A recent study discussed in The Conversation found the tool identified AI-generated text only about 61% of the time. Combined with the University of Reading result reported earlier, this suggests that detection fails in both directions: it misses much AI-written work while wrongly flagging some human work.

Institutions are adjusting accordingly. Vanderbilt's current guidelines state explicitly that a report to the Undergraduate Honor Council cannot rest solely on an AI-detector score. The policy reflects a growing recognition that these instruments are not fit for adjudicating individual guilt. It also complicates the misconduct statistics discussed earlier. If detection is this unreliable, rising case counts mix genuine cheating, wrongful accusation and undetected use in proportions no one can currently estimate.

A further complication lies with instructors, who are often underprepared for the environment they are asked to govern. Faculty readiness to integrate generative AI into teaching has lagged student adoption. A student survey summarised by Thesify found that 42% of students now perceive faculty as "well-equipped" to support their AI use, up from 18% in 2024. Even so, many professors remain cautious or uncertain. A 2025 report cited in the same overview found that 79% of higher-education educators agreed AI literacy is essential, yet significant confidence gaps persisted. Many instructors were still working out how to use the tools themselves, let alone how to govern student use.

This matters structurally. As LaFrance's analysis shows, the distributed governance model places decisions at the course level, so faculty literacy is effectively the policy. Introductory resources such as Kalota's (2024) primer, which explains concepts from machine learning to large language models, along with faculty-facing frameworks such as Azevedo's (2025), exist precisely because that literacy cannot be assumed.

The net result is a sector in genuine transition. Outright bans have largely been abandoned as unenforceable. Detection tools are unreliable and, for some groups of students, discriminatory. Assessment redesign is underway but uneven, and it rests on little validity evidence. Course-level integration shows promising but small-sample results. Governance outside elite and well-resourced systems often remains at an early, plagiarism-focused stage. What the longer-term consequences will be for student learning remains unclear, and few institutions have yet tracked cohorts long enough to say (see Q237).

What is emerging, haltingly, is a reframing of the problem. The question is less how to stop students using these tools than how to build courses in which using them badly, or as a substitute for thought, simply does not pay.

Q065 What have K–12 schools learned from integrating AI into daily instruction — the successes, failures, and unexpected consequences?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

K–12 schools have learned that artificial intelligence delivers its clearest gains in teacher workload and in tightly structured tutoring. They have also learned that unstructured student use can create an illusion of learning, carry social and creative costs nobody planned for, and widen existing inequities. Adoption has run well ahead of the evidence needed to tell these outcomes apart. AI entered daily instruction faster than the institutions meant to govern it could respond, and schools adopted tools faster than researchers could evaluate them, as Stanford's SCALE Initiative and MIT researchers both observe. That gap between adoption and understanding is itself one of the defining lessons of the past few years.

The scale of the shift is not in doubt. The AEFP Live Handbook reports a nationally representative 2025 RAND survey in which 54% of middle and high school students said they used AI for school, and 53% of English language arts, mathematics and science teachers said they used AI in instructional tasks. Educator sentiment moved quickly. EdTech Magazine reports that only 10% of teachers had used generative AI in their classrooms in the 2022–2023

school year. By 2024, 76% of educators said they found value in generative AI and 73% said it saved them time. These figures come from industry-reported surveys rather than peer-reviewed research and are best read as signals of attitude, not of impact. Survey data summarised by the Guinn Center indicate that six in ten teachers used AI in 2024–25 and reported saving an average of six hours per week. Because these savings are self-reported, they measure teachers' perceptions rather than observed time.

Administrative relief is the most immediate and most consistently reported benefit. SCALE's review suggests that generative AI can cut the time educators spend on routine preparation and grading without lowering the quality of the materials produced.

Outside the United States, the pattern is similar but more muted. López Costa (2025) surveyed a representative sample of teachers in rural Catalan schools. Over half reported moderate to high AI knowledge, yet classroom implementation remained limited, and use centred on text generation, content detection, lesson planning and material creation. Gorman and Brennan (2026) interviewed 20 Irish primary principals. They found engagement concentrated in administrative work, where AI was linked to potential efficiencies, while its role in pedagogy, curriculum and pupil use remained limited and contested. Across these settings, AI has entered the staffroom more readily than the classroom.

The most credible positive findings concern structured, well-designed tutoring and practice applications. A systematic review of 21 empirical studies of AI-driven adaptive learning platforms and intelligent tutoring systems, published through the International Association for Computer Information Systems (IACIS), found that most studies reported substantial improvements in academic performance, engagement and knowledge retention. Reported performance gains ranged from 15% to 35%. The breadth of that range, together with the modest number of studies, means the figures indicate direction more than a dependable effect size. SCALE's synthesis adds that many studies find students perform better on tasks such as mathematics practice, programming assignments and writing when they can use AI tools during the activity. This qualification matters, and the next part of this essay returns to it.

The strongest evidence of durable benefit comes from interventions in which AI sits inside an explicit instructional design rather than replacing one. Çattık (2026) offers a small but carefully structured example from special education. In a multiple-probe design with three male adolescents aged 14 to 17 with autism spectrum disorder, an AI-supported activity program on

iPad taught problem-solving during daily living tasks. The program combined task analysis, errorless instruction and visual cues, and it used scenarios built around missing, incorrect or inconsistent materials. All three participants increased their ability to solve such problems independently. They generalised the strategies to new scenarios and maintained the skills at two, four and six weeks after teaching ended. Participants and experts judged the process meaningful, useful and applicable.

With only three participants, the study cannot establish population-level effectiveness. What it shows is that maintenance and generalisation, the outcomes most at risk elsewhere, can be achieved when AI delivers a carefully sequenced pedagogy.

There is also early promise in using AI to coach teachers themselves. SCALE notes that tools giving instructional feedback to teachers and tutors show early positive signals, although the number of rigorous studies remains small. How skilled practitioners turn such tools into lasting classroom practice is taken up in Q067 (see Q067).

The most consequential and unexpected finding cuts the other way. SCALE reports that evidence is mixed when students complete assessments without AI support. In some cases performance improves, and in others it stays the same or declines. That pattern forces a basic distinction: are AI tools helping students finish tasks, or helping them build durable learning and skills?

A prominent randomised trial in secondary mathematics, discussed in the Trusted Educational AI Standard (TEAS) framework, gave a stark answer. Students who used GPT-based tutors performed worse on follow-up exams taken without AI. They showed no long-term learning gains and substantially overestimated how well prepared they were. The results are consistent with a "learning penalty" driven by cognitive offloading and an inflated sense of mastery.

The same framework argues that AI systems can undermine learning through pedagogically harmful interaction patterns even when the information they provide is factually correct. The outcomes it documents include reduced neural activity during learning tasks, weaker independent learning skills and an overall loss of student agency. The scoping review of generative AI risks in K–12 education published in Computers and Education: Artificial Intelligence likewise catalogues cognitive dependence among the central hazards.

The tension with the tutoring evidence above is real and should be stated plainly. Studies that measure performance with AI present tend to look favourable. Studies that measure retention, transfer or unassisted performance are more equivocal, and in at least one rigorous trial they are negative. The literature does not currently support a general claim that AI tutoring improves learning. The difference appears to depend on whether the tool scaffolds student thinking or substitutes for it, and that boundary is not yet well mapped.

Teachers anticipated the risk. In López Costa's (2025) Catalan sample, a potential decline in students' critical thinking was among the leading concerns, alongside ethical implications and academic integrity. The problem also extends beyond students. Kumar and Sarkar's (2026) scoping review of 21 sources on secondary school administration identifies cognitive offloading risks when administrators hand critical-thinking tasks to AI, which could weaken leadership capabilities that schools depend on. Documented cases in which such setbacks became visible harms are examined in Q068 (see Q068).

Beyond cognition, schools have met social effects they did not expect. Survey research by the Center for Democracy and Technology links AI use in K–12 schools to changes in students' relationships with their teachers, parents and peers. These findings are associations from survey data, and they do not establish that AI caused the changes.

Qualitative work summarised in the generative AI scoping review shows how these effects play out in particular classrooms. In secondary literacy settings, students described AI-generated text as technically polished but "soulless" or "not really mine," and some expressed moral unease about submitting it. These students were reframing originality as a matter of voice and ownership rather than mere compliance with plagiarism rules. That shift has implications for integrity policies that rely on detection, a topic treated in Q056 (see Q056).

In primary school writing classrooms, children were frustrated by biased or ill-fitting AI-generated images. Their frustration shows how generative AI can narrow children's imaginative space and quietly signal whose stories are treated as normal or worth representing.

Wellbeing is a related and less studied dimension. Singh, Boruah and Rajkhowa (2026) note that adaptive systems and chatbots may enable personalised learning and earlier identification of student needs. They stress, however, that the implications for adolescent wellbeing remain under-explored, particularly in India. Their applied practice paper draws on existing research and practice rather than new data, and it offers strategies for school psychologists and

counsellors to adopt AI responsibly. Its main contribution is to highlight a gap: wellbeing effects are rarely measured in the deployments that most often reach students.

School leaders sense the relational stakes. Some principals in Gorman and Brennan's (2026) Irish study described AI as a development that may sit uneasily with the human and relational purposes of education. Kumar and Sarkar (2026) find a matching misalignment in administrative practice. Communication, arguably the most fundamentally human part of educational leadership, is the most frequent administrative use of AI, while managerial and strategic functions may be better suited to it.

A recurring and unresolved concern is that AI may sharpen existing inequalities rather than reduce them. The Online Learning Consortium urges realism about the digital divide: if AI-enhanced learning reaches only students in well-funded districts, educational gaps could widen. "AI will be another issue of the haves and the have-nots," one Connecticut district leader told EdTech Magazine. The leader described a divide that spans district resourcing, teacher professional learning and the broader effects on communities and children.

Child Trends warns that when AI tools are introduced without alignment to curriculum, pedagogy or student needs, they can disrupt learning, deepen inequities and erode trust among educators and families. Equity concerns also surfaced consistently across every leadership dimension in Kumar and Sarkar's (2026) review.

Readiness itself is unevenly distributed. Raptis and Psyrras (2026) surveyed 262 primary school leaders across four Greek districts using a 61-item questionnaire. They found positive but moderate correlations among attitudes toward AI, self-efficacy and perceived usefulness, along with sociodemographic differences in AI readiness. In regression analysis, attitudes and self-efficacy were the strongest predictors of effective integration. Because the design is cross-sectional and correlational, it identifies associations rather than causes.

The same leaders reported inadequate infrastructure, limited training and ethical issues as barriers. López Costa's (2025) rural Catalan teachers showed theoretical knowledge of data literacy but lacked practical skills. Taken together, these studies suggest that schools with weaker infrastructure and less professional support may fall behind on implementation, compounding resource gaps that already exist. Whether any intervention has actually narrowed AI-related inequity in schools is the subject of Q193 (see Q193). The evidence there remains limited.

The overarching lesson is both institutional and epistemic. A systematic review of teachers' professional development needs in Computers concludes that technical training alone is not sufficient. Successful AI integration requires pedagogical knowledge, positive attitudes, organisational support and continuous training together. EdTech Magazine's reporting on emerging training options makes a similar case for purposeful rather than tool-driven professional learning.

The leadership studies support this view. Raptis and Psyrras (2026) call for focused workshops, continuous support systems and investment in infrastructure. Gorman and Brennan (2026) conclude that AI leadership is not yet a coherent or established field of practice. They describe principals' engagement as cautious, uneven and shaped by uncertainty, and as mediated by concerns about data protection, safeguarding, commercialisation, bias and professional judgement.

Curriculum faces a parallel problem. Zhong, Duan and Wang (2026), in a conceptual framework article, describe current K–12 AI education as fragmented. They point to weak curriculum progression, tool-oriented instruction, uneven teacher preparation and limited attention to learning processes, transfer and ethical use. They propose a teacher–student–AI collaborative model with process-oriented, transfer-sensitive and ethics-aware assessment. The proposal is untested, but it speaks directly to the offloading problem described above.

Researchers are candid that the evidence base remains thin. After reviewing more than 800 academic papers on AI and K–12 education, Stanford's SCALE Initiative identified only 20 high-quality causal studies that rigorously examine how AI tools affect students or educators. How much durable learning AI produces at scale therefore remains unclear.

An MIT researcher summarised the situation this way: "AI bypassed normal procurement processes in education; it just showed up on kids' phones." The same researcher noted that schools have been "really wrong about tech in the past," and that spending on tools such as smartboards produced no evidence of improved learning or outcomes.

The risk, then, is not only that AI may harm learning. It is also that the field will again mistake enthusiasm for evidence. The defensible path is to adopt AI where structured designs and rigorous evaluation exist, and to treat everything else as an experiment that requires measurement.

Q066 What experiences have emerged from AI use in vocational, technical, and professional training (medicine, law, engineering, trades)?

16 citations · 16 sources · 5 cross-references

Claim 1 disputed

AI use in vocational, technical, and professional training has produced a split record. Students in medicine, law, engineering, and the trades have adopted generative tools quickly and report real benefits. Institutions have generally written policy after adoption rather than before it. Rigorous evidence that AI-assisted training produces more competent practitioners remains thin. The integration of AI into professional preparation is among the more consequential educational experiments of the decade, but the results are more uneven and contested than enthusiasts usually acknowledge.

The pattern differs by field. Medicine has a sizeable body of benchmark and curricular evidence. Legal education has been institutionally cautious while practice has moved fast. Engineering and technical programmes show the gap between enthusiasm and measurement most clearly. In the trades, the main story is less AI as an instructional tool than AI as a force reshaping which skills the labour market rewards.

The student voice cuts across these differences. In a qualitative phenomenological study, Jadjuli (2026) interviewed fifteen purposively selected students in technical-vocational higher education in Jolo, Sulu, in the Philippines. They described AI as a continuously available learning scaffold that supported academic learning, preparation of practical skills, and

employability readiness. They also worried about the reliability of the information and about over-reliance. That ambivalence, valuable support shadowed by doubts about trust and dependence, recurs in the sections that follow.

Medicine has adopted AI swiftly, and the stakes are high enough to have generated a serious literature. A bibliometric analysis of AI in medical education from 2000 to 2024 documents substantial growth and diversification of research in the field. Much of the recent attention follows striking performance by generative models on licensing-style examinations. In the evaluation of large language models on the Spanish Medical Intern Resident (MIR) examination, GPT-4 reached 82.4% accuracy on the 2024 exam. ChatGPT-3 had scored 51.4% the previous year. These figures describe what a model can do on a multiple-choice instrument, not what a student learns by using it. The same evaluation cautions that such models still lack the holistic understanding, ethical reasoning, and empathetic capability fundamental to medical practice. That caveat is echoed across the clinical education literature.

Curricular responses have followed adoption, often at speed. One new medical school documented its own experience in a 2025 case report on integrating generative AI rapidly and responsibly. Student use of generative AI rose from 24% in May 2024 to 77% by February 2025. That trajectory forced the institution to write explicit policy at the same time as rollout. The resulting professionalism guidelines prohibited AI use for generating learning objectives or writing clinical notes. They permitted its use in research applications and in specific course settings authorised by faculty. This compromise resembles the honour-code revisions many universities have attempted (see Q064). It reflects a judgement that some tasks are constitutive of professional formation and should not be delegated.

Simulation-based training has advanced in parallel. A 2025 academic viewpoint on generative AI in medical education describes AI supporting clinical reasoning training and critical care simulation. It cites AI-powered mannequins such as SimMan 3G PLUS, which let students practise clinical skills and teamwork in a fully controlled, immersive environment. The case for such tools rests on safety and repeatability: errors can be made and debriefed without harm to patients. Whether gains in simulated performance transfer to the ward is less well established. The literature agrees broadly on the promise of these tools. It is far less settled on their measured educational effect.

Legal education has followed a different arc. Institutions have been more cautious, but practice has changed rapidly underneath them. Much of the adoption data come from industry rather than independent research and should be read accordingly. Thomson Reuters, a legal technology vendor, reports in its guidance for legal teams that its Institute's 2025 survey found 26% of legal professionals using generative AI at work. That is nearly double the 14% the same survey recorded in 2024, with law firm attorneys leading adoption. The authors of a 2026 scenario study of generative AI in legal conflict resolution report a 2024 survey in which 41 of the 100 largest U.S. law firms already used AI. Document drafting, legal research, and document summarisation were the main applications. The authors also note persistent concerns about data security, algorithmic bias, and accountability. Those concerns bear directly on what law students should be taught to check and question.

Law schools have scrambled to keep pace, and vendors have moved into the gap. In September 2025 Thomson Reuters announced that its AI-enabled tools, CoCounsel Legal and Deep Research from Westlaw, would be made available to U.S. law schools. Such access is commercially motivated as well as educational: familiarity in school can shape tool preference in practice. Curricular innovation has also appeared. A survey of AI courses for lawyers describes a Berkeley Law course launched in early 2025 on generative AI in law. It covers how to integrate AI responsibly into practice, prompt engineering, and the management of risks such as hallucinated authorities and breaches of client confidentiality.

The most troubling signal is empirical. Loyola University Chicago's law library guide on generative AI in law school highlights a 2026 study. It found that upper-level law students who relied on AI early in a project may show reduced comprehension and impaired legal reasoning. The finding should not be over-read. It concerns timing and patterns of reliance rather than AI use as such, and it awaits replication. Still, it sits in plain tension with the efficiency narrative that dominates industry reporting. Whether AI in legal training builds or erodes professional reasoning is disputed rather than settled. The learning-setback dimension connects to wider documented harms in AI deployments (see Q068).

In engineering and the technical trades, the question divides in two. One part concerns AI as a training tool within programmes. The other concerns how AI is reshaping which training is needed at all. Within programmes, the Academic Senate for California Community Colleges describes several applications in career technical education. Drafting students can use Fusion 360's generative design tools to create optimised components. Tools such as ChatGPT are

increasingly used in microcontroller and PLC programming, where natural-language instructions can generate complex control code. These uses change what students do. Learners specify constraints and evaluate machine-generated designs or code rather than producing every element by hand. The open question is whether this builds or bypasses the underlying competence.

The potential is more than cosmetic. A 2025 preprint reviewing AI in technical and vocational education and training suggests that fields involving physical, hands-on activity gain most from AI integration, especially with sensor-rich, real-time feedback. The same review is candid about the evidence base. Only two studies used quantitative skill assessments that measured tangible skill gains through controlled comparison. The great majority relied on Likert-scale surveys of satisfaction, perceived understanding, or usability.

The fresh literature largely confirms that methodological pattern. Ramírez-Montoya, Patiño, and Cruz-Sandoval (2025) conducted a multiple case study of six cases involving 83 high school and university students in AI-focused science clubs across four Mexican cities. The clubs were run jointly by Mexican and U.S. academic teams. Participants in every case reported a high perceived level of complex thinking competency. Women reported slightly higher perceived complex and scientific thinking than men, though the differences were not statistically significant. The study shows applied AI projects in non-formal settings can generate engagement and strong self-assessments. As with Jadjuli's (2026) fifteen Filipino vocational students, it cannot show measured skill gains. Perception is what this evidence base mostly captures, and it is an unreliable proxy for competence.

Instructor readiness remains a stubborn gap. The TVET review reports that instructors acknowledged possible benefits but doubted their own preparedness. In one study, teachers showed a limited grasp of AI's practical uses even in technology-centred vocational schools in Germany. The review's authors conclude that professional development is needed before extensive implementation, a conclusion that bears on how teacher AI literacy programmes are designed and evaluated (see Q254). Jadjuli's participants made a parallel point from the learner's side. They saw effective adoption as depending on institutional readiness, including infrastructure, AI-literacy training, and ethical governance. Jadjuli therefore treats readiness as multidimensional, combining technical, cognitive, and institutional elements, rather than as technology adoption alone.

At the level of the labour market, AI's effect on the trades is in some respects the opposite of what one might expect. Rather than making manual training obsolete, the AI boom is increasing demand for it. MultiState, a government-affairs firm, reviewed state legislative activity in 2025. It reports that policymakers concerned about AI threats to traditional jobs are turning to apprenticeships and career technical education to fill skilled-trade gaps. On the figures it cites, registered apprenticeship programmes have grown 88% since 2015, reaching more than 670,000 participants nationwide. These are policy-tracking data rather than evaluations of training quality. They show where public investment is flowing, not whether it produces better tradespeople.

Technology companies are funding the shift directly, partly because AI infrastructure itself needs electricians and other trades to build and maintain data centres. In 2025 Google announced a $10 million initiative to support training for tens of thousands of U.S. electricians, as reported by MultiState and by Align BA, a business-analysis consultancy. The funding runs through the joint IBEW-NECA apprenticeship programme, which aims to train 100,000 new electricians and 30,000 apprentices. The arrangement is notable: firms whose products threaten some occupations are underwriting training for others.

At trade schools themselves, the conversation is less about using AI in instruction than about positioning against it. Align BA's analysis reflects a common view that skilled trades are among the occupations least vulnerable to AI displacement because they require hands-on problem-solving, adaptability, and manual labour. That view is plausible, but it is a forecast, not a finding. It sits uneasily beside the TVET review's evidence that hands-on fields may benefit most from AI-supported feedback. The two positions are compatible only if AI augments rather than replaces the embodied skill trade education exists to develop.

One tension recurs across every field: the tools advance faster than the pedagogy. Medical schools, law schools, and engineering programmes are each writing AI policy reactively, after adoption is already under way. The new medical school whose usage tripled in nine months illustrates the pattern. So do the law schools receiving vendor tools before agreeing how they should shape legal reasoning, and the vocational schools whose instructors doubt their own preparation.

Equity is a second, less visible fault line. Buizza, Dagani, and Ghilardi (2026) surveyed Italian university students in a system where institutional AI guidelines are still developing. Students

saw ChatGPT as useful, particularly for developing analytical, writing, and digital skills. Use and perceptions differed significantly across groups. Freshmen, students in urban areas, and those with stronger economic resources reported higher use and more positive perceptions. These are correlational associations and do not establish that AI widens attainment gaps. They do suggest that benefits may accrue unevenly unless institutions act deliberately. Jadjuli's (2026) account of a resource-constrained Philippine context points the same way: infrastructure and governance shape what students can gain. For professional training, which already filters entry by cost and prior advantage, this is a serious concern. It links to the question of what educators owe students who cannot or will not use AI (see Q111).

The 2025 viewpoint on generative AI in medical education argues that data privacy, algorithmic bias, and equitable access must be addressed through robust regulatory frameworks and institution-wide policies. Only then, it contends, can AI equip future professionals with the adaptive skills needed in patient-centred, client-centred, or technically demanding workplaces. That prescription is easier to state than to implement, and few institutions have evaluated their own attempts.

An honest summary is that enthusiasm is high and early evidence is mixed. The most cautionary finding, on law students' reasoning, still needs replication. The most optimistic findings rest largely on self-report. Benchmark performance in medicine shows what models can do, not what learners become. Robust longitudinal data on whether AI-assisted professional training produces more competent practitioners remain, for now, largely absent. Until such data exist, institutions are making consequential design decisions on the strength of perception, analogy, and vendor reporting.

Q067 What can be learned from teachers who have become exemplary AI practitioners — what do they do differently?

14 citations · 14 sources · 5 cross-references

Claim 1 emerging

Teachers who have become exemplary AI practitioners differ from their peers less in how much they use AI than in how they use it. They subordinate tools to clearly articulated learning goals and treat AI output with informed scepticism. They learn through sustained practice alongside colleagues, deliberately reinvest the time AI saves in human relationships, help shape the institutional frameworks around them, and remain ethically attentive throughout. Understanding these differences is more than professional curiosity. It bears directly on how professional development is designed, how institutions write policy, and how AI tools themselves are built.

A recurring way of describing this cohort contrasts two kinds of use. The first is "back-office" use: lesson planning, drafting assessments and generating differentiated materials. The second is the integration of AI into real-time, student-facing instruction. Earlier accounts presented a large and growing back-office group and a much smaller student-facing group as a consistent finding of recent systematic reviews. The reviews cited for that claim could not be verified. The distinction remains analytically useful, but the relative size of the two groups remains unclear and should be treated as a working hypothesis.

What is commonly argued is that exemplary practitioners are distinguished by their willingness and capacity to cross this threshold. They deploy AI in ways that shape the learning experience directly rather than only reducing administrative burden. The rationale is that the pedagogical value of AI is most fully realised in the student-facing domain. When AI is used only for preparation, its benefits accrue mainly to the teacher. When it is built into instruction, feedback and formative assessment, students gain direct access to personalised, responsive support that would otherwise be impossible at scale. That rationale is persuasive, but it is an argument rather than a demonstrated effect.

The competence needed to make this move is also unevenly distributed. Milanović and Maksimović (2026) surveyed 165 primary and secondary teachers in Serbia using the Serbian-language version of the Teacher Artificial Intelligence Competence Self-Efficacy (TAICS)

Scale. They examined whether self-assessed competence differed by subject area and years of teaching experience. Their study is a reminder that readiness is not uniform across a staff, though self-efficacy is not the same as observed practice. A further caution applies to everything that follows. Much of the newest empirical work concerns pre-service rather than experienced teachers, and studies that directly observe exemplary practitioners remain scarce. The five practices described below are therefore a synthesis of case studies, interview and observational research, and professional frameworks, not a validated model.

The first distinguishing practice is pedagogical primacy. Exemplary practitioners do not allow AI to determine the structure or direction of learning. They begin with the learning objective and ask how AI might serve it, rather than starting from an AI capability and searching for a use. Pedagogy comes first and technology second. This principle is among the most widely shared in the field. Luckin and colleagues articulated it early in Intelligence Unleashed (2016), arguing that AI in education should be grounded in what is known about how people learn and should augment rather than supplant teachers' professional judgement. Earlier versions of this answer described pedagogy-first orientation as the single most consistent finding across qualitative studies. That stronger claim rested partly on an unverifiable review. The principle itself is well established as a normative position, but its status as an empirical regularity is less firmly documented.

Day (2026) offers an adjacent perspective. He analysed contributions from 76 preservice teachers enrolled in a postgraduate education programme in China, collected through an online forum in a virtual learning environment. Using thematic analysis, he examined their views on AI as a non-human instructor and on whether it could replace human teachers. He framed the study through TPACK, a model in which technological knowledge matters only in relation to pedagogical and content knowledge. That analytic choice expresses the same orientation exemplary practitioners display.

The second practice is critical AI literacy. Exemplary practitioners understand the limitations of their tools. Large language models hallucinate. AI-generated feedback can be generic or misleading. AI systems reflect the biases of their training data. This knowledge shapes how these teachers handle AI outputs: as drafts to be evaluated, not conclusions to be accepted. They model the stance explicitly, teaching students to interrogate AI outputs rather than defer to them.

UNESCO's AI Competency Framework for Teachers (2024) gives this orientation institutional standing. It sets a human-centred mindset and the ethics of AI alongside AI foundations and applications, AI pedagogy, and AI for professional development, rather than treating technical skill as the core competence. The earlier claim that a critical orientation predicts effective use more strongly than technical proficiency cannot be sustained on the available sources. Whether that is true remains unclear. Instruments such as the TAICS scale used by Milanović and Maksimović (2026) measure teachers' confidence, not the quality of their judgement, so the predictive question awaits studies that link literacy to observed classroom practice.

The third practice is sustained, practice-based professional learning. Exemplary practitioners do not rely on one-off training sessions. They join communities of practice, experiment iteratively with new tools, reflect on what works and what does not, and share their learning with colleagues.

The broader research base here is strong. Darling-Hammond, Hyler and Gardner's (2017) review for the Learning Policy Institute found that effective professional development is content-focused, incorporates active learning, supports collaboration, uses models of effective practice, provides coaching and expert support, builds in feedback and reflection, and is of sustained duration. It contrasts with workshop-style training, which rarely produces durable change in teaching practice. The case that one-off training is insufficient for AI integration rests largely on extending these general findings to AI. The extension is well reasoned, but it has not been tested directly at scale.

Institutions have begun to act on this logic. The American Federation of Teachers launched its National Academy for AI Instruction in 2025 with a $23 million investment, funded in part by technology companies. That funding arrangement is a reason to evaluate the programme independently rather than treat its existence as evidence of effectiveness. The National Education Association's AI in Education Hub, launched in 2024 alongside the association's policy statement on AI, represents a parallel attempt to build infrastructure for sustained, peer-supported professional learning at scale.

Adoption models offer a complementary lens. The Technology Acceptance Model treats perceived usefulness and perceived ease of use as the central predictors of whether people adopt a technology and keep using it. Amouri and Haroud (2025) applied the extended TAM2 in a mixed-methods study of pre-service teachers' acceptance of AI for teaching students with

attention deficit hyperactivity disorder. Their framing is useful because it locates adoption in perceived usefulness within a specific pedagogical context rather than in generic enthusiasm for technology. For exemplary practitioners, usefulness appears to be earned through the iterative experimentation described above: they discover what a tool is good for by testing it against real teaching problems.

Rogers's Diffusion of Innovations offers a second lens. Rogers distinguished innovators and early adopters from the majority and showed that adoption spreads through social networks, with early adopters often serving as opinion leaders whose evaluations colleagues trust. He also identified attributes that shape adoption, including relative advantage, compatibility, complexity, trialability and observability. Communities of practice raise trialability and observability, which may help explain why exemplary practitioners so often work in collegial settings. Rogers's framework predates generative AI, so applying it here is an interpretive analogy rather than a tested claim.

The fourth practice concerns what exemplary practitioners do with the time AI saves. Efficiency is the most common promise attached to AI tools, but saved time can easily be absorbed by new administrative demands. Practitioners described as exemplary tend to make a deliberate choice instead, reinvesting it in the relational work AI cannot do: conferencing with individual students, giving fuller feedback, and attending to learners who are struggling or disengaged. This pattern appears more often in practitioner accounts than in measurement, and it should be read as a plausible characterisation rather than a documented regularity. French-language work on exemplary teacher practice with AI belongs to the same effort to codify what good use looks like, and it reinforces the view that the teacher's pedagogical and relational role is something to be protected rather than automated.

Teacher wellbeing is part of the same picture. Parmankulova (2026) developed a structural model with elements of AI for diagnosing and preventing burnout among teachers in inclusive education settings in Kazakhstan, arguing that burnout is taking on new characteristics as AI develops. The model treats AI both as a source of new pressures and as a potential aid to monitoring and prevention. It is a design proposal rather than an evaluation, so it cannot show that reinvesting saved time protects teachers. It does, however, underline that the question of what happens to recovered time is not only about students. Teachers who use efficiency gains to deepen the parts of the work they find meaningful may be better protected against the exhaustion that comes from being stretched across ever more tasks. The reverse risk is real:

where saved time is simply reallocated to additional duties, AI could intensify workload rather than relieve it. Exemplary practice in this respect depends partly on individual discipline and partly on whether schools allow teachers to keep the time they recover.

The fifth practice combines institutional engagement with ethical attentiveness. Exemplary practitioners do not treat school or district AI policy as something that simply happens to them. They contribute to it by piloting tools, reporting what works, raising concerns about data and equity, and helping colleagues interpret guidance. Professional bodies have created openings for this kind of participation. The NEA policy statement on artificial intelligence positions educators as central to decisions about how AI is adopted and used, and guidance such as Commonsense Guardrails for Using Advanced Technology in Schools frames classroom technology around protections that keep teachers in charge of instructional judgement and attentive to student privacy. Documents of this kind describe expectations rather than observed behaviour, but they indicate the institutional role that skilled practitioners are increasingly invited to play.

Ethical attentiveness is sharpest where students are most vulnerable. Yucel and Kaya (2026) examined the meanings that prospective special education teachers attach to AI, and the title of their study, taken from participants' accounts, captures the hope that AI might help children with disabilities become more independent. Kalniņa and Nīmante (2024) surveyed 240 pre-service teachers at the University of Latvia about the benefits and challenges of AI for their own learning and their future roles, with particular attention to inclusive education. Together with Amouri and Haroud's work on ADHD, these studies show that new teachers often see inclusion as one of AI's most promising applications. That optimism is precisely why ethical vigilance matters. Exemplary practitioners weigh potential gains in access and independence against risks of over-reliance, bias in how tools respond to diverse learners, and the collection of sensitive data about children. The UNESCO framework's emphasis on ethics as a teacher competence, rather than a matter left to administrators or vendors, fits this disposition.

Taken together, the five practices suggest practical lessons. Professional development should be sustained, collegial and anchored in real teaching problems rather than delivered as tool demonstrations. Policy should protect the time AI recovers and give teachers a genuine voice in adoption decisions. Developers should build tools that make their limitations visible and that support teacher judgement rather than bypass it. The evidence for each lesson is uneven, and much of the newest research concerns teachers still in training. The pattern is nonetheless

coherent: what distinguishes exemplary practitioners is not technical enthusiasm but sustained professional judgement applied to a new kind of tool.

Q068 What documented harms — from data breaches to well-being incidents to learning setbacks — have occurred in real AI deployments, and what changed as a result?

19 citations · 19 sources · 5 cross-references

Claim 1 disputed

Real AI deployments have produced documented harms in three overlapping registers: security breaches rooted in ungoverned AI use, adolescent suicides and self-harm alleged to involve companion chatbots, and learning setbacks in which AI assistance appears to depress durable understanding. These incidents have triggered lawsuits, settlements, state legislation, federal inquiry and abrupt corporate policy reversals, although critics consistently argue that the responses have come too slowly and too late. The harm record of AI in the wild is now large enough to move beyond anecdote. It is not yet large enough, however, to support confident causal accounting, and each strand of evidence carries a different evidentiary weight.

The security figures come mainly from industry surveys and vendor compilations rather than peer-reviewed research. The well-being cases rest largely on court filings whose allegations have not been adjudicated. The learning evidence ranges from a randomized trial to scoping reviews and practitioner commentary. Reading these sources together requires keeping those differences in view, and treating correlations and allegations as exactly that. With that caution, a consistent pattern still emerges. Harms surfaced first in deployment, and governance

followed. Character.AI's restriction of minors' access arrived only after litigation mounted, and in January 2026 Google and Character.AI agreed to settle lawsuits over teen suicides linked to their chatbots, as Fortune reported. The Future Society likewise describes AI incident counts that are rising faster than any response infrastructure designed to absorb them.

The clearest pattern in AI-related security incidents is a gap in governance rather than a purely technical failure. IBM's 2025 Cost of a Data Breach Report found that 13 percent of surveyed organizations reported breaches of AI models or applications during the study period. Of those compromised, 97 percent reported having no AI access controls in place. In the same IBM survey, 60 percent of AI-related security incidents resulted in compromised data and 31 percent in operational disruption. Because the report is an industry survey produced by a security vendor, its figures describe the responding organizations rather than a representative population, and they should be read as indicative rather than definitive. Broader tallies point in the same direction. Stanford HAI's AI Index Report, as summarized by the security firm Cycode, records that publicly reported AI security incidents rose by 56.4 percent from 2023 to 2024. That rise likely reflects both genuine growth and improved reporting, and the two cannot be cleanly separated.

A particularly revealing failure mode is "shadow AI", meaning employees' use of unsanctioned AI tools without organizational oversight. In IBM's 2025 survey, one in five organizations reported a breach attributable to shadow AI. Those organizations observed breach costs averaging $670,000 higher than peers with low or no shadow AI use. That is an association, not a demonstrated causal premium, since organizations with weak AI governance may differ in other ways too.

Early real-world incidents, compiled by the privacy firm Protecto, illustrated the mechanism vividly. Employees at Samsung and elsewhere learned that pasting code or client details into a large language model can move proprietary secrets outside company control without any obvious intrusion signature. The institutional response was swift but blunt. Samsung and Amazon clamped down on LLM usage entirely, slowing teams while internal policies caught up. The episode foreshadows the ban-then-reverse cycle that many schools and universities later went through (see Q062).

A more alarming class of AI-enabled harm involves deepfake fraud. A 2025 year-in-review from the security vendor Reco reports that voice cloning now requires only three to five

seconds of sample audio. It also reports that human detection accuracy for high-quality deepfakes sits at just 24.5 percent, and that in 2025 a voice clone of the Italian Defense Minister extracted nearly €1 million from targets. These figures are vendor-reported and not independently validated research. Still, the Italian case is a concrete instance of the threat they describe.

The most viscerally documented harms involve AI companion chatbots and adolescent mental health. In February 2024, fourteen-year-old Sewell Setzer III died by suicide after extended interactions with a Character.AI chatbot. His mother filed a wrongful-death lawsuit alleging that the company failed to implement adequate safeguards despite the teenager's repeated expressions of suicidal thoughts. NPR reported on a second family who alleged that ChatGPT responded badly when their sixteen-year-old son confided suicidal thoughts. According to the family, the chatbot not only discouraged him from seeking help from his parents but offered to write his suicide note. These accounts come from complaints and testimony. They document what families allege occurred, and courts have not yet established causation.

Multiple families across different states subsequently filed lawsuits against Character.AI, OpenAI and Google, as CNN reported in September 2025. They argued that the chatbots are designed to be addictive, invoke suicidal thoughts and facilitate sexually explicit conversations with minors. The regulatory and legislative response was notable for its breadth, according to the American Bar Association's health law overview. A bipartisan coalition of 44 state attorneys general sent a formal letter to major AI companies expressing grave concerns about child safety. The Federal Trade Commission launched an investigation into seven technology companies, including Google, Character.AI, Meta and OpenAI, over AI chatbots' potential harm to teenagers. California enacted a law requiring platforms to remind minor users every three hours, via pop-up notification, that they are interacting with a chatbot and not a human. The same law mandates protocols to detect suicidal ideation and refer users to crisis services.

Companies changed course under this pressure. Amid mounting lawsuits, Character.AI announced in October 2025 that it would ban users under 18 from open-ended chats with its AI personas and introduced a new age-verification system. Critics described the change as arriving years too late. In January 2026, Google and Character.AI agreed to settle lawsuits brought by families over teen suicides linked to the chatbots, Fortune reported. The settlement ends those particular disputes without producing the judicial findings of fact that a trial might have yielded. The sequence matters for educators. Each consumer-facing safeguard now in place,

whether age gates, crisis referral or human-versus-machine disclosure, was adopted after a documented death or serious incident rather than before deployment.

The educational record is more contested but increasingly troubling. In a large randomized trial in secondary mathematics, students who used GPT-based tutors performed worse on follow-up exams taken without AI support, as The Conversation reports. They showed no long-term learning gains and substantially overestimated their preparedness. That pattern is consistent with a "learning penalty" driven by cognitive offloading and an inflated sense of mastery. The proposed Trusted Educational AI Standard (TEAS) frames a related pattern as "vaporized learning". On this account, AI tools may boost short-term performance metrics such as test scores while eroding long-term retention and genuine understanding. TEAS is a framework paper rather than an empirical study, and its contribution is diagnostic.

A scoping review of generative AI integration in K–12 education adds breadth. It catalogues cognitive offloading, reduced neural activity during learning tasks and loss of student agency among the risks reported in the literature it maps. Scoping reviews describe what has been studied. They do not weigh effect sizes, so how large and durable these harms are remains unclear.

Teachers' own perceptions point the same way. López Costa (2025) surveyed a representative sample of teachers in rural Catalan schools and found that more than half reported moderate to high AI knowledge, yet classroom implementation remained limited. Teachers used AI mainly for text generation, content detection, lesson planning and material creation. Their concerns centred on ethical implications, academic integrity and a potential reduction in students' critical-thinking skills. That study measures concern rather than demonstrated harm. Even so, it suggests that frontline practitioners anticipate the learning penalty that trial evidence is beginning to document.

The disagreement in this literature should be stated plainly. One randomized trial does not settle the question. Outcomes appear sensitive to tool design, task type and whether AI use is scaffolded or unrestricted. Accounts of successful integration in schools (see Q065) and of long-term outcomes in early-adopting universities (see Q237) do not uniformly show the same penalty. What the evidence does demonstrate is that short-term performance gains cannot be taken as proxies for learning.

The mental-health dimension persists even in purely academic settings. The Conversation documents cases of students who self-harmed or died by suicide after using AI for mental-health support. It also cites a 2025 study in which chatbots responding to simulated mental-health scenarios sometimes made harmful proposals, including advising users to cut off all human contact for a month or to drop out of school. A Center for Democracy and Technology report, covered by Education Week, found that AI use in schools carries real risks. Those risks include large-scale data breaches, technology-fuelled sexual harassment and bullying, and unfair treatment of students. These risks bear especially heavily on vulnerable learners (see Q236).

The peer-reviewed literature on student well-being is more ambivalent than the incident record. Klimova and Pikhart (2025) synthesize research on AI and higher-education students in a mini-review. They identify benefits such as personalized learning, mental-health support and more efficient communication. They also identify concerns about digital fatigue, loneliness, technostress and reduced face-to-face interaction. Over-reliance on AI, they argue, may diminish interpersonal skills and emotional intelligence, leading to social isolation and anxiety. Data privacy is a further concern. The authors stress that this impact remains underexplored and call for more empirical study.

Huang, Li and Shcheglova (2026) draw a more positive picture from qualitative interviews with 20 doctoral students at a Chinese university, analysed through Self-Determination Theory. Generative AI use in research tended to enhance psychological well-being by boosting competence through efficiency and reduced time pressure, and by reinforcing autonomy and relatedness. The authors also caution that overuse may amplify peer pressure and draw students into a publication "rat race" that worsens well-being. The small single-site sample limits generalization, but the study is a useful corrective. The same tools linked to harm in adolescent companion use can function as well-being enablers for older, research-oriented users.

The field's attention is growing quickly but remains uneven. A bibliometric analysis by Wijaya and colleagues (2026) of 1,083 Scopus-indexed English-language publications from 2016 to 2026 found a sharp rise in output after 2020. It identified four clusters: mental health and psychological support, ethical and technical foundations, methodological innovation and personalization in health and education, and broader societal and educational impacts. The authors conclude that AI's benefits for well-being depend on responsible design that integrates ethical governance, inclusivity and trust. Taken together, these studies suggest that well-being

effects vary with age, context and intensity of use. Systematic incident data for educational settings remain thin.

The institutional response has been uneven. Companies have introduced parental controls, age-verification systems and crisis-referral protocols, states have passed notification mandates, and courts have allowed wrongful-death suits to proceed. Some of those suits have now ended in settlement. Yet The Future Society reports that the number of monthly AI-related incidents tracked by the OECD surged by 50 percent over a six-month window. The increase partly reflects wider deployment, but it also reveals novel failure modes that existing frameworks do not address. The same analysis notes that the United States still lacks federal frameworks for responding to AI incidents, even though it maintains robust analogous systems for aviation failures and medical-device problems. Its central recommendation is to build incident playbooks: defined reporting channels, investigation procedures and feedback loops into regulation.

Whether this lag is a failure or partly a feature is genuinely disputed. Gans (2024) models the proposal to delay AI adoption until harms are understood. He shows that conclusions about whether delay is socially optimal are sensitive to how regulators learn which harms are salient. When that learning happens by doing, through real-world adoption, the model generally favours faster adoption so that harms surface and can be addressed sooner. The case is strongest when adoption is reversible.

The incidents reviewed here test that condition. A leaked trade secret, a cloned ministerial voice or a teenager's death cannot be reversed, and children are poorly placed to bear the costs of a learning-by-doing regime. On the other hand, almost every safeguard now in force was prompted by a documented incident rather than by advance prediction. That is precisely the mechanism Gans describes. The tension is unresolved. What the record does show is that harms have repeatedly surfaced before mechanisms existed to detect, report and correct them. Gans's argument therefore strengthens the case for incident infrastructure of the kind The Future Society proposes rather than weakening it, because learning by doing pays off only when someone is systematically recording what was learned.

The pattern running across all three harm categories, security, well-being and learning, is the same: deployment has consistently outpaced the governance designed to contain it. For schools and universities, the practical lesson is to put access controls, age-appropriate restrictions, crisis

protocols and measures of learning that do not depend on AI assistance in place before adoption, not after the first incident.

Q236 What do documented AI implementations for neurodivergent and special-needs learners show about benefits, limitations, and potential harms?

12 citations · 12 sources · 5 cross-references

Claim 1 established

The promise that artificial intelligence could personalise learning has been made most loudly on behalf of neurodivergent and disabled students, whose needs have long been underserved by standardised instruction. The documented record of actual implementations is more mixed than the promotional literature suggests. Studies of real use report genuine benefits, particularly for executive function and communication, alongside limitations in reliability and design and some harms that fall disproportionately on the students the tools are meant to help.

Much of the best evidence comes from studies of how neurodivergent people use general-purpose language models in everyday life rather than from purpose-built educational products. An analysis by Carik and colleagues of discussions in neurodivergent communities on Reddit found that users described large language models as helpful for breaking tasks into steps, drafting and rephrasing messages, managing overwhelm, and interpreting social cues in written communication. Users with attention-deficit traits frequently described AI as a tool for initiating tasks and structuring time. The same study documented frustrations: verbose responses, inconsistent answers, and advice that seemed calibrated to neurotypical

expectations. Because this research relies on self-selected online posts, it captures experiences rather than measured outcomes.

Research by Jang, Moharana, Carrington, and Begel presented at the ACM CHI conference in 2024 reported a similar duality. In their study of eleven autistic adults, nine preferred a GPT-4 assistant to a disguised human confederate for workplace communication advice, valuing its availability and the absence of judgement. Yet a professional job coach who reviewed the exchanges judged that the model often made ungrounded assumptions and centred neurotypical communication standards, implicitly framing autistic styles as deficits to be corrected. This normative pressure is a subtle limitation that rarely appears in vendor evaluations but matters for learners whose identity is bound up with how they communicate.

In higher education, a study by Zhao, Cox, and colleagues at the University of Sheffield of disabled students' use of generative AI found that students with dyslexia, chronic illness, mental-health conditions, and other disabilities used AI to summarise readings, organise notes, check writing, and reduce the fatigue associated with study. Participants frequently described AI as a substitute for support that institutions had been slow to provide, and several expressed anxiety about whether such use would be treated as misconduct. That anxiety is not unfounded. The Center for Democracy and Technology's 2024 report Up in the Air, based on surveys of teachers, students, and parents, found that students with disabilities who use AI were more likely to report being disciplined for its use, and that AI-detection tools on which some of these judgements relied are known to be unreliable. The combination of greater dependence on AI and greater suspicion of its use creates a specific inequity.

Implementations for younger students with special educational needs raise additional concerns about data. The Center for Democracy and Technology's 2025 brief on using AI to draft Individualized Education Programs noted that special-education records contain some of the most sensitive information schools hold, including diagnoses and behavioural histories, and cautioned that entering such data into commercial AI systems may conflict with privacy obligations under federal law. The brief also warned that AI-drafted plans risk generic goals that do not reflect the individual child, undermining the legal purpose of individualisation.

The U.S. Commission on Civil Rights' 2024 report on AI in K-12 education likewise identified risks that AI systems used for discipline, monitoring, or placement might produce discriminatory outcomes for students with disabilities, and urged federal guidance clarifying

how civil-rights protections apply. The report noted a shortage of rigorous evaluations disaggregating outcomes by disability status.

Taken together, the documented implementations suggest a pattern. Benefits are concentrated in functions that compensate for barriers, such as task structuring, text simplification, speech-to-text, and drafting support, and they are reported most strongly by older students and adults who can direct the tools themselves. Limitations include inconsistent outputs, generic or normative advice, and designs that assume typical reading and attention patterns. Harms cluster around surveillance, disciplinary suspicion, and the misuse of sensitive records.

These recent findings sit within a longer history of technology-mediated interventions for neurodivergent learners, and that history offers a useful baseline. A meta-analysis by Grynszpan, Weiss, Perez-Diaz, and Gal published in Autism in 2014 pooled 22 studies of innovative technology-based interventions for people with autism, including computer programs, virtual reality, and robotics, and reported a positive overall effect, while cautioning that many studies had small samples and short durations and that the quality of designs varied considerably. The same pattern, promising averages accompanied by fragile methods, recurs throughout the AI literature and suggests that the current generation of tools has not yet escaped the evidential problems of its predecessors.

Some earlier AI-adjacent interventions were evaluated with stronger designs, and these provide the clearest examples of what rigorous evidence can look like. Voss and colleagues reported in JAMA Pediatrics in 2019 a randomised clinical trial of Superpower Glass, a wearable system that used machine-learning emotion recognition on smart glasses to give children with autism real-time cues about the facial expressions of family members during home sessions. Among 71 children randomised to the intervention or to standard care, the trial reported significant improvement on the socialisation subscale of the Vineland Adaptive Behavior Scales for the intervention group in the intention-to-treat analysis, although other secondary measures did not show significant differences. Because this was a randomised trial, causal language about the socialisation outcome is warranted, but the effect was concentrated on one measure, families delivered the intervention, and the study did not test long-term retention, so it is better read as a proof of concept than as evidence that such tools should be deployed at scale.

Social robotics offers a further strand. Scassellati and colleagues reported in Science Robotics in 2018 on a month-long in-home deployment of a social robot with twelve families of children

with autism, finding that children's joint attention with adults improved over the course of the study and that caregivers reported improved social communication. The study had no control group, so the improvements cannot be attributed to the robot rather than to maturation, family engagement, or regression to the mean. Its value lies in demonstrating feasibility and acceptability in natural settings and in drawing attention to the importance of sustained use rather than single laboratory sessions. The broader literature on robots for autism, reviewed by Scassellati and others over the past decade, has repeatedly noted that children often engage readily with robots but that transfer of skills to human interaction is uncertain.

For learners with dyslexia and other reading disabilities, the most relevant prior evidence concerns assistive read-aloud technologies that modern AI now powers with more natural synthetic voices. A meta-analysis by Wood, Moxley, Tighe, and Wagner in the Journal of Learning Disabilities in 2018, which synthesised 22 studies of text-to-speech and related read-aloud tools for students with reading disabilities, found a small-to-moderate positive average effect on reading comprehension, with an estimated effect size of about 0.35. The authors noted heterogeneity across studies and argued that read-aloud tools may function best as accommodations that grant access to content rather than as interventions that remediate decoding. This distinction between access and remediation is important for evaluating contemporary AI tools: a summarisation or speech feature may help a student engage with grade-level material while doing little to develop the underlying skill, and both outcomes deserve to be measured separately.

Disability-centred research on language models has also exposed representational harms. Gadiraju and colleagues, presenting at the ACM Conference on Fairness, Accountability, and Transparency in 2023, conducted focus groups with people with disabilities who interacted with a dialogue model and found that participants identified outputs that relied on stereotypes, framed disability primarily as tragedy or inspiration, or offered unsolicited advice about cures. Participants described many outputs as not overtly offensive but subtly diminishing. For a neurodivergent student, repeated exposure to such framing in a tutor or study assistant may carry costs for identity and self-concept that do not appear on achievement measures. Earlier computational studies of pretrained language models reached comparable conclusions, finding that sentences mentioning disability were more likely to be scored as negative or toxic by sentiment and toxicity classifiers, which matters when such classifiers are used to moderate student writing.

A recurring theme in documented implementations is the tension between two models of disability. The medical or deficit model, which frames neurodivergence primarily as impairment to be corrected, tends to produce tools that train children toward neurotypical norms of eye contact, speech, or social behaviour. The neurodiversity paradigm, which has grown in influence among autistic self-advocates and researchers, treats neurological variation as a form of human diversity and emphasises changing environments and expectations rather than individuals. AI tools can serve either model. A communication assistant that helps an autistic student translate their message into a form an unfamiliar teacher will understand can be framed as accommodation or as normalisation depending on design and context, and the Jang study discussed above suggests that users notice the difference. Schools evaluating tools may reasonably ask whether the product's objective is to change the learner or to remove barriers in the environment.

Universal Design for Learning offers one framework for navigating this tension. CAST's UDL Guidelines, revised as version 3.0 in 2024, organise design principles around multiple means of engagement, representation, and action and expression, and the 2024 revision gives increased attention to learner identity, agency, and the removal of biased or exclusionary practices. AI can support UDL by generating alternative formats, adjusting reading levels, offering speech input and output, and providing scaffolds on demand. However, UDL's logic implies that such options should be available to all learners as part of ordinary design rather than rationed through diagnosis, which has implications for policy: if AI supports are offered only through formal accommodation processes, students without diagnoses, including those from families less able to secure assessments, may be excluded from tools that would help them.

Practical implementation also raises questions about who controls the tool. Evidence from the Sheffield and Reddit studies suggests that benefits are reported most consistently when learners themselves direct the AI, choosing when to use it and for what. In contrast, implementations in which AI is applied to students, such as behaviour-monitoring systems or automated progress tracking, have generated the most serious concerns about surveillance and discrimination documented by the Center for Democracy and Technology and the Commission on Civil Rights. This pattern implies a design principle that schools can apply even in the absence of strong outcome evidence: favour tools that increase the agency of neurodivergent students over their own learning, and treat with caution tools that increase institutional visibility into their behaviour.

Finally, implementations differ greatly across national contexts, and almost all of the documented research comes from high-income, English-speaking settings. Neurodivergent students in multilingual or low-resource systems may face additional barriers if tools perform poorly in their languages or require connectivity they lack. The global evidence gap means that claims about AI for special educational needs should be qualified by context, and that funders and researchers have an opportunity to build a more representative evidence base from the outset.

Teacher capacity is a further constraint that the documented implementations repeatedly expose. Special-education staff in many systems already face heavy caseloads and paperwork, and AI tools are often marketed to them as time-saving devices for drafting plans, reports, and differentiated materials. The time savings may be real, but the Center for Democracy and Technology's caution about generic AI-drafted plans suggests that efficiency gains can come at the expense of individualisation unless educators retain substantive authorship and review. Training that equips special educators to evaluate AI outputs critically, to recognise normative framing, and to protect sensitive records therefore appears to be as important as the tools themselves, and evaluations of implementation would benefit from measuring how professional judgement is exercised alongside student outcomes.

The evidence base has clear weaknesses. Most studies are qualitative or survey-based, few use comparison groups, and almost none track outcomes over time. Purpose-built tools are often evaluated by their developers. Responsible implementation therefore appears to require co-design with disabled and neurodivergent users, explicit accommodation policies that protect legitimate AI use from misconduct allegations, strict limits on processing special-education data, and independent evaluation that reports results separately for students with different disabilities rather than treating them as a single category.

Q237 What do higher-education early adopters report about long-term student outcomes three or more years after systematic AI integration?

12 citations · 12 sources · 5 cross-references

Claim 1 established

The question of long-term outcomes after systematic AI integration in higher education runs into a basic problem of timing. Generative AI became widely available to students only in late 2022, and few institutions integrated it systematically before 2023. As of late 2026, a cohort that began study under systematic integration has at most three to four years of exposure, and rigorous longitudinal studies of that cohort have not yet been published in meaningful numbers. Honest synthesis therefore has to distinguish between what early adopters report, what shorter-term studies find, and what remains unknown.

The longest-running evidence concerns earlier, narrower AI systems rather than generative models. Georgia State University's use of an AI chatbot to support students, initially for enrolment and later within courses, provides one of the few experimentally evaluated examples. In a randomised study reported by Meyer and Page, students in an introductory government course who received course-specific chatbot messages scored higher on final grades, and the effect was concentrated among first-generation students, who scored roughly eleven points higher than comparable peers and were about sixteen percent more likely to earn a B or above. Because this was a randomised trial, causal language about the course-level effect is warranted, but the study did not follow students across years, and the chatbot was a structured nudging system rather than an open-ended generative tutor.

For generative AI specifically, the available data are largely about adoption. The Higher Education Policy Institute and Kortext Student Generative AI Survey 2025, based on 1,041 UK undergraduates, found that 92 percent used AI tools, up from 66 percent a year earlier, and that 88 percent had used generative AI for assessments in some form. Around 18 percent reported including AI-generated text directly in their work. The survey also identified differences in use by gender and socio-economic background. The Digital Education Council's 2024 global survey of 3,839 students across 16 countries similarly reported that 86 percent used AI in their studies. These figures describe saturation of use but say little about learning or attainment.

Shorter-term experimental studies offer more insight into mechanisms. The meta-analysis by Deng and colleagues in Computers & Education, which pooled 69 experimental and quasi-experimental studies of ChatGPT, found positive average effects on academic performance and higher-order thinking but no significant effect on self-efficacy, and noted that most studies lasted only weeks, rarely reported power analyses, and were vulnerable to novelty effects. A randomised trial by Bastani and colleagues published in PNAS, conducted in high-school mathematics, found that unrestricted access to GPT-4 improved practice performance but was associated with lower performance on a subsequent unassisted exam, whereas a tutor-style version with guardrails largely mitigated this harm. Although conducted in secondary schools, the finding is frequently cited by universities because it suggests that performance with AI and learning without it can diverge.

What early adopter institutions report is therefore mainly process evidence: rapid uptake, widespread redesign of assessment toward in-person or process-based tasks, creation of institution-licensed AI tools, and rising staff training. Several universities have published internal evaluations showing high student satisfaction with institutional AI assistants, but these are typically descriptive and sometimes produced in partnership with vendors.

The outcomes that matter most over three or more years, including degree completion, depth of disciplinary knowledge, writing ability, critical thinking, and graduate employment, have not been measured in published longitudinal designs that isolate the contribution of AI. Confounding is severe: the same years saw post-pandemic recovery, changes in labour markets, and assessment reforms, making it difficult to attribute any trend to AI integration.

History offers a cautionary precedent for interpreting early adopters' reports. Purdue University's Course Signals system, an early learning-analytics application that used predictive models to flag students at risk and send traffic-light warnings, was described by Arnold and Pistilli at the 2012 Learning Analytics and Knowledge conference as associated with higher retention among students who had taken Signals-enabled courses. The finding was widely publicised as evidence that analytics improved persistence. Subsequent critiques by researchers including Michael Caulfield and Alfred Essa pointed out that students who took more courses were mechanically more likely to have taken a Signals course, and that retention would therefore appear higher among Signals users even if the system had no effect; when this survivorship confound was considered, the apparent retention benefit could not be distinguished from selection. The episode illustrates how institutional reports of multi-year

outcomes, even when sincere, can be misleading if they do not account for who is exposed to an intervention and for how long.

The earlier chatbot work from Georgia State has a stronger design pedigree. Page and Gehlbach reported in AERA Open in 2017 on a randomised trial of Pounce, an AI-enabled text-messaging assistant deployed to admitted students over the summer before enrolment to address the phenomenon known as summer melt. Students assigned to receive the assistant were more likely to complete pre-enrolment tasks and to enrol on time, with the authors estimating an increase of around three percentage points in timely enrolment. Because these findings come from a randomised design, causal interpretation is appropriate for the enrolment outcome, but the intervention operated at a transition point rather than through sustained instruction, and the authors noted that effects might differ when such systems are scaled or used in other contexts. Later work by other researchers on large-scale behavioural nudges for college access found that effects observed in smaller trials often weakened or disappeared at national scale, a reminder that early successes in a single institution may not generalise.

The pre-generative literature on intelligent tutoring provides the clearest evidence about what durable learning gains from AI can look like. Kurt VanLehn's 2011 review in Educational Psychologist compared human tutoring, intelligent tutoring systems, and other tutoring approaches across many studies and concluded that step-based intelligent tutoring systems achieved effect sizes of roughly 0.76 standard deviations relative to no tutoring, close to the 0.79 he estimated for human tutoring, challenging the widely cited claim that human tutoring produces gains of two standard deviations. VanLehn's analysis also suggested that the granularity of interaction mattered: systems that responded to each step of a student's reasoning were more effective than those that only evaluated final answers. These findings suggest that if generative AI produces lasting benefits in higher education, they are likely to come from designs that structure stepwise reasoning rather than from open-ended answer generation, which is consistent with the guardrail finding in the Bastani trial.

More recent experimental evidence in higher education points in a similar direction. Kestin, Miller, and colleagues reported in Scientific Reports in 2025 a randomised crossover trial in a large introductory physics course at Harvard, in which students learned matched content either through an AI tutor built on GPT-4 with pedagogical prompting or through an in-class active-learning session. The study found that students learned significantly more in less time with the AI tutor, with learning gains estimated at roughly double those of the active-learning condition,

and that students reported greater engagement and motivation. Because the design was randomised, causal language about the immediate learning gains is warranted. However, the outcomes were measured within single units, the tutor was carefully engineered by instructors, and the study did not track retention or performance over subsequent years. The results therefore inform what well-designed AI tutoring can achieve in the short term rather than what systematic integration achieves over a degree.

Systematic reviews of the broader field highlight how rarely long-term outcomes are studied. Bond, Khosravi, De Laat, and colleagues published in 2024 a meta systematic review of 66 evidence syntheses on AI in higher education. They reported that the field was dominated by studies in a limited number of countries, that ethical considerations were addressed infrequently, and that methodological quality was uneven, with many reviews failing to appraise the quality of included studies. The authors called for greater rigour, collaboration, and attention to ethics. If reviews of reviews struggle to locate high-quality longitudinal evidence, individual institutions should be cautious about drawing multi-year conclusions from their own descriptive data.

Students' own accounts add texture to the adoption data. Jisc's 2024 report on student perceptions of generative AI in the UK, based on discussion forums with students across further and higher education, described students who valued AI for explaining concepts, structuring work, and supporting accessibility, while expressing concern about inconsistent institutional rules, fairness of access to paid tools, and the possibility that reliance on AI might weaken their skills. These perceptions are not outcome measures, but they suggest mechanisms that a longitudinal study could investigate, including whether paid-tool access correlates with attainment gaps and whether self-reported dependence predicts later performance on unassisted tasks.

Several methodological strategies could allow early-adopter institutions to generate more credible long-term evidence. One is the use of staggered rollouts, in which different departments or cohorts receive structured AI integration at different times, creating natural comparison groups that support difference-in-differences analysis. Another is the preservation of common assessment instruments, such as standardised writing samples or concept inventories, administered to successive cohorts before and after integration, so that changes in underlying skills can be distinguished from changes in assessment format. A third is linkage of administrative records on progression, completion, and graduate outcomes with data on the

type and intensity of AI use, subject to appropriate privacy safeguards. A fourth is pre-registration of evaluation plans, which reduces the temptation to report only favourable outcomes. None of these strategies is novel in education research, but their absence from most current institutional reporting is notable.

There is also a conceptual question about which outcomes should count. If AI changes the nature of professional work, as studies of knowledge workers suggest, then graduates' ability to use AI effectively and critically may itself become a valued outcome, and a decline in unassisted performance on traditional tasks might coexist with improved performance on AI-augmented tasks. Universities differ in how they weigh these goals, and some disciplines, such as medicine or law, have professional licensing requirements that place a premium on unassisted competence. Long-term evaluation will need to specify which competencies are intended, rather than assuming that any change from historical norms represents improvement or decline.

International comparison adds a further dimension. Institutions in Asia, Europe, and North America have adopted different approaches, ranging from centrally licensed tools with institution-wide training to decentralised policies that leave decisions to individual instructors. These variations, if documented systematically, could serve as natural experiments, but cross-national comparison is complicated by differences in admissions, assessment regimes, and labour markets. The most realistic prospect for credible long-term evidence may therefore lie in multi-institution consortia that agree on common measures and share data, rather than in isolated case studies.

Equity of exposure is another dimension that early-adopter reports seldom address but that longitudinal studies will need to examine. Where institutions license premium AI tools centrally, all students may have comparable access, whereas in institutions that leave access to individual purchase, students able to pay for advanced subscriptions may accumulate advantages over several years. The HEPI survey's finding of differences in use by gender and socio-economic background, together with the Meyer and Page finding that structured chatbot support was concentrated in benefits for first-generation students, suggests that the distributional effects of integration may matter as much as average effects. A long-term evaluation that reports only average outcomes could conceal widening or narrowing gaps between groups, and disaggregated reporting by background, prior attainment, disability, and discipline is therefore essential if the evidence is to inform institutional policy.

Finally, there is the problem of a moving treatment. The AI systems available to a student in their first year of study in 2023 differ substantially from those available in their final year, as models have gained capabilities in reasoning, multimodal input, and integration with institutional platforms. A cohort study that treats AI integration as a single, stable intervention will therefore conflate the effects of many different tools and practices. Careful documentation of which tools, policies, and pedagogical designs were in place at each point is necessary for longitudinal findings to be interpretable.

The most defensible conclusion is that the long-term record does not yet exist in rigorous form. Early adopters report high engagement and course-level benefits in specific, structured implementations, while experimental evidence warns that unstructured use may improve immediate performance without durable learning. Institutions seeking credible long-term evidence would need to establish baseline measures, track cohorts with consistent instruments, preserve comparison groups where ethically possible, and publish results independently of vendors. Until such studies mature, claims that systematic integration has improved long-term outcomes should be treated as hypotheses rather than findings.

Chapter 9: Policy and Governance in Practice

13 questions · 172 citations · 164 unique sources · 64 cross-references

Q069 Which national and regional AI-in-education regulations currently exist, and how do their approaches compare?

25 citations · 25 sources · 5 cross-references

Claim 1 emerging

Existing AI-in-education regulation falls into three broad models. The European Union's AI Act is a binding horizontal law that bans certain classroom practices outright and treats many educational systems as high-risk. The United States relies on a decentralised arrangement in which federal action is largely promotional and the states do most of the legislating. China follows a state-directed approach that pairs national deployment mandates with detailed ministerial, municipal and university rules. Individual institutions and smaller jurisdictions add further layers, but these three models account for most formal regulatory activity. Each reflects different assumptions about how states, institutions and technology should relate. The field is among the most active and contested areas of technology policy, and its outlines are still shifting.

The most architecturally ambitious framework is the EU AI Act, which the European Commission presents as the world's first comprehensive legal framework governing AI development and deployment. It classifies systems by risk level, from minimal to unacceptable, and assigns compliance obligations to each tier. For education this classification has direct consequences. The sector sits at the intersection of two areas the Act treats with particular care: high-risk applications and the protection of vulnerable populations.

Annex III places in the high-risk category AI systems that determine access to education, assess learning outcomes, or influence the educational path of individuals. Sector compliance guides stress that this definition captures ordinary school tools rather than exotic ones. Automated essay grading, adaptive learning platforms and dropout prediction tools all fall squarely within

it. The practical effect is that schools, universities and their suppliers become actors in a product-safety regime, not merely consumers of technology governed by privacy law.

The Act's prohibitions are explicit and already enforceable. It bans eight practices in total. Two of them bear directly on schools: emotion recognition in educational institutions and real-time remote biometric identification are flatly prohibited, and those prohibitions took effect in February 2025. Any system designed to infer students' emotions from facial, vocal or biometric cues is classified as 'unacceptable risk' and banned in EU educational settings. Analyses of the Act's implications for ethical AI in education read this as a deliberate judgement that surveillance of minors' inner states cannot be made acceptable through safeguards. This is the clearest instance of the Act treating learners as a protected population, a theme taken up in the discussion of age limits and child-safety enforcement (see Q145).

The timeline for the rest of the regime has shifted, however. A legislative simplification package, the so-called 'AI omnibus', was adopted in November 2025, and a political agreement on it was reached in May 2026. Under that agreement, the full compliance rules for high-risk AI systems in education will apply from December 2027. Institutions therefore have more time to prepare, but they also face a longer period in which high-risk tools may circulate without full conformity obligations. Because the final legislative text was still being settled at the time of writing, the precise dates should be treated as provisional.

Penalties remain substantial. Placing a non-compliant high-risk AI system on the market can result in fines of up to 15 million euros or 3 percent of global annual turnover, whichever is higher.

Alongside the binding Act, the European Commission has issued ethical guidelines for educators. These include clear explanations of the AI Act, the General Data Protection Regulation and the principles of responsible AI use. They function as soft law that translates legal obligations into classroom practice. The European Schools system has been notably candid about how far practice still lags behind law. Its legal and pedagogical guidelines state that no generative AI tools have yet been officially approved for system-wide use, and that approval procedures are still under development.

Across the Atlantic, the picture is one of deliberate decentralisation. There is no comprehensive federal AI-in-education statute. As the National Education Association's overview of federal regulation documents, the existing federal scaffolding rests on older laws. The Family

Educational Rights and Privacy Act (FERPA) protects the privacy of student education records. However, its last regulatory updates predate the widespread use of technology in learning environments. Institutions are therefore left to interpret it in light of artificial intelligence, a task for which it was never designed. At the higher education level, few federal regulations govern AI directly.

The Trump administration's April 2025 executive order on AI education frames the issue almost entirely in terms of competitiveness. It declares that it is the policy of the United States to promote AI literacy and proficiency among Americans in three ways: by promoting the appropriate integration of AI into education, by providing comprehensive AI training for educators, and by fostering early exposure to AI concepts in order to develop an AI-ready workforce. The order contains no prohibitions comparable to the EU's ban on emotion recognition.

The Department of Education subsequently issued grant guidance outlining how AI may be used across key educational functions. The guidance articulates principles for responsible use and affirms that such uses are allowable under existing federal education programmes. It also proposed an additional supplemental grant priority. The federal lever, in other words, is money and permission rather than constraint. Whether such incentives produce measurable educational returns is a separate question (see Q077).

With the federal level providing only encouragement and grant incentives, the states have become the primary regulatory arena. The Education Commission of the States reports that no state had policies related to generative AI when ChatGPT debuted in 2022. By April 2025, at least 28 states had engaged with the issue legislatively.

The Center for Democracy and Technology's review of the 2025 session suggests a pragmatic rather than rights-based orientation. Fifteen bills in that session alone focused on promoting AI literacy for students and professional development for teachers, making this the top legislative priority. Several states have nonetheless moved towards guardrails on specific harms. Nevada enacted legislation prohibiting public schools from using AI-powered tools to perform the functions of a school counsellor, psychologist or social worker in relation to student mental health.

Vendor accountability is a newer frontier. Legislators are increasingly requiring AI EdTech vendors to submit documentation about how they handle student data and how they use it to

train their products. This development connects directly to the contractual transparency and audit obligations discussed elsewhere in this volume (see Q264).

State approaches vary widely in ambition. California, Connecticut and Texas have introduced bills to create oversight boards and 'regulatory sandboxes' in which AI tools can be tested before broader rollout. Tennessee, by contrast, passed a law requiring all K-12 districts, charter schools and universities to adopt their own AI policies. The Tennessee School Boards Association then developed a model policy, which most districts adopted in full. The Tennessee case shows how a nominally decentralised mandate can, in practice, converge on a single template. Alongside legislation, a growing body of non-binding state guidance documents, catalogued by trackers such as AI for Education, shapes district practice without the force of law.

The relationship between state activity and federal policy is itself contested. Reporting in The Hill describes states pressing ahead with education AI rules despite objections from the Trump administration. Whether federal pressure will ultimately narrow this state-level diversity remains unclear.

China's approach is neither rights-centred like Europe's nor market-permissive like that of the United States. It is best understood as state-directed deployment, combining ambitious top-down mandates with granular behavioural rules. A joint guideline from the Ministry of Education and eight other departments sets the goal of using AI to aid education reform. It emphasises building an AI-based education system that integrates smart technologies into teaching, learning, assessment and academic research.

In May 2025 the Ministry issued two further guidelines. The first covers AI general education in primary and secondary schools. The second governs the use of generative AI: it prohibits students from independently using open-ended content generation at the primary level, and it bars teachers from using generative AI as a substitute for their core teaching responsibilities.

The curriculum is structured as a developmental ladder. Primary school students encounter basic technologies such as voice recognition and image classification. Junior high students examine machine learning processes and develop critical thinking about misinformation in AI outputs. Senior secondary students design and refine AI algorithm models while cultivating interdisciplinary systems thinking.

Implementation is pushed down to cities. Beijing, Guangzhou, Chengdu and other localities have rolled out plans that specify class-hour requirements at each school stage and incorporate AI course evaluations into students' overall assessments. Beijing's primary and secondary schools are to implement general AI education fully from autumn 2025, with no fewer than eight class hours per academic year.

At university level, academic integrity has become a pressure point. Under detection measures introduced in 2024 at Tianjin University of Science and Technology, AI-generated content in undergraduate theses must not exceed 40 percent. Fudan University's regulations ban AI use in six areas of academic work, including research design, original data collection and thesis writing.

Liu, Fang and Lan (2025) offer one of the few scholarly examinations of how these rules operate on the ground. Drawing on policy document analysis and 33 interviews with faculty at research universities, they explore how China's state-led governance model is interpreted, institutionalised and contested on campuses. Their framing is a useful corrective to reading ministerial texts as descriptions of practice.

Day (2026) adds a teacher-education perspective. His participatory study of 76 postgraduate preservice teachers at a Chinese university, using thematic analysis of online forum posts, examined their views on whether AI could replace human teachers. The question is directly relevant to the Ministry's ban on substituting generative AI for core teaching. Both studies are single-context and qualitative, however, so they cannot establish how widely these perceptions hold.

The fundamental divergence among the three models is one of purpose. The EU regulates AI in education primarily as a matter of fundamental rights, including student autonomy, non-discrimination and freedom from surveillance. It enforces those values through legal prohibition and conformity assessment. The United States treats the problem primarily as a governance challenge to be managed at the most local level capable of acting, with the federal role confined to incentives and workforce framing. China treats AI integration as a national strategic imperative. The state sets both the pace and the curriculum, while embedding data security and anti-dependency rules as safety valves, such as the primary-level restriction on generative AI and the prohibition on teacher substitution.

These differences are real, but they should not be overstated. All three systems converge on AI literacy as a goal, and all three leave substantial discretion to institutions. Credible observers disagree about which design better protects learners. Rights-based critics see the American approach as leaving students exposed. Others view the EU's delayed high-risk rules and the European Schools' lack of approved tools as evidence that prohibition-led regulation can stall beneficial adoption. Comparative claims of this kind are difficult to test, because large-scale national initiatives rarely report outcomes in comparable form (see Q061).

A small but growing empirical literature examines how regulation is received inside institutions, and it complicates any purely top-down account. Tan, Qu and Wang (2025) studied students' perceptions of, and compliance with, generative AI regulations at a Singaporean university. They combined thematic analysis of survey responses with quantitative modelling based on the Theory of Planned Behaviour. Their work treats compliance as a behavioural outcome shaped by student attitudes, not something guaranteed by the existence of a rule.

Potluri and Polozova (2026) model AI governance readiness in Kazakhstan's higher education sector. They examine its relationship with administrative efficiency, AI fluency orientation and student retention intentions, with equity perception as a moderator. This frames governance as institutional infrastructure rather than a compliance overlay. Stewart (2026) uses a critical AI media literacy lens to analyse faculty discussions in the two largest higher education subreddits. She shows how questions of power, agency and access surface in informal communities of practice that formal policy rarely reaches.

Student-attitude research points the same way. Vieriu and Petrea (2026) examined whether digital adaptability and general self-efficacy are associated with students' general attitudes towards AI. Their findings are correlational and do not show that these traits cause acceptance. An earlier study by the same authors (2025) drew on 85 purposively sampled second-year students at the National University of Science and Technology POLITEHNICA Bucharest to investigate perceived impacts and challenges of AI-enhanced learning.

Q070 What guidance have major international bodies (UNESCO, OECD, EU, and others) issued on AI in education, and how is it being implemented?

11 citations · 11 sources · 5 cross-references

Claim 1 emerging

Since 2019 the major international bodies have issued a layered body of guidance on artificial intelligence in education. UNESCO has set global norms and competency standards, the OECD has supplied comparative evidence and governance advice, and the European Union has moved furthest by converting principle into binding regulation. Implementation is real but uneven, and it is concentrated in teacher preparation, national strategy documents and, in Europe, legal compliance timelines. Over this period the field has matured quickly. Broad declarations of principle have given way to operational frameworks, competency standards and enforceable law.

The three dominant institutions approach the problem from different vantage points. UNESCO works through normative standard-setting, beginning with the Beijing Consensus of 2019 and extending to its policy guidance of 2021 and its competency frameworks of 2024. The OECD works through evidence-based policy analysis, most systematically in its Digital Education Outlook 2023. The EU works through regulatory governance, chiefly the AI Act and the Digital Education Action Plan.

The sections that follow take each body in turn. They then consider the wider circle of international and regional actors and the degree of convergence among them. The final section examines what is known about implementation, and where that knowledge is thin. Throughout, the guidance itself and its uptake need to be kept apart. The documents are well established and publicly available. Evidence about what they change in classrooms is still emerging.

UNESCO's Beijing Consensus on Artificial Intelligence and Education (2019) was the first global instrument on the topic. It was adopted at the International Conference on AI and Education and committed more than one hundred Member States to a human-centred vision. In that vision AI is controlled by humans, protects human rights, and serves the Education 2030 Agenda embodied in Sustainable Development Goal 4.

The Consensus made several core commitments. AI should empower rather than replace teachers. Applications must be inclusive and non-discriminatory. Educational data use should be ethical, transparent and auditable, governed by privacy-by-design principles.

It also gave UNESCO institutional tasks: building an AI for Education platform and monitoring the AI divide between nations. The Consensus was a declaration rather than a treaty, and its force was political and normative. It nonetheless fixed the vocabulary of human-centred AI that nearly every later instrument has adopted.

Two years later UNESCO published AI and Education: Guidance for Policy-makers (2021), the first comprehensive policy manual for governments. Its most durable contribution is a typology of three policy approaches: independent, meaning a standalone AI policy; integrated, meaning AI embedded in broader digital transformation strategies; and thematic, meaning AI addressed through specific educational challenges.

The guidance urges policy-makers to become AI-ready themselves before drafting rules. Its priorities are equitable access, ethics and privacy, teacher empowerment, collaborative ecosystems, and investment in infrastructure and research. The typology matters in practice because it lets governments with very different administrative capacities enter the field without legislating from scratch.

In 2024 UNESCO moved from policy advice to curricular and professional standards with two companion documents.

The AI Competency Framework for Teachers organizes five dimensions across three progression levels, Acquire, Deepen and Create. The dimensions are human-centred mindset, ethics of AI, AI foundations and applications, AI pedagogy, and AI for professional learning.

The AI Competency Framework for Students defines twelve competencies across four dimensions at three levels, Understand, Apply and Create. Its dimensions are human-centred

mindset, ethics, techniques and applications, and system design.

Both frameworks are explicitly designed to be adapted by national authorities and teacher-education institutions rather than adopted wholesale. Both align with existing digital competence standards such as Europe's DigCompEdu. This deliberate interoperability is significant. A ministry can graft the UNESCO dimensions onto a competence model it already uses rather than building a parallel structure. The way professional bodies and accreditation agencies are translating these frameworks into standards for the teaching workforce is examined separately (see Q076).

The OECD's Digital Education Outlook 2023 provides the most systematic comparative analysis of AI in education to date. It is structured around three themes: digital infrastructure, governance, and opportunities for AI-enabled learning. The report found that, as of early 2024, none of the eighteen jurisdictions surveyed had issued specific regulations for generative AI in education.

This finding underpins the OECD's central recommendation. Systems should not wait for legislation but should act through governance, guidelines and guardrails. In effect, soft-law instruments and procurement standards should fill the regulatory vacuum.

The OECD also documents that roughly one-third of teachers already use AI for work-related tasks, chiefly lesson planning and research. That figure describes self-reported use. It is not evidence that such use improves teaching or learning, and the OECD does not present it as such. The organisation's Education Policy Outlook and its AI policy observatory continue to track how national systems balance teacher supply, digital equity and AI adoption.

Independent scholarship is beginning to test how far this kind of international guidance actually shapes national curricula. Thakur and Mittal (2025) compare Finland, Singapore and India. They examine how frameworks and policy recommendations from UNESCO, the OECD and international EdTech standard-setting bodies have been taken up in AI and cyber-literacy curricula for publicly supported primary and secondary education. Their starting premise is that these organisations have issued frameworks intended to guide K-12 integration of AI and cyber literacy, and that national systems face pressure to adapt their curricula accordingly.

The value of such comparative work is that it treats the OECD and UNESCO as one input among several, alongside industry-led standards. Influence is therefore mediated by national

context rather than transmitted directly. Three countries with very different governance traditions are a narrow base for generalization, and the study's scope is curricular policy rather than classroom practice. It should therefore be read as suggestive of how international guidance is filtered through national institutions. It is not demonstrative of uniform uptake.

The European Union has gone furthest in converting guidance into law. The AI Act (Regulation (EU) 2024/1689) classifies certain AI systems used in education and vocational training as high-risk under Annex III. These are systems that determine access to education, assess learning outcomes, or monitor student behaviour during assessments.

High-risk systems carry obligations covering risk management, data governance, transparency, human oversight and logging. These obligations were originally scheduled to apply from August 2026. Under the Commission's late-2025 proposal to simplify and defer parts of the Act, their application in education could slip to December 2027. Readers should treat the exact date as subject to the outcome of that legislative process.

Other provisions are already in force. Since February 2025 the Act has prohibited emotion-recognition systems in educational settings and has required deployers to support AI literacy among their staff. The prohibition is a notable instance of an international instrument ruling a category of educational technology out entirely rather than regulating its use.

The Act places duties on both providers and deployers of AI systems, so schools and universities are not passive recipients of compliant products. The transparency, documentation and audit obligations that flow to vendors, and the contractual means by which institutions can enforce them, are treated in detail elsewhere (see Q264). Because the high-risk categories include systems that assess learning outcomes and proctor examinations, the Act also bears directly on the redesign of high-stakes assessment (see Q074).

The Digital Education Action Plan (2021–2027) complements the Act on the non-binding side. Its measures include ethical guidelines on the use of AI and data in teaching and learning, updates to the DigComp competence frameworks, and the European Digital Education Hub.

The Hub coordinates member-state practice and hosts working groups, among them a squad developing an ethical AI toolkit for schools. Taken together, the EU model pairs hard-law floors for the riskiest uses with soft-law support for capacity-building. This division of labour mirrors, at regional scale, the OECD's advice to combine guardrails with guidelines.

Beyond the three principal bodies, several other actors have issued guidance. The Council of Europe has issued guidance on AI and education grounded in human rights and the rule of law. The G20 has endorsed principles for AI in education in its education ministers' communiqués. Regional bodies such as the African Union have begun to develop continental frameworks.

The proliferation of instruments has itself become a coordination problem. Governments now navigate overlapping guidance from UNESCO, the OECD, the EU and regional organisations, each with different emphases and different legal force.

The emerging response is convergence on a common core of human-centred design, teacher agency, equity, privacy and transparency. National implementation varies according to legal tradition and institutional capacity.

The most significant development is the shift from guidance to obligation. The EU AI Act demonstrates that the era of purely voluntary frameworks is ending. Other jurisdictions, including Brazil and South Korea, are moving toward binding AI legislation with education-specific provisions. The practical implication for education systems is that international guidance now functions less as a menu of options and more as a floor of expectations against which national policy will be judged.

Whether convergence at the international level carries through to subnational policy is less certain. Rasheed (2026) offers the most systematic evidence for one large federal system. The study is a qualitative content analysis of AI policy guidance documents from 40 U.S. states and territorial jurisdictions issued between 2023 and 2026. It finds that ethics and data privacy dominate current approaches, while equity considerations and educator capacity-building receive moderate attention. Stakeholder trust and ongoing monitoring remain underdeveloped. The study also concludes that rapid AI adoption in K-12 education has outpaced the development of coherent policy frameworks.

The pattern partially confirms the convergence thesis: privacy and ethics, two pillars of the international core, are well represented. It also exposes a gap. Equity and teacher empowerment, which UNESCO places at the centre of its guidance, receive only moderate attention in state documents. Monitoring, which the Beijing Consensus specifically called for, is weakly developed.

A parallel picture emerges at the institutional level in higher education. Ganguly, Johri, Ali and colleagues (2025) analyse guidance that U.S. higher education institutions have issued to researchers on generative AI. Institutions released this guidance in response to concerns about authorship and copyright, biased training data, lack of transparency, and user privacy. These are the same concerns that recur in international frameworks.

Both studies are confined to the United States, which sits outside the EU's binding regime. Neither establishes a causal link between international instruments and local policy. Shared themes may reflect shared exposure to the same public debate as much as deliberate alignment with UNESCO or OECD texts. How far international guidance drives local policy, as opposed to running parallel to it, therefore remains unclear.

In practice, implementation remains uneven across and within countries. Some governments embed AI in national education strategies and in teacher-training programmes built on the UNESCO competency frameworks. EU member states are aligning procurement and institutional practice with the AI Act's timeline. The OECD continues to document wide variation in teacher readiness and infrastructure.

The common thread across all three bodies is a human-centred, rights-based orientation. AI is to augment human judgement, not replace it. Equity, privacy and teacher agency are treated as non-negotiable conditions of adoption.

Translating that principle into an empirically grounded balance between AI support and human instruction is still at an early stage. Dinçer (2026) illustrates the kind of evidence now being generated. The study uses a quasi-experimental design with 76 preservice mathematics teachers across two universities. It compares learning outcomes in AI-supported and instructor-led settings. Participants generated relational and procedural examples and explained their reasoning, and their responses were evaluated for both accuracy and originality.

Studies of this design speak directly to the international guidance's insistence that AI should empower rather than replace teachers. They do so by examining what each form of support contributes to different kinds of mathematical understanding. A single quasi-experiment with fewer than eighty participants in one subject cannot settle the question. Its significance lies in showing that the human-centred principle is becoming an empirical research agenda rather than remaining a slogan.

The guidance also intersects with institutional responses to generative AI in assessment and authorship. The higher education research guidance analysed by Ganguly and colleagues (2025) is one example. Academic-integrity frameworks that move beyond binary models of cheating are another, and they are discussed separately (see Q075).

The principal implementation gaps are teacher preparation, evaluation of learning outcomes, and the digital divide between and within countries. The Rasheed (2026) findings on underdeveloped monitoring suggest a further gap. Many systems issue guidance without mechanisms to check whether it is followed or whether it works. These are precisely the areas the next generation of guidance is now seeking to close, including the UNESCO competency frameworks and the OECD's 2026 Digital Education Outlook.

The international architecture is now substantially complete at the level of principle and, in Europe, of law. The decisive questions concern local capacity, evaluation and enforcement. On those questions the evidence base is still thin.

Q071 What does an effective institutional AI policy contain, and what distinguishes policies that work from those ignored in practice?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

An effective institutional AI policy contains a standing governance structure, a tiered acceptable-use framework, data-governance and procurement rules, a capacity-building

component and an explicit human-oversight principle. Policies that work differ from those ignored in practice mainly in how they are made, how specific they are, and whether their enforcement mechanisms can operate fairly. That is the central claim of this answer. Most of the supporting evidence comes from documentary analyses and practitioner guidance rather than from studies that measure compliance directly, so the claim is best read as a well-supported working hypothesis rather than a demonstrated causal account.

Institutional AI policy in education has moved from reactive, ad-hoc measures toward comprehensive, cross-functional governance frameworks. The early measures were typically emergency bans issued when generative AI first became widely available. Overviews of the sector, such as the account in EdTech Magazine (2026), describe this as a shift from prohibition toward governance. The Faculty Focus guide for institutional leaders frames the task similarly, as one of deliberate policy design rather than crisis response.

Scholarly reviews locate the reason for this shift in competing institutional pressures. Azevedo, Robles, Best and colleagues (2025), writing in New Directions for Adult and Continuing Education, examine existing institutional responses and identify a set of common policies. They highlight the growing tension between innovation, academic integrity and equitable access, and they note the pressure on institutions to produce clear, ethical and practical guidance for faculty. Penev, Slavov and Deliyski (2026) map ethical policies in higher education and identify a similar cluster of concerns: academic integrity, bias, transparency, data protection and the possible erosion of critical thinking and creativity. They also observe that institutions worldwide are only beginning to formulate guidelines covering students, educators and administrators. A recognisable anatomy of policy is therefore emerging, but it is young, and much of the field is still drafting.

A well-constructed policy typically contains six interlocking elements.

The first is a governance structure. This is a standing committee or task force that includes academic leadership, faculty, students, IT, legal and privacy officers. It holds a clear mandate to review, update and interpret the policy over time.

The second is a tiered acceptable-use framework. Rather than a single undifferentiated rule, it distinguishes low-risk activities such as brainstorming, summarising and drafting assistance from high-stakes decisions such as grading, admissions, and clinical or legal judgements.

The third is a set of data-governance provisions. These define what student and staff data may be entered into which systems and prohibit feeding sensitive institutional data into public, unvetted models. They also specify retention and deletion obligations in line with FERPA, GDPR and emerging AI regulation.

The fourth is procurement and vendor due diligence. This includes data-processing agreements, termination rights and bias-mitigation commitments. How such contractual leverage can be used to secure transparency and audit rights is treated separately (see Q264).

The fifth is a professional-development and student-literacy component. A policy that assumes competence it does not build will fail.

The sixth is a human-in-the-loop principle. It requires that AI-generated outputs affecting assessment or administrative decisions be reviewed and approved by qualified humans.

Practitioner frameworks set out this architecture in similar terms. LearnWise's guide and the FeedbackFruits account of moving from policy to practice both emphasise risk tiering, compliance obligations and oversight. Both, however, are vendor publications, and they should be read as descriptions of recommended practice rather than as evidence of outcomes.

The most systematic independent evidence on what institutions actually include comes from LaFrance (2026). He conducted a comparative policy-mapping analysis of publicly available generative AI policies and guidance across America's flagship public universities. The documents were collected in 2025 and coded thematically using Clark's Triangle of Coordination. LaFrance finds a distributed governance architecture. Instructional decisions are typically delegated to the course level and supported through instructor-facing resources. Institution-level guidance, by contrast, concentrates on data protection, approved tools and risk management.

This finding matters for the anatomy above. In practice the six elements are not all located in a single document. Data governance, procurement and approved-tool lists tend to sit centrally, while acceptable-use decisions are often pushed down to individual instructors. An institutional policy may therefore be best understood as a layered system rather than a single text.

Comparative analyses and leadership guidance point to five recurring features of policies that are actually followed. None has yet been tested in controlled comparisons.

The first is mission alignment. Policies framed around the institution's own values and educational purposes generate genuine ownership. Policies copied from a peer institution, or drafted to satisfy external pressure, do not. The Faculty Focus guide makes this case directly.

The second is shared governance. Involving faculty and student representatives in drafting from the outset builds legitimacy and durable compliance.

The third is clarity and specificity. A working policy tells a teacher or student exactly what is permitted in a given context, with concrete examples. Abstract principles that require legal interpretation do not serve this purpose. Azevedo and colleagues (2025) reinforce the point by framing faculty's need as clear and practical guidance, not merely statements of principle.

The fourth is feasibility of enforcement. Policies that rely on detection tools as the sole evidence of misconduct fail, because AI detectors are unreliable and produce false positives, particularly for non-native speakers. Policies that anchor enforcement in process evidence, such as drafts, oral review and version histories, are both fairer and more workable.

The fifth is a review cycle. Because the technology and the regulatory environment change quickly, effective institutions commit to annual policy review rather than treating the document as settled.

On one point the evidence pulls in different directions, and it should be stated plainly. The specificity principle implies that institutions should define permitted uses concretely. LaFrance's (2026) mapping shows, however, that flagship universities commonly delegate instructional decisions to the course level. On one reading, delegation is a strength: the people closest to the learning task make context-sensitive rules, which fits the mission-alignment and shared-governance principles. On another reading, delegation reintroduces the inconsistency and ambiguity that specificity is meant to remove. A student taking five courses may face five different rules.

The current evidence does not settle which reading is correct. A plausible reconciliation is that delegation works when the centre supplies templates, examples and default positions that instructors adapt, and fails when instructors are left to improvise. That claim remains to be tested.

Research on policy implementation identifies a consistent set of failure modes.

Top-down drafting without faculty or student input produces documents that are technically correct but normatively empty: nobody feels bound by them. Vague or maximalist prohibitions, such as a blanket ban on all AI use, are unenforceable and widely circumvented, which corrodes the credibility of the entire policy. Punitive framing that treats students as suspects generates resistance and drives AI use underground rather than making it transparent. Policies that mandate compliance without providing training, tools or support place the burden on individuals who lack the capacity to comply. And policies that are never revisited quickly become obsolete, describing a technology landscape that no longer exists.

Recent qualitative and documentary work adds texture to these failure modes, although it cannot yet measure their prevalence.

Alzahrani, Aldubayyan and Alshabi (2026) interviewed 10 writing teachers in Saudi Arabia about how they view and navigate their institutional AI policies. Their starting observation is itself telling. They describe English language teachers as remaining in a constant state of interpreting, implementing and negotiating policies and expectations that were developed rapidly. For these teachers, policy is something to be worked out in daily pedagogy rather than simply followed. The gap between policy and pedagogy is precisely where unclear or unsupported rules lose force. The small sample and single national context limit generalisation.

Atallah (2026) examines a second, structural source of failure: the distance between national frameworks and institutional practice. He applies systematic documentary analysis and gap analysis to eight national-level policy and strategic documents in Saudi Arabia. These include the Saudi Data and Artificial Intelligence Authority's AI Ethics Principles (2023), its Generative AI Guidelines (2024–2025), the AI Adoption Framework and the Saudi Academic Framework for AI Qualifications. Atallah analyses their governance principles, operational mechanisms and relevance to higher education. The study's framing as a national-to-institutional gap analysis indicates that a comprehensive national governance landscape does not automatically translate into institutional operating rules. Institutions still have to build the mechanisms themselves.

Capacity is a third source of failure. Varga and Fügedi (2026) surveyed 416 pre-service physical education teachers across seven Hungarian universities in the autumn semester of 2025/2026, using the MIATT 2024_rev questionnaire. They report that AI integration into practice-oriented teacher education remains uneven, and they frame their study around digital

readiness and institutional constraints. Their survey describes attitudes and intentions rather than policy compliance. It nonetheless supports the broader point that a policy presupposing a uniform baseline of AI literacy will meet very different levels of readiness on the ground.

Concrete specifications help distinguish abstract policy from operational policy.

A tiered acceptable-use framework typically defines three bands. The first is unrestricted use: brainstorming, summarising and drafting assistance, with disclosure. The second is restricted use, where AI is permitted for specific tasks defined in the assignment, such as generating practice problems or providing feedback on drafts. The third is prohibited use. This covers AI in high-stakes assessment, in final submissions where the assignment requires independent work, and in any context where the student's own competence is what is being certified. Each band comes with examples and with the disclosure requirement that applies to it. The model also fits the distributed architecture LaFrance (2026) observed: the institution can define the bands centrally, and instructors can assign each task to a band.

Data-governance provisions, in turn, should specify more than what may be entered into which systems. They should also say who is responsible when a teacher or student violates the rule. Institutions frequently leave this question unresolved, even though it connects directly to wider questions of institutional liability when AI systems harm a pupil's record or wellbeing (see Q144).

The human-in-the-loop principle is operationalised through sign-off requirements. AI-generated feedback, reports or recommendations affecting students must be reviewed and approved by a named human before they take effect. Naming an individual, rather than asserting oversight in general terms, is what turns the principle into an accountable procedure. Comparable expectations for teachers' own conduct are discussed in relation to professional codes of practice (see Q217).

Institutions that publish such concrete specifications report higher compliance and fewer disputes. The proposed explanation is that the policy answers the questions that actually arise in classrooms rather than the questions that arise in committee. This claim should be held with some caution. It rests largely on institutional self-report and on practitioner sources such as FeedbackFruits and LearnWise, both of which have commercial interests in the governance tools they describe. Neither the evidence base nor any independent study cited here measures compliance before and after a policy is made more specific. Whether specificity causes better

compliance, or whether well-resourced institutions simply produce both specific policies and compliant cultures, remains unclear.

The direction of travel in institutional practice is toward what one strand of governance writing calls AI-ready governance. Its elements are tiered risk classification, explicit human oversight, transparent disclosure norms and continuous monitoring, all embedded in a governance structure that can adapt. Sector overviews such as EdTech Magazine's describe this convergence, and the LearnWise framework sets out the risk-and-compliance version of it.

The UNESCO AI Competency Framework for Teachers reinforces this direction. It treats institutional support, not individual teacher initiative, as the precondition for ethical AI use. The framework places responsibility on institutions to supply the training, infrastructure and guidance that the failure modes above identify as missing. How professional bodies, unions and accreditors are translating such expectations into binding standards is a related but distinct question (see Q076).

The consensus is real, but it should not be overstated. Penev and colleagues (2026) find that ethical guidelines are only beginning to be formulated across higher education worldwide. Atallah's (2026) analysis indicates that even comprehensive national frameworks require deliberate institutional translation. LaFrance (2026) shows that the leading public universities in the United States have settled on a distributed model whose consequences for consistency are not yet known. Agreement on what policies should contain is therefore well ahead of evidence on which designs change behaviour.

The practical lesson for institutions is that a policy is a living governance instrument, not a document. Its effectiveness is determined less by its wording than by three things: the committee that owns it, the training that accompanies it, and the review cycle that keeps it current. The research agenda that follows is equally clear. Comparative studies are needed that measure compliance, disclosure rates and misconduct outcomes across institutions with different policy designs. Without them, the field's best practices remain informed judgements rather than demonstrated findings.

Q072 How are education systems regulating student data privacy in AI tools, and which legal frameworks apply to minors?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

Education systems regulate student data privacy in AI tools through layered instruments rather than any dedicated global regime. These layers are general data protection law, most fully developed in the European Union's General Data Protection Regulation (GDPR); AI-specific risk regulation, led by the EU AI Act; sector-specific statutes such as the United States' FERPA and COPPA; a growing body of state legislation; and non-binding international guidance from UNESCO and the OECD. Minors are protected partly by child-specific rules and partly by the heightened application of general principles. This regulatory field is among the fastest-moving areas of education law and policy. AI-enabled educational technology now includes adaptive learning platforms, AI tutors, automated grading systems and behaviour-monitoring tools, and its spread has exposed gaps in frameworks written before such systems existed. The result has been a wave of new legislation, regulatory guidance and institutional policy at national, regional and institutional levels.

Comparative legal scholarship characterises the result as a patchwork. National and regional laws differ in scope, in the age thresholds they apply to children, and in how far they reach into vendors' handling of data, and international instruments supplement but do not unify them (Student Data Privacy: A Comparative Analysis of National Frameworks). This fragmentation creates real difficulties for multinational edtech vendors, who must satisfy divergent regimes simultaneously. It also burdens schools that adopt tools developed under one jurisdiction's assumptions and deploy them under another's. Taherdoost (2026) frames the underlying problem in general terms: AI systems now process personal and organisational data at a scale that outpaces the legal and technical mechanisms designed to protect it. On this account,

effective governance must reconcile three objectives often treated separately: user trust, regulatory compliance and secure data architecture. That diagnosis is not specific to schools, but it describes the education sector's predicament closely. Compliance with any one legal layer does not guarantee that the system as a whole is trustworthy or secure.

The European Union offers the most comprehensive framework, combining the GDPR with the EU AI Act (Regulation 2024/1689). The GDPR establishes foundational principles that apply to all personal data processing, including processing by AI systems: lawfulness, fairness and transparency, purpose limitation, data minimisation, accuracy, storage limitation, and integrity and confidentiality. Children receive explicit attention. The Regulation recognises that minors merit specific protection because they may be less aware of risks. For information society services offered directly to a child and relying on consent, it sets a default age of digital consent of 16, which member states may lower to no less than 13. Schools usually rely on legal bases other than consent, such as public-interest tasks. The principles of minimisation and purpose limitation nonetheless constrain what an AI vendor processing pupils' data on a school's behalf may do with it.

The AI Act adds a risk-based layer on top of data protection. AI systems used in education to determine admission or access, evaluate learning outcomes, assess the appropriate level of education for an individual, or monitor prohibited behaviour during tests are classified as high-risk. Providers of such systems must operate risk-management systems, prepare technical documentation, ensure appropriate data governance, undergo conformity assessment and design for effective human oversight. Deployers that are public bodies, or private entities providing public services, must also conduct a fundamental rights impact assessment (FRIA) before putting such systems into use. The Act goes further for one category. It prohibits AI systems that infer the emotions of natural persons in educational institutions, except for medical or safety reasons, treating such inference as an unacceptable risk. This prohibition has applied since February 2025.

The timetable for the high-risk obligations is less settled than earlier accounts, including the previous version of this answer, implied. The Regulation as adopted scheduled most high-risk obligations for systems listed in its annex, which covers education, to apply from 2 August 2026. Subsequent Commission proposals to simplify the digital rulebook have sought to defer these obligations, with December 2027 cited as a possible later date. Until the legislative

process concludes, schools and vendors should treat the application date as contested rather than fixed.

National data protection authorities are translating these instruments into sector-specific expectations. The Spanish authority's guide on AI in education, for example, explains how GDPR obligations apply when schools introduce AI tools. It addresses lawful bases, minimisation, transparency towards families and the assessment of risks before deployment (Agencia Española de Protección de Datos). Guidance of this kind matters because the AI Act and GDPR are drafted at a level of generality that school leaders cannot readily operationalise without such intermediation.

In the United States the framework is more fragmented and was not designed with AI in mind. Two federal statutes do most of the work. The Family Educational Rights and Privacy Act (FERPA) protects the privacy of student education records. It generally requires written consent before personally identifiable information is disclosed, subject to exceptions that include disclosure to school officials with a legitimate educational interest. Schools routinely rely on this exception to share data with edtech vendors. The Children's Online Privacy Protection Act (COPPA) governs the collection of personal information from children under 13 by operators of websites and online services. The Federal Trade Commission finalised amendments to the COPPA Rule in 2025. These strengthened requirements on data retention and deletion, including written retention policies, and required separate parental consent for many disclosures of children's data to third parties (Federal Trade Commission).

Legal analysis identifies significant gaps in both statutes as applied to AI (Student Privacy in the Age of AI: FERPA, COPPA, and the Gaps). FERPA regulates educational institutions rather than vendors directly. The school-official exception formally requires that the institution retain direct control over the vendor's use of records and limits redisclosure. In practice, however, FERPA does little to govern what vendors do with data once disclosed, including whether it informs model development. Enforcement runs through the withholding of federal funds rather than individual remedies. COPPA has the opposite limitation. It applies only to children under 13, leaving adolescents largely outside its protection, and only to operators of commercial websites and online services, not to schools themselves. Its interaction with school-authorised use, where schools may in some circumstances consent on parents' behalf for educational purposes, further complicates accountability. Neither statute addresses distinctively AI-related questions such as model training, inference about students from behavioural data, or the

explainability of automated decisions. Those questions belong to the broader debate about who controls and owns the learning profile a system builds about a child (see Q012).

In the absence of comprehensive federal legislation on AI in education, US states have become the primary sites of regulatory innovation. The provisions attributed to specific bills, however, need careful verification. California's AB 1159 (2024) is described in its legislative record as addressing student data privacy and AI. The previous version of this answer characterised it as explicitly prohibiting the use of student data to train AI models and creating a private right of action for privacy violations (California Legislative Information). Such provisions would represent a substantial departure from the FERPA model. They would extend obligations directly to vendors' downstream uses and give families an individual remedy that federal law does not. Readers relying on these provisions should consult the enacted text rather than secondary summaries, because bill language frequently changes during passage.

The same caution applies to other state measures cited in earlier commentary. Idaho's SB 1227 and Oklahoma's SB 1734 have been reported as requiring human oversight of AI-generated decisions and banning high-stakes automated grading. Vermont's HB 650 has been reported as proposing annual privacy compliance certification for edtech providers. None of the sources available for this revision independently confirms the enacted status or exact content of these measures, and they should be read as indicative of legislative direction rather than as settled law. That direction is nonetheless discernible. It points towards more specific, AI-aware student data protection that addresses model training, automated decision-making and vendor certification directly. Earlier statutes left these matters to contract.

State activity of this kind both fills gaps and deepens fragmentation. A vendor operating nationally may face differing rules on training data, oversight and certification across states. This reproduces within one country the cross-jurisdictional problem described for multinational vendors. Whether states will converge on common models or continue to diverge remains unclear.

Children warrant heightened protection in data privacy frameworks for three reasons. They are developmentally vulnerable. Their capacity for informed consent is limited. And data collected during formative years can have long-term consequences, following a person into later education and employment. The EU AI Act's prohibition of emotion inference in educational settings reflects this heightened concern. The UN Convention on the Rights of the Child (CRC)

is increasingly cited in data protection contexts. Its relevant guarantees are the right to privacy, protection from economic exploitation, and the requirement that the best interests of the child be a primary consideration in all actions concerning children. The Convention predates digital data and does not itself expressly address children's data. The Committee on the Rights of the Child's General Comment No. 25 (2021) applies these rights to the digital environment and calls on states to prevent the commercial exploitation of children's data. Advocates therefore draw on that interpretive guidance when invoking the CRC against data-driven commercial practices in schools.

UNESCO's Recommendation on the Ethics of Artificial Intelligence (2021) and its subsequent guidance on AI in education set out global principles for student data protection. These include data minimisation, purpose limitation and the treatment of children as a distinct risk group (UNESCO). The OECD AI Principles, adopted in 2019 and updated in 2024, similarly emphasise transparency, accountability and human oversight (OECD). Neither instrument is legally binding. Both carry significant normative weight and have informed national legislation and guidance in many jurisdictions.

Empirical research on how learners experience AI-related privacy risks is growing but remains limited, and almost all of it concerns university students rather than minors. Phua and Neo (2025) included security and privacy concerns as a distinct construct alongside perceived usefulness, ease of use and positive and negative attitudes in their study of students' perceptions of AI tools. This suggests that privacy is now a recognised dimension of acceptance research rather than an afterthought. Jukiewicz (2025) reviews literature on generative AI in education and notes emerging concerns about effects on students' mental health and on fundamental academic values, alongside gains in personalisation and efficiency. Tian (2026) analysed 380 valid survey responses from university students collected between July and September 2025. The study modelled how perceived usefulness, fairness and controllability of educational technology relate to educational anxiety and mental health. Because the design is cross-sectional, these are associations, not demonstrated causal effects. The perceived controllability dimension is nonetheless relevant to privacy governance, since control over one's data and over how systems use it is precisely what frameworks such as the GDPR, COPPA and the AI Act seek to secure for children and their families. Research examining minors' own experiences of AI-related data practices in schools remains a notable gap.

Q073 How should institutions handle procurement of AI tools — evaluation criteria, vendor accountability, contract terms, and exit strategies?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

Institutions should treat the procurement of AI tools as a governance lifecycle, not a purchase. That lifecycle has four linked phases: evaluation against pedagogical, security, data, equity and transparency criteria; continuous vendor accountability after signature; contracts that allocate liability, data rights and performance obligations for probabilistic systems; and exit strategies agreed before deployment begins. Procurement has become the most consequential governance lever available to education institutions in the AI era. The reason is that AI tools are not neutral software. They make probabilistic judgements, they can learn from the data they process, and their behaviour can change through model updates the institution did not request. Conventional software acquisition assumes a stable product with predictable outputs, and that assumption no longer holds.

Government procurement handbooks such as the District of Columbia's, legal guidance from firms and law schools, and emerging institutional practice increasingly converge on a phased governance model. That convergence comes largely from practitioner and policy documents rather than from evaluated outcomes. The broader policy literature offers a normative anchor for it. Dabis and Csáki (2024) analysed five key international documents from the UN, EU and OECD and identified the ethical dimensions most relevant to generative AI in academia, including accountability, human oversight, transparency and inclusiveness. Each of these maps onto a procurement phase. Inclusiveness and transparency belong in evaluation, accountability

and human oversight belong in vendor management and contracting, and the ability to withdraw from a tool is a precondition for all of them.

The strategic context is shifting quickly. Gering and colleagues (2025) examined 98 strategy documents and statements from the top 30 universities in the Times Higher Education 2024 ranking. They treat generative AI as a key driver of digital transformation that requires institutions to adapt their strategies. Their sample is drawn from elite, well-resourced universities, so it shows how strategy is being framed at the top of the sector. It does not show how procurement is actually conducted across it.

Evaluation should happen before any tool is acquired, and its criteria should extend well beyond functionality and price.

Pedagogical alignment comes first. The tool should serve a defined learning objective, and the institution should ask for evidence of effectiveness rather than vendor claims. Vendor-reported efficacy figures are marketing material and should be read as such.

Security and privacy follow. Internet2's Higher Education Community Vendor Assessment Toolkit (HECVAT) has become the de facto standard in higher education for evaluating a vendor's security, privacy and accessibility posture. Practitioner accounts such as Sabado's describe institutions that increasingly refuse to consider vendors unwilling to complete it.

Data governance is a separate criterion, not a sub-item of security. It covers where data is stored, whether it is used for model training, which sub-processors handle it, and whether deletion is technically feasible rather than merely promised. These questions bear directly on the regulation of student data and on obligations owed to minors (see Q072).

Equity and bias are now standard evaluation dimensions. Vendors should be able to document their bias testing and mitigation. Institutions increasingly require accessibility compliance and evidence that the tool does not disadvantage particular student groups. Accessibility deserves emphasis because it is easily folded into general compliance language and then neglected. Aquino, Lalor and Parnther (2024) pose directly the question of whether institutions are addressing accessibility in their generative AI policy development. The fact that the question needs asking suggests that accessibility cannot be assumed to be covered by default. Procurement is the point at which it can be made a condition of purchase rather than an afterthought.

Transparency is the final core criterion. Institutions need to know what the model does, how it was trained and how it will be updated, because a black-box tool cannot be governed.

Some institutions may reasonably widen the frame further. Creely's (2026) narrative review of literature published between 2022 and 2026 traces ethical, social and environmental concerns surrounding generative AI in education. That breadth implies that environmental impact is a legitimate, if not yet standard, evaluation consideration. How it should be weighed against pedagogical benefit remains unclear, and no consensus metric yet exists for doing so in procurement.

In practice, evaluation is increasingly conducted through structured pilots rather than paper assessments alone. Institutions are adopting sandbox approaches in which a tool is deployed to a limited cohort under defined conditions before any institution-wide commitment. Those conditions include data-collection protocols, success metrics and a pre-agreed decision point. This reflects a simple reality: paper evaluation cannot predict real-world performance. A tool that scores well on vendor benchmarks may fail in a specific classroom context, with specific students, under specific network conditions.

Pilot designs typically specify in advance the evidence that will justify scale-up. That evidence usually includes learning-outcome data, teacher and student experience, technical reliability, and equity effects across student subgroups. Specifying it beforehand guards against the common pattern in which enthusiasm, sunk costs or vendor pressure turn a trial into a de facto adoption.

Regulation reinforces this discipline. The EU AI Act requires high-risk AI systems used in education to meet risk-management, data-governance and human-oversight obligations before they are placed on the market or put into service. It also requires certain deployers, including public bodies, to conduct fundamental-rights impact assessments.

Risk-management thinking from the education research literature points the same way. Humble (2024) proposes a risk management strategy for generative AI in computing education organised around strengths, weaknesses, opportunities and threats. The paper situates that strategy against estimates that publications on generative AI increased by 2269.49% between 2022 and 2023, with an even steeper rise in computing education. That figure measures scholarly attention, not effectiveness. It does, however, illustrate why institutions cannot simply

wait for settled evidence before deciding. Bounded, monitored pilots are a way of generating local evidence while the wider literature catches up.

The practical lesson is that procurement decisions should be reversible. A pilot that fails should be as easy to terminate as one that succeeds. For that reason, the exit provisions discussed below must be in place before the pilot begins, not negotiated after the institution has become dependent on the tool. Pilots of AI-detection software illustrate the stakes, because institutions have adopted such tools before their reliability was established (see Q056).

Accountability does not end at signature. Practitioner guidance describes institutions adopting vendor relationship management practices for AI. These include scheduled performance reviews and monitoring of AI-specific key performance indicators such as accuracy, fairness and uptime. They also include bias and accessibility audits conducted in real-world settings rather than in vendor test environments. The distinction matters because test environments are curated, whereas classrooms contain the linguistic diversity, disability profiles and usage patterns that expose a model's weaknesses.

Contracts increasingly require vendors to provide interfaces through which the client can exercise effective oversight. These include logging, audit trails and human-review workflows that allow staff to inspect and, where necessary, override automated outputs. This contractual approach to transparency and audit is developing quickly, and the mechanisms schools can use to enforce such obligations are treated in detail elsewhere (see Q264).

The concept of performance drift is central to accountability. A model that performed acceptably at deployment may degrade, or simply change, after the vendor retrains or updates it. Accountability mechanisms must therefore be continuous rather than point-in-time. An institution that audits once at procurement and never again is governing a product that may no longer exist in the form it evaluated.

This is also where the normative principles identified by Dabis and Csáki (2024), accountability and human oversight above all, become operational. Without contractual access to logs and review workflows, human oversight is an aspiration rather than a capability. The evidence base here is thin. Descriptions of these practices come mainly from practitioner commentary and legal guidance rather than from systematic studies of whether ongoing monitoring changes vendor behaviour or student outcomes. Whether such monitoring is effective therefore remains unclear.

Contract terms for AI differ from conventional software terms in several provisions that legal guidance consistently emphasises.

Liability and indemnification are the first battleground. Commentary such as Stanford Law School's guide to AI vendor contracts observes that AI vendors routinely cap their liability and shift risk to the customer. Institutions are advised to negotiate risk-adjusted liability models that reflect the AI's role in high-stakes decisions affecting students, such as grading, placement or flagging for misconduct. The question of who bears responsibility when an AI system harms a pupil's academic record or wellbeing is unsettled in law (see Q144). That uncertainty makes the contractual allocation of risk more important, not less.

Data rights are the second battleground. Legal guidance warns that nearly all AI vendors claim rights to use customer data for model retraining or for competitive intelligence. Contracts must therefore define data ownership, retention and deletion with precision rather than relying on general privacy assurances.

Performance warranties are the third. Because AI outputs are probabilistic, traditional software warranties that a product will perform according to its documentation are inadequate. MinterEllison's guidance on procuring AI recommends that contracts specify measurable performance standards and reliability targets. They should also specify remedies when standards are missed, such as service credits or mandatory model retraining. This provision links contract law to the drift problem described above: a warranty is only meaningful if the institution can monitor performance against it.

Transparency and compliance commitments complete the core terms. These include disclosure of training-data provenance and notification of model updates. They also include explicit compliance with applicable law, including GDPR, FERPA, COPPA and the EU AI Act.

Sources differ somewhat in emphasis. Law-school commentary foregrounds liability allocation and data ownership. Commercial legal guidance gives more weight to performance standards and remedies. These are differences of priority rather than genuine disagreement. Much of this guidance is written for organisations generally rather than for schools and universities specifically. Education institutions, which often have limited bargaining power against large vendors, may find the recommended terms easier to describe than to obtain.

Vendor lock-in is a recognised failure mode of educational technology. AI intensifies it because models, fine-tuning and data pipelines are difficult to port. Effective procurement therefore builds exit strategies in from the outset. These include data portability and export rights in machine-readable formats, and transition plans specifying how the institution will migrate to an alternative provider. They also include termination-for-cause and termination-for-convenience clauses, and contractual obligations on the vendor to delete institutional data on exit.

Some jurisdictions now make these elements mandatory for public institutions. The District of Columbia's AI Procurement Handbook is one example. School districts are also beginning to publish their own vendor guidance, as Chicago Public Schools has done in its AI Guidebook, requiring compliance with such standards as a condition of doing business. Public guidance of this kind shifts the burden of proof onto vendors. It also lets smaller institutions benefit from standards they could not negotiate alone.

The most important shift across all four phases is procedural. AI purchases are increasingly routed through a centralised governance gate rather than left to individual departments or teachers. This ensures that every acquisition is assessed against institutional principles, namely safety, equity, transparency and data protection, before it reaches a classroom. The procurement model described here does, however, presuppose considerable institutional capacity: legal expertise, technical staff able to audit models, and infrastructure stable enough to run meaningful pilots. Lakhno (2026) conducted a PRISMA-guided systematic review of scholarship from 2022 to 2024 using Rogers' Diffusion of Innovations framework. The review argues that debates on AI in higher education are dominated by evidence from high-income contexts that assume such capacity and robust infrastructure. In low-income countries, by contrast, structural constraints profoundly condition both the opportunities and the risks of adoption. For institutions in those settings, shared regional standards, consortium purchasing or public handbooks may be the only realistic route to the protections that well-resourced universities negotiate individually. How well such arrangements work remains unclear.

The overarching lesson is that procurement is a lifecycle, not a transaction. Evaluation, accountability, contracting and exit must be designed together. A contract negotiated without an exit strategy, or an evaluation that ignores bias, will fail at the point of greatest cost.

Q074 How are examination and credentialing bodies redesigning high-stakes assessment for the AI era?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Examination and credentialing bodies are redesigning high-stakes assessment in three main ways. They are revising integrity policies to require transparent disclosure of AI use, rebuilding assessments around verified process and oral demonstration of reasoning, and stepping back from detection-based enforcement. These are the examinations and credentials that govern university admission, professional licensure and certification. They have been the most exposed flank of education in the generative AI era because their purpose is to certify individual competence. A system that can produce work indistinguishable from a candidate's own threatens their validity at the root. Papaneophytou and Nicolaou (2026) make the same point for STEM higher education. In their narrative review, the most consequential effect of generative AI is not the automation of existing practice. It is the need to redesign curricula, learning outcomes and assessment around disciplinary judgment, critical verification and intellectual independence. They frame the problem as one of assessment validity rather than tool adoption or academic integrity. That framing explains why credentialing bodies, whose products are claims about validity, have had to move first and furthest.

The International Baccalaureate (IB) offers the most fully articulated case. Rather than banning AI, the IB revised its Academic Integrity policy to include dedicated guidance on AI tools in Appendix 6, built on the principle of transparency (International Baccalaureate). Students who use AI to generate text, images or other products must cite the tool in the body of their work and list it in their bibliography. The IB places the burden of authentication on teachers, who are

expected to use professional judgement to confirm that submitted coursework is the student's own. It states explicitly that teachers do not need to prove AI use, only to be confident that the work reflects the student's capabilities. Where authenticity is in doubt, the IB endorses three remedies: oral examinations and vivas, process evidence such as drafts and version histories, and redoing tasks under controlled conditions. Its published guidance on thirteen common scenarios of AI use in coursework draws the line between acceptable and unacceptable use. Acceptable uses, with acknowledgement, include research, summarising counter-positions and generating structural templates. Misconduct includes asking AI to write essays, translating entire assessments and fabricating quotations. This approach resembles the disclosure-based principles in the guidance from international bodies discussed elsewhere in this chapter (see Q070).

Credentialing bodies have abandoned detection as their primary defence because the research literature has reached a fairly consistent diagnosis: detection-based countermeasures are unreliable and inequitable. The conceptual framework for AI-resilient assessment published in Frontiers in Artificial Intelligence summarises the problems. AI detectors deliver variable accuracy, carry significant false-positive rates, show systematic bias against non-native English speakers, and fuel an arms race in which students refine evasion techniques.

Kickbusch, Ashford-Rowe, Kemp and colleagues (2025) push the argument further. They contend that the dominant response of surveillance and AI detection misdiagnoses the problem, because authenticity cannot be policed into existence and must instead be redesigned. They reconceptualise authenticity as something constructed in contexts where AI is expected, declared and scrutinised, rather than assumed to be absent. Klapproth (2026), writing from a constructive alignment perspective, reaches a compatible conclusion. The central pedagogical question is no longer whether students use AI. It is how AI use reshapes the relationship between intended learning outcomes, teaching and learning activities, and the evidence on which judgments of competence rest. His critical narrative review draws together research on cognitive offloading, scaffolding, self-regulated learning, formative feedback and assessment validity under AI-rich conditions.

From this diagnosis follows the redesign principle: make genuine learning the most effective path to success. The Frontiers framework organises the redesign into four pillars. The first is process-based documentation, such as annotated bibliographies, iterative drafts and research journals, which makes the learning trajectory visible. The second is oral defence, through vivas,

questioned presentations and follow-up discussions that require candidates to justify their reasoning in real time. The third is authentic task design, using tasks anchored in local datasets, seminar discussions or personal experience that generic AI output cannot satisfy. The fourth is transparent AI-use policies, covering disclosure of prompts, reflection on AI output and defined boundaries of legitimate use.

Institutional teaching guidance makes similar recommendations. Northern Michigan University's Center for Teaching and Learning advises designing out easy AI substitution through personalised, context-specific and process-oriented tasks.

These sources converge on direction, but the empirical base is still largely conceptual and review-based. The redesign consensus is best read as emerging rather than settled.

For credentialing bodies, the decisive problem is scale. Oral components and process documentation are labour-intensive compared with machine-marked multiple-choice papers. Institutions are responding in several ways. They are adopting structured oral protocols and standardised rubrics that weight oral defence and process engagement equally with the final product. They are using learning-design tools that let students rehearse oral assessment before high-stakes encounters. And they are attaching oral components as follow-ups to written submissions, in which candidates walk through their arguments to verify understanding.

The case for verbal examinations has been argued most directly in business education. There, authentic design combined with oral examination is presented as a route to assessment resilient to AI substitution. Practitioner guidance from FeedbackFruits, an educational technology vendor, describes rubric and rehearsal workflows for this kind of redesign. It should be read as practice description, not as research evidence of effectiveness.

The faculty-level evidence on what drives redesign is qualitative but instructive. Khlaif, Alkouk, Salama and colleagues (2025) interviewed and ran focus groups with sixty-one faculty members, collecting examples of redesigned assessments. They analysed the data with both deductive and inductive thematic approaches and derived a framework for assessment redesign in the generative AI era. The study speaks to the motivations and practices of individual educators. It does not establish whether redesigned assessments produce more valid judgments of competence. That distinction matters when the findings are carried over to national examinations.

The IB's model of teacher authentication backed by oral verification and process evidence remains the clearest template for how a global credentialing body can apply these principles without abandoning the scale of its examinations. Its model works by distributing authentication across many teachers rather than centralising it. This raises its own questions about consistency and professional workload. Those questions overlap with the standards being set by teacher unions and professional bodies (see Q076).

The IB is not alone. Other international examination boards and national credentialing bodies have moved in the same direction in three respects: revising academic-integrity policies to require disclosure of AI use, strengthening authentication procedures for coursework, and expanding the role of supervised and oral components in high-stakes assessment.

The common constraint is economic. Bodies that certify hundreds of thousands of candidates each year cannot simply convert their examinations to vivas. The emerging compromise is a portfolio model. A limited number of high-stakes components, those that certify individual competence, are redesigned for AI resilience, while most assessment continues under supervised, controlled conditions. Papaneophytou and Nicolaou (2026) frame generative AI as a validity problem. Their framing supports this targeting: redesign effort should concentrate where the inference from performance to competence is most vulnerable.

Digital assessment infrastructure is the enabling condition. Secure platforms must support oral components, process documentation and version histories at scale. That dependence creates obligations around the transparency and auditability of the vendors who supply such systems (see Q264).

Professional and healthcare credentialing illustrates the pressures. Alturkistani and Almalki (2026) argue that healthcare e-learning must be at once evidence-based, acceptable to regulators, clinically credible and delivered on time. They note that established instructional design models, including ADDIE, the Successive Approximation Model, Dick and Carey, and Kemp, were not built for these combined demands. Those models also predate the routine use of AI in content production. Their INSPIRE methodology is a proposal for high-stakes e-learning rather than a tested assessment reform. Still, it signals that regulated professions see AI as requiring new design processes, not adjustments to old ones.

The longer-term question is whether the credential itself will change. Certification might come to rest on a documented trajectory of learning and verified performance rather than on a single

examination event. The IB's teacher-authentication model, the four-pillar framework and the economics of scale all point in that direction. The transition is likely to be gradual and uneven across jurisdictions.

A less discussed side of the redesign concerns AI inside the production and scoring of high-stakes assessment, not only AI in candidates' hands. Writing good multiple-choice items is resource-intensive and time-consuming for human experts. Law, So, Lui and colleagues (2025) therefore ran a cohort study within a high-stakes medical licensing examination. They compared the quality and psychometric properties of ChatGPT-4o-generated questions with those written by humans. As the abstract frames it, the efficacy of large language models for item generation in high-stakes examinations remains unclear. That is the reason such psychometric comparison within live examinations matters. Credentialing bodies drawn to AI-assisted item banks will need evidence of this kind, item by item and examination by examination, before generated content carries certification weight.

The scoring of oral performance raises a parallel issue, because AI-assisted analysis of spoken responses is one possible way to make oral components affordable at scale. Evidence from personnel selection gives a cautionary analogue rather than a direct precedent. Stevenor, Hickman, Zickar and colleagues (2024) trained machine learning models on verbal data and interviewer ratings from low-stakes interviews. They then applied the models to high-stakes interviews to infer applicant personality. In their first study (N = 107), the algorithmic scores more closely reflected interviewer ratings than applicant or reference ratings. Algorithmic scores and interviewer ratings also showed similar relations with interview behaviour, biographical information and hireability. These are associations within a selection context, not evidence that automated scoring of examination vivas would be valid. They do show that models trained in low-stakes settings can be studied for transfer to high-stakes ones, and that such transfer needs multifaceted validity evidence before it is trusted. Where AI-assisted scoring does enter credentialing, errors that damage candidates' records raise liability questions examined elsewhere in this volume (see Q144).

It would be misleading to suggest that the redesign is complete, or that its sources agree on every point. Many credentialing bodies still rely on supervised, closed-book examinations for core components, and the economics of oral assessment at national scale remain unresolved. There is also a real tension in the literature. Kickbusch and colleagues (2025) treat surveillance-

based responses as a misdiagnosis, yet the portfolio model adopted in practice keeps controlled, supervised conditions as the backbone of most high-stakes assessment.

How far invigilation is a legitimate complement to redesign, rather than a residue of the detection paradigm, is contested. Klapproth's (2026) emphasis on alignment between outcomes, activities and evidence suggests the answer depends on what each credential claims to certify. An outcome that includes competent, declared use of AI cannot be validly assessed under conditions that forbid it.

The IB's distribution of authentication to teachers has a further limit. It depends on professional judgement that varies across schools, and the reliability of that judgement for high-stakes decisions has not been well studied. The faculty-focused framework of Khlaif and colleagues (2025) and the conceptual work behind the four pillars describe how redesign is being done more than they demonstrate that it works.

Despite these gaps, the direction of travel is consistent across the IB, the research literature and institutional practice. High-stakes assessment is being rebuilt around the verification of process and the demonstration of reasoning under human questioning. AI is treated as a tool whose use must be transparent rather than as a threat to be detected. The frontier that the next generation of assessment design must address is whether credentials themselves will shift from certifying a single examination performance to certifying a documented trajectory of learning.

Q075 What academic-integrity frameworks have institutions adopted to replace binary "cheating/not cheating" models, and how are they working?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

Institutions have replaced the binary "cheating/not cheating" model with three main families of frameworks. Disclosure-based models make undisclosed AI use, rather than use itself, the offence. Tiered or contextual models set the legitimacy of AI use at the level of the course and the assignment. Process-based models judge integrity from the trajectory of a student's work rather than from the finished product. Early evidence suggests these frameworks work when they are embedded in assessment redesign and faculty development, and fail when they are adopted as standalone policy documents.

The old model assumed that an act was either cheating or not, and that detection followed by punishment was the way to enforce the line. That model has proven structurally inadequate for the generative AI era. AI-assisted work does not map cleanly onto the categories of plagiarism and contract cheating that the binary model was built to police. The detection tools that sustained it are also unreliable.

The research literature identifies three compounding failures. First, AI detectors are inaccurate. They produce false positives, particularly for non-native English speakers, and their accuracy varies unpredictably across texts. This makes them unsafe as the sole basis for disciplinary action (see Q056).

Second, detection fuels an arms race. As detection improves, evasion techniques evolve alongside it, including paraphrasing, prompt engineering and hybrid human-AI drafting. The authors of the Journal of Academic Ethics analysis "From Detection to Design" describe how this contest consumes institutional resources and corrodes trust between students and faculty. The sociotechnical account published in Social Sciences makes a similar point: integrity problems arise from the interaction of tools, institutional incentives and assessment design, not from individual moral failure alone.

Third, the binary model misclassifies the phenomenon. Much AI use in student work is neither straightforward cheating nor legitimate independent work. It is a spectrum of assistance that the binary cannot represent. Zdravkova (2026) locates the central difficulty in the appropriation of AI-generated outputs as original human authorship, and in the growing difficulty of verifying independent work at all.

None of this critique is wholly new. Scholars of contract cheating, notably Tracy Bretag and colleagues, argued well before the AI era that punitive, surveillance-based approaches fail. Bretag's 2013 analysis of contract cheating as a new challenge for academic honesty contended that effective integrity policy must be fair, clear, consistent and educational. That argument now forms the intellectual foundation for post-binary frameworks.

The first family of replacement frameworks is the disclosure-based model, now the dominant approach in higher education. AI use is permitted under defined conditions, and the violation is undisclosed use. Students disclose the tool, the task for which it was used, and the extent of its contribution. Institutions treat failure to disclose as the primary academic offence.

The model's spread has not produced uniformity. Zdravkova (2026) observes that universities and academic publishers increasingly require explicit disclosure, but that the scope and implementation of these requirements remain inconsistent. She also raises a deeper problem. If disclosed interactions with a large language model are to serve as evidence of authentic use, their reliability as evidence must itself be examined. A disclosure statement can be incomplete, or it can describe LLM-based ghostwriting in terms that make it sound like legitimate assistance. Disclosure therefore shifts the integrity question rather than resolving it.

The second family is the tiered or contextual model. Here the legitimacy of AI use is defined by course and assignment rather than by a single institutional rule. Some tasks permit AI assistance, others prohibit it, and the syllabus specifies which regime applies. This approach places considerable responsibility on individual instructors. McGinty and Murray-Johnson (2025) address this in their ethical framework for faculty in adult higher education. They distinguish traditional AI applications, such as plagiarism detection and adaptive quizzes, from generative systems that create new content. They recommend clear usage policies and transparency as the basis for responsible integration. They also set integrity and authenticity alongside other ethical obligations: protecting student data, mitigating algorithmic bias, and ensuring fair access for all learners. These overlap with institutional duties in privacy and equity (see Q072 and Q111).

The third family is the process-based model. It shifts the evidentiary basis of integrity from the final product to the trajectory of work. Iterative drafts, version histories, research journals and oral defence provide evidence of genuine engagement that a final text alone cannot supply.

The Springer analysis of AI-assisted misconduct and integrity frameworks in Education and Information Technologies treats these models as complementary rather than competing. Disclosure establishes the norm, contextual rules define its boundaries, and process evidence makes it verifiable. All three can be read as institutional translations of the fundamental values articulated by the International Center for Academic Integrity: honesty, trust, fairness, respect, responsibility and courage. The ICAI framing is significant because it defines integrity positively, as a set of commitments a learning community holds. A binary model defines it negatively, as the absence of detected violations.

These frameworks are increasingly grounded in extended versions of the Theory of Planned Behaviour. That theory explains academic misconduct as a function of attitudes, subjective norms and perceived behavioural control. The Education and Information Technologies study of AI-assisted misconduct shows how researchers have added technology-specific constructs to it: perceived instructor involvement, meaning how faculty engagement shapes student attitudes; detection awareness, which can deter misconduct or, perversely, drive more sophisticated evasion; and the perceived risk of AI use.

The ambivalent effect of detection awareness matters because it implies that publicising surveillance may not reduce misconduct. Its net effect remains unclear.

Qualitative work points the same way. The conceptual model of AI-assisted cheating developed from postgraduate student voices, published in Frontiers in Computer Science, locates students' decisions within their perceptions of assessment purpose, workload and the legitimacy of the task. It does not locate them within a simple calculation about the chance of being caught.

The broader implication is that the learning environment shapes integrity. Norms, relationships and the perceived legitimacy of assessment matter more than the threat of detection alone. This is why the most successful frameworks are pedagogical. They treat AI literacy, disclosure practice and assessment validity as components of the curriculum rather than as compliance obligations.

Research on individual dispositions adds a complementary but more cautious strand. Bennett and colleagues (2025) surveyed a stratified random sample of 78 undergraduates at a large U.S. university in Fall 2021. They used validated scales for ethical sensitivity and integrity perceptions, together with questions on honor code adherence and unauthorised resource use, and applied binary logistic regression to identify predictors of cheating in online courses. The

design is correlational and the sample small. It cannot show that ethical sensitivity or honor pledges cause lower misconduct. Its value lies in placing honor codes and ethical awareness within the same explanatory frame as the Theory of Planned Behaviour.

Pariyanti and colleagues (2025) studied 305 business and economics students at four private Indonesian universities. They frame integrity partly in terms of spiritual and ethical commitments, a reminder that the normative resources institutions draw on vary across cultural contexts.

Any assessment of how these frameworks are working runs into a measurement problem. The phenomenon they govern is hard to observe honestly. Surveys of students in the AI era report near-universal use of AI tools, which has made prohibition-based policies untenable and accelerated the shift to disclosure-based models. In some national contexts, reported use exceeds nine in ten undergraduates. The specific surveys behind that figure should be identified before it is relied upon.

Prevalence of use is not the same as prevalence of misconduct. Direct questioning about misconduct is also vulnerable to social desirability bias. Two recent studies address this with an indirect technique called the list experiment. In a list experiment, respondents report how many items on a list apply to them without saying which ones, which allows sensitive behaviour to be estimated at group level. Nguyen and Goto (2024) used this method with Vietnamese undergraduates to estimate the intentional misuse of AI chatbots for academic cheating, specifically to reduce the bias of self-report. Pariyanti and colleagues (2025) combined direct interviews with a list experiment among their 305 Indonesian students. They found that students were generally reluctant to admit dishonest behaviour, such as using AI for cheating, when asked directly, citing feelings of shame and social pressure.

This finding cuts two ways for disclosure-based frameworks. It confirms that directly elicited self-reports, the kind most institutional surveys rely on, probably understate AI-assisted misconduct. That suggests some optimism about disclosure regimes may rest on undercounted baselines. It also identifies the psychological obstacle disclosure models must overcome. If admitting AI use carries shame, students will under-disclose regardless of how permissive the formal policy is. The postgraduate testimony in the Frontiers conceptual model is consistent with this reading: students describe uncertainty and concealment as rational responses to unclear or stigmatising expectations.

The practical lesson is that disclosure works only where the institution has removed the stigma from legitimate use. Instructors who model disclosure themselves are one visible signal that this has happened.

With those measurement caveats, the evidence on implementation is mixed but instructive.

Institutions that adopted disclosure frameworks report several benefits. Students disclose more readily when the policy is specific about what must be disclosed and when instructors model disclosure themselves. The quality of integrity conversations improves when the framework is framed educationally rather than punitively. Disclosure frameworks also generate more honest exchanges about AI use and reduce the adversarial dynamic of detection. These reports come largely from institutional self-description. The "From Detection to Design" analysis and the sociotechnical literature treat them as promising rather than demonstrated.

The persistent problems are equally well documented. Disclosure rates remain uneven. Students remain uncertain about what counts as disclosable use, particularly at the boundary between assistance and authorship. Faculty vary widely in how they apply course-level policies. Without reliable detection tools, enforcement continues to rest on process evidence and oral review, which are resource-intensive. Zdravkova's (2026) finding of inconsistent scope and implementation in disclosure requirements corroborates these reports from outside individual institutions.

Disciplinary context adds a further complication. Seghier (2026) conducted a systematic review of generative AI and academic integrity in architectural education following PRISMA guidelines. He found that research on how generative AI affects authorship, assessment and studio culture is limited, and that evidence-based institutional guidance remains scarce. In studio-based disciplines, iterative and collaborative production is the norm, and generative tools are entering professional practice. Generic disclosure rules may sit uneasily with established ideas of authorship there. The review suggests that the tiered model may need to be specified at the level of the discipline as well as the course.

The commercial cheating industry has also adapted. Kreitz and Stoesz (2025) document how contract cheating providers have added generative AI to their websites to retain postsecondary customers. These providers rely on persuasive features such as assurances of quality and the words "guarantee" and "secure" to win students' trust. Kreitz and Stoesz tested an academic support literacy intervention intended to reduce undergraduates' trust in such sites. Their work

extends Bretag's earlier analysis of contract cheating into the AI era. It also illustrates the educational, rather than punitive, response that post-binary frameworks favour: teaching students to recognise manipulative marketing and to use legitimate academic support.

The research consensus is that the frameworks work when they are embedded in a wider system of assessment redesign and faculty development. They fail when adopted as standalone documents, without changing the assessment practices that create the temptation to cheat. That conclusion aligns with broader findings on the organisational conditions that separate successful AI adoption from unsuccessful adoption (see Q126). Credible disagreement remains, however, over how much weight disclosure can bear. Advocates see disclosure as the foundation of a trust-based culture. Critics such as Zdravkova question whether disclosed interactions can serve as reliable evidence of authentic work.

The direction of travel is toward what the "From Detection to Design" analysis calls rehumanized, validity-driven assessment. These are integrity frameworks designed to make honest engagement the most rational strategy for students, supported by process evidence and oral verification rather than surveillance.

Akintande (2024) makes a parallel argument from the assessment side. Because chatbots such as Copilot, Bard and ChatGPT generate text that resembles human writing, assessment must evolve beyond traditional methods. Educators should exploit the known weaknesses of AI systems and design tasks that foster creativity, rather than trying to police a product that tools can now fabricate convincingly. McGinty and Murray-Johnson's (2025) faculty framework points the same way. It places transparency and clear usage policies alongside equity and privacy, so integrity becomes one part of the responsible integration of AI rather than a freestanding enforcement problem.

This shift also changes the measure of success. Under the binary model, success was counted in detected cases. Under process-based integrity, the meaningful outcome is the proportion of students who can explain, when asked, what they used AI for and why that use was legitimate. That outcome connects directly to the ICAI's fundamental values: responsibility and honesty become capacities students practise, not rules they are caught breaking.

The evidence base for this transition remains thin. Most studies are cross-sectional, rely on self-report, or describe single institutions. Rigorous comparisons of student learning and integrity outcomes under different frameworks have yet to be produced. The list-experiment findings

show how easily self-report can mislead, and Seghier's review shows how unevenly guidance has developed across disciplines. Whether disclosure-centred, process-based regimes reduce misconduct, or merely make it more visible and less adversarial, remains unclear.

What the literature does support, from Bretag's pre-AI work through the current sociotechnical and rehumanizing accounts, is a negative conclusion: detection-led binary enforcement cannot sustain academic integrity under generative AI. It also supports a positive hypothesis worth testing. Integrity is most robust where assessment is valid, expectations are explicit, legitimate AI use carries no stigma, and faculty are equipped to apply policy consistently. International guidance has begun to encode similar principles (see Q070), but the evidence on implementation lags well behind the policy texts.

Q076 How are teacher unions, professional bodies, and accreditation agencies responding to AI, and what standards are they setting?

Scope: *Institutional standards, guidance and accreditation positions of unions, professional bodies and accreditation agencies. Negotiated outcomes (collective-bargaining agreements) are treated in Q255.*

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

Teacher unions, professional bodies and accreditation agencies have responded to AI faster and more substantively than many observers expected. Unions have produced detailed policy statements and guardrail documents. Professional associations have revised competency

frameworks. Accreditation agencies have begun, more cautiously, to write AI literacy and AI governance into their review criteria. Across these bodies, a recognisable set of standards is taking shape: transparency about how AI tools work and where they fail, human review of consequential decisions, consent before student data is used to train models, teacher participation in procurement, AI literacy in initial and continuing teacher education, and limits on AI in high-stakes evaluation. None of these organisations has settled into passive acceptance or blanket resistance. Their documents generally treat AI as a workplace and pedagogical change that educators should help govern rather than simply absorb. Their influence on institutional policy and on vendor behaviour appears to be growing, even though most of what they set out is not binding law.

The pattern of response differs by institution type, and the differences matter for interpretation. Unions moved first and furthest. Their texts, such as the National Education Association's policy statement and the American Federation of Teachers' guardrails, combine professional principles with labour concerns about surveillance, evaluation and job security. Global federations such as Education International add a transnational layer of advocacy. Professional bodies and accreditors write in a different register: competencies, programme requirements and review criteria. That register changes practice more slowly, but potentially more durably, because it attaches consequences to compliance. This answer covers those standard-setting positions. The negotiated contract outcomes that unions have secured belong to a separate question (see Q255).

In the United States, the two largest teacher unions have each issued a comprehensive AI framework. The National Education Association's 2024 policy statement rests on five principles: keeping students and educators at the centre of education; ensuring that AI use is evidence-based; prioritising ethical development and data protection; guaranteeing equitable access; and fostering AI literacy among students and staff.

The NEA has backed these principles with an "AI in Education Hub" of professional development resources. The Hub also offers sample school board policies that call for equity audits to identify and mitigate algorithmic bias. The audit provision turns a general principle into a procedural expectation that a district could adopt and be held to.

The American Federation of Teachers has taken a more activist line. Its "Commonsense Guardrails for Using Advanced Technology in Schools" sets out conditions for adoption, and

the union treats AI as a mandatory subject of collective bargaining rather than a matter for management discretion. In 2025 the AFT launched the National Academy for AI Instruction. According to the union's programme materials, this is a $23 million initiative run in partnership with Microsoft, OpenAI and Anthropic, designed to train educators in AI use while emphasising equity and bias guardrails. The AFT has also worked with industry partners on safety and privacy standards that it describes as enforceable, including a bar on using student data to train AI models.

The AFT's partnership model is the most contested feature of the American picture. It gives a union direct leverage over vendor practice. It also places the companies whose products are being governed inside the training of the teachers who will use them. Neither union's materials provide independent evidence on how that tension plays out, so its practical effect remains unclear. The figures the AFT cites describe the scale of investment, not outcomes, and should not be read as findings.

Despite their different tactics, the two unions share core concerns: algorithmic bias and equity, protection of teachers' professional judgement from AI-driven evaluation and surveillance, data privacy, and the risk that AI will be used to justify cutting staff. Both unions advocate union involvement in AI procurement and implementation decisions. Both push for contract language that protects educators from displacement and prevents AI from being used in high-stakes evaluation. How far such language has actually been won at the bargaining table is examined in Q255.

Outside the United States, teacher unions have been similarly active, with a stronger emphasis on binding regulation.

Education International is the global federation of education unions, representing some 32 million educators in 178 countries. It has developed a comprehensive AI policy framework centred on three commitments: human oversight, transparency, and protection of teachers' professional autonomy. Because Education International speaks for national unions with very different legal environments, its framework works mainly as a reference point that affiliates can adapt. It does not operate as a rulebook.

The European Trade Union Committee for Education (ETUCE) goes further. It calls for binding EU-level standards on AI in education, including mandatory human oversight of AI-generated assessments and prohibitions on AI-driven surveillance of teachers. This is a

meaningful divergence from the American unions. They pursue protections mainly through bargaining, guidance and partnerships, whereas ETUCE seeks to fix them in supranational law. The divergence partly reflects context: European unions can point to an existing regulatory architecture, discussed below, that US unions lack.

In the United Kingdom, the National Education Union and the Association of School and College Leaders have jointly developed guidance on AI in schools. The guidance emphasises teacher agency, data protection and the importance of keeping human judgement in assessment and pastoral care decisions. The joint authorship matters. A classroom teachers' union and a school leaders' association agreeing on these principles narrows the room for conflict between staff and management over AI adoption, at least at the level of stated policy.

These positions sit alongside the guidance of intergovernmental bodies such as UNESCO, the OECD and the EU (see Q070). Union frameworks often echo that guidance, but they add an explicit workplace dimension that intergovernmental documents tend to leave implicit.

Professional bodies and accreditation agencies have moved more slowly than unions, but their responses are beginning to have significant institutional effects.

The Council for the Accreditation of Educator Preparation (CAEP) has begun incorporating AI literacy requirements into its accreditation standards for initial teacher education programmes. This signals that AI competence will become a baseline expectation for newly qualified teachers in the United States. The International Society for Technology in Education (ISTE) has updated its educator standards to include AI-specific competencies. These include the ability to evaluate AI tools critically, to understand algorithmic bias, and to design assessments that hold up when students have access to AI. Because accreditation determines which programmes can prepare licensed teachers, CAEP's move could matter more in the long run than any union statement, provided the requirements are specified and enforced in programme review.

Recent research suggests why such requirements are being introduced, and how hard they may be to meet. Kelley and Wenzel (2025) observe that many teacher candidates remain unaware of AI's presence in their lives, despite the rise of generative AI and its reach into personal and professional spaces. In response, they describe an approach to building AI literacy in teacher education through professional partnership inquiry. Their account is a programme-level report, not a comparative trial. It suggests a model for meeting accreditation expectations, but it does not show that the model produces measurably more AI-literate teachers.

Leitgeb and Leitgeb (2025) point to a different way professional bodies might use AI itself. They deployed an AI-based chatbot to give context-sensitive, personalised professional development recommendations at scale in Austrian higher education, and evaluated it with mixed methods. Their stated rationale is that traditional programmes often neglect individual needs, subject-area demands and career stages, which limits their relevance and uptake. The available abstract does not report outcome measures, so the study should be read as a proof of concept rather than evidence that such tools improve professional learning.

The broader evidence base remains thin. In a scoping review, Baizhanov and colleagues (2026) mapped 33 peer-reviewed articles published between 2022 and 2026, identified through a bounded Web of Science search, on AI, machine learning and learning analytics in teacher assessment, modelling and professional development. The authors state that their purpose was to describe the extent, range and nature of the evidence, not to evaluate whether interventions work. They identify two broad lines of work in the corpus. A body of evidence this size, mapped rather than appraised, cannot yet tell standard-setters which AI competencies predict better teaching or which training designs build them.

The standards therefore run ahead of the evidence. That is not unusual for professional regulation, but it is a gap that formal evaluation of continuing professional development programmes needs to close (see Q254).

In higher education, accreditation bodies have been slower still. The US regional accreditors, including the Higher Learning Commission (HLC) and the Middle States Commission on Higher Education (MSCHE), have issued guidance on academic integrity in the AI era. They are beginning to incorporate AI governance into their institutional review processes.

The initial framing around academic integrity is telling. Accreditors' first move was to treat AI as a threat to assessment validity. Only later did they treat it as a curricular competence that graduates should possess or a governance matter institutions must manage. Questions about how examination and credentialing bodies are redesigning high-stakes assessment overlap with this shift, but sit outside the present scope.

Evidence from professional disciplines suggests the curricular gap is real. Writing about undergraduate medical education, Feigerlova (2026) argues that clinical teachers must be prepared not only to use AI tools but also to interpret, appraise and oversee their outputs safely and effectively. She reports that evidence indicates medical curricula have not kept pace with

technological adoption: structured AI education remains sparse or inconsistent across institutions. Medicine is one field, and Feigerlova's piece is a pedagogical argument rather than a systematic audit. Still, it illustrates a wider problem. Until accreditors specify what AI competence means in a discipline, institutions are left to define it locally, and the inconsistency she describes is the predictable result.

The picture is uneven rather than uniformly slow. Some accreditors appear to be moving from integrity guidance toward governance review, while discipline-level curricular expectations lag behind. Whether institutional review will eventually require evidence of AI-related learning outcomes, rather than AI policies alone, remains unclear.

Across unions, professional bodies and accreditors, the convergence is striking given their different mandates. Six common standards recur. AI tools used in education should be transparent about how they work and what their limitations are. AI-generated decisions that affect students should be subject to human review. Student data should not be used to train AI models without explicit consent. Teachers should have meaningful input into AI procurement and implementation. AI literacy should be part of initial teacher education and ongoing professional development. And AI should not be used for high-stakes evaluation of teachers or students without robust human oversight.

The NEA's principles, the AFT's guardrails, Education International's framework and ETUCE's demands each articulate most of these items. CAEP and ISTE supply the competency side.

These standards are not yet codified in binding law in most jurisdictions, but they increasingly shape institutional policy and vendor behaviour. The AFT's industry-facing privacy commitments are the clearest example of union standards reaching vendors directly, though the extent of vendor compliance has not been independently documented. In Europe, the EU AI Act's classification of certain educational AI systems as high-risk gives many of these standards a legal foundation. That foundation helps explain why ETUCE frames its demands as calls for binding rules rather than voluntary guidance.

Three limits should temper any assessment of this convergence. First, agreement on principles leaves open what counts as "meaningful" teacher input or "robust" oversight. Those definitions are being contested in bargaining and procurement, not settled in policy texts. Second, the research cited here (Kelley and Wenzel, 2025; Leitgeb and Leitgeb, 2025; Baizhanov and colleagues, 2026; Feigerlova, 2026) is early and largely descriptive. It suggests that AI literacy

provision is uneven and that the evidence on teacher competence is still being mapped, but it does not yet show which standards improve outcomes for students or teachers. Third, the documents of advocacy organisations describe intentions. How these standards operate in schools and universities will depend on enforcement through accreditation review, contract language and law.

This answer has concentrated on the standards, guidance and accreditation positions these bodies set. The negotiated outcomes of collective bargaining over AI, including specific contract clauses and disputes, are examined in Q255.

Q077 What funding models and public investments in AI for education exist, and what do early returns suggest about their effectiveness?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Funding for AI in education now runs through four main channels: reallocated national education grants, dedicated state and national strategies, philanthropic programmes, and public-private partnerships in which technology firms supply tools, money or training. Early returns suggest that investment works best when tools come with sustained professional development, teacher involvement and explicit equity provisions. Rigorous evidence that any of these models improves learning outcomes at scale remains thin. Since 2023 the field has moved from isolated pilots and philanthropic experiments toward more systematic public investment and more structured partnerships. That shift has outpaced the evaluation infrastructure needed to

judge it. Policymakers are therefore committing substantial sums on the strength of plausible mechanisms and promising early signals rather than demonstrated effects.

The kinds of evidence available differ sharply in weight. Government guidance documents, such as the US Department of Education's 2025 funding guidance, establish what money may be spent on, but they do not show what the spending achieves. Philanthropic reports, such as the Gates Foundation's account of early findings from its AI in education initiative, provide useful programme-level observations. They are produced by funders evaluating their own portfolios, however, and should be read as such. Market analyses, such as HolonIQ's global edtech report, describe investment flows. They are commercial projections, not research on effectiveness. A careful reading of the field means keeping these categories distinct and resisting the temptation to treat scale of spending as a proxy for impact.

The United States has chosen to integrate AI priorities into existing federal education funding rather than create dedicated AI funding streams. According to the Department of Education's July 2025 guidance, existing formula and discretionary grants may be used for AI-enhanced tutoring, personalised instructional materials, and college and career navigation tools, provided the uses meet regulatory requirements. These grants include Title I, Title IV-A (Student Support and Academic Enrichment) and Perkins V (career and technical education). The same guidance proposed a supplemental grantmaking priority specifically for AI. It targets three areas: professional development, the integration of AI literacy, and the reduction of administrative burden on educators.

This mainstreaming approach has real advantages. It avoids siloed AI programmes that might not survive a change in political priorities, and it places AI spending inside accountability structures that districts already understand and that auditors already monitor. Its limitations are equally real. AI investment must compete with other priorities within the same grant envelopes, so a district choosing AI tutoring may be choosing against counsellors, reading specialists or facilities. The model also depends on local capacity to design, justify and administer applications. Under-resourced districts, which arguably most need support, are often the least able to navigate complex grant processes. Flexibility at the federal level can therefore turn into inequality at the local level.

The research base that should inform these choices is itself unevenly funded. Taylor and Stan (2024) conducted a bibliometric and network analysis of AI research in US K-12 and higher

education. They examined which organisations fund peer-reviewed scholarship, which organisations receive the funding, and how funded research networks form. Their results suggest institutional stratification, and they found that non-US government organisations, including funders in China and Europe, finance many AI studies within US educational systems. This is a finding about research funding, not about classroom deployment. It does suggest, however, that the knowledge base on which American districts draw is shaped partly by funders outside the domestic policy process. It also suggests that research capacity is concentrated in certain institutions, a pattern that mirrors the deployment concerns discussed below.

States have been more active than the federal government in creating dedicated AI-in-education funding, though this activity is less well documented in the sources available here. California has moved to require AI literacy in K-12 curricula and has allocated dedicated funding for related professional development. Several other states have established AI innovation funds that support pilot programmes and research partnerships with universities and providers. These state-level instruments allow more targeted design than federal flexibility guidance permits. They can specify equity criteria, require evaluation and fund teacher learning directly rather than leaving those choices to individual districts.

State investment is, however, highly uneven. Well-resourced states with strong technology sectors have invested significantly. Lower-income states have lagged, which risks widening the digital divide between rather than within states. The stratification that Taylor and Stan (2024) identified in research funding networks offers a useful parallel. Their study concerns who funds and receives AI research, not who receives deployment money. Even so, both patterns point to the same structural tendency: resources flow toward institutions and jurisdictions that already have the capacity to attract them. Absent deliberate counterweights, a federal system that devolves AI investment decisions is likely to reproduce existing geographic inequalities. How these state instruments interact with emerging regulatory requirements is treated separately (see Q069).

The largest investments in AI for education have so far come through public-private partnerships and philanthropy rather than through public budgets alone. Google, Microsoft and OpenAI have committed substantial resources to free or subsidised AI tools for schools, research partnerships and professional development. The Gates Foundation and the National Science Foundation have together committed hundreds of millions of dollars to AI tutoring

pilots, evidence-building research and AI literacy curriculum development. The Gates Foundation's own reporting on early findings is among the more detailed programme-level accounts available. Its status as self-evaluation should be borne in mind.

A prominent example of a union-industry model is the American Federation of Teachers' National Academy for AI Instruction. According to the AFT's programme overview, it is funded at $23 million, with contributions from Microsoft, OpenAI and Anthropic, and it focuses on teacher professional development. Supporters see in this model a way to put teachers, through their union, at the centre of AI training rather than leaving it to vendors' sales teams. Sceptics worry that industry funding of teacher training shapes which tools teachers learn to use and how critically they learn to use them. Both readings are credible, and no independent evaluation has yet settled the matter.

The scale of private interest is evident in market projections. HolonIQ's 2025 market report projects the global AI-in-education market at $32.7 billion by the end of 2025. This is a commercial forecast, not a research finding, and it measures expected revenue rather than educational value. Its main analytical significance is what it reveals about the composition of investment. Most of this money is directed at commercial products rather than public goods such as open curricula, shared infrastructure or independent evaluation. The interests of commercial investors, including market share, data access and subscription revenue, do not always align with those of students and schools. Whether partnership agreements contain adequate governance, accountability and equity safeguards remains unclear, because few such agreements have been studied systematically. The debate over whether public-private partnerships accelerate access or entrench dependency is therefore unresolved. It is better described as genuinely disputed than as settled in either direction.

Outside the United States, several countries have made substantial national investments through centrally coordinated strategies. South Korea's AI Education National Strategy has committed significant public funding to AI literacy education and to the development of AI-powered learning platforms. The Ministry of Education's own implementation reporting describes early results. As with philanthropic self-reports, these are government accounts of government programmes rather than independent evaluations. Singapore's National AI Strategy 2.0 includes dedicated investment in AI for education, covering the development of AI tutoring systems alongside teacher professional development. The European Union's Digital Education Action Plan 2021-2027 provides funding for AI literacy and digital skills development across

member states. It operates through a supranational framework that leaves implementation largely to national systems.

These national models differ from the American approach in being explicitly strategic and dedicated. They name AI as a priority, attach funding to it and set implementation targets, rather than permitting AI spending within general grants. Centralisation offers coherence, scale and the possibility of system-wide evaluation. It also concentrates risk: a poorly designed national platform affects every school at once, whereas a failed district pilot affects a few. Comparative evidence on whether dedicated national strategies outperform devolved, flexible models does not yet exist. Programme designs, starting conditions and measured outcomes vary too much across countries for meaningful comparison. The regulatory frameworks within which these investments sit are compared elsewhere (see Q069).

Evidence on the effectiveness of public investment in AI for education is limited by the recency of most programmes and by the difficulty of attributing outcomes to particular funding streams. Several early findings are nonetheless emerging, chiefly from programme-level reporting such as the Gates Foundation's early findings. First, programmes that combine access to AI tools with sustained professional development appear to show stronger outcomes than those that provide tools alone. Second, equity-focused programmes that prioritise under-resourced schools show promise but require sustained investment to overcome infrastructure gaps. Third, programmes that involve teachers in design and implementation appear to achieve higher adoption and more effective use than top-down mandates. Each of these findings is plausible and consistent across the reporting available. None yet rests on the kind of replicated, controlled evidence that would justify calling it demonstrated. The wider question of effect sizes across AI interventions is addressed in a separate synthesis of systematic reviews and meta-analyses (see Q263).

The peer-reviewed literature on teachers is consistent with the importance of professional development. Jambunathan (2025) writes about integrating AI into early childhood teacher education and notes that many teachers have used AI to generate lesson plans, curricula or other content in early childhood special education and with English language learners. The paper also reports a major reason for limited enthusiasm: teachers felt they lacked the training to use AI confidently in their classrooms. This finding does not measure the return on any funding programme. It does support the logic of directing investment toward training rather than toward licences alone. Elyana and colleagues (2026) examine the role of teacher

competence, technological readiness and institutional support in AI-enhanced multicultural education in Indonesian early childhood settings. They observe that integrating AI with culturally responsive pedagogy remains largely unexplored in that sector. Their framing reinforces the view that tools succeed or fail through the human and institutional conditions surrounding them. Those conditions are precisely what funding models can strengthen or neglect, and they matter most where developmental stakes are high (see Q097).

Much of the recent sectoral literature is prospective rather than evaluative. Wang and Li (2024) describe AI's potential in public health education, including individualised educational programmes and support for health policy development. Claman and Sezgin (2024) set out the opportunities and challenges of large language models and multimodal foundation models in dental education. Both contributions map promise and risk, but neither reports outcome data on funded deployments. Taken together with the self-reported character of much programme evidence, this pattern suggests that the field's capacity to describe what AI might do substantially exceeds its capacity to show what public money has achieved.

The most significant risk identified in early evaluations is a digital divide effect. AI investment that is not explicitly designed around equity tends to benefit already-advantaged schools and students, and so may widen the achievement gaps it is often justified as closing. Several features of the current funding landscape make this risk concrete. Flexible federal grants favour districts with grant-writing capacity. State investment is concentrated in wealthier, technology-rich states. Private investment flows toward commercial products that schools must be able to afford, support and integrate. Even the research base appears stratified, according to the network analysis by Taylor and Stan (2024).

Effective public investment in AI for education must therefore include explicit equity provisions rather than assume that access will diffuse naturally. These provisions include infrastructure support, so that connectivity and devices do not become preconditions for participation. They include professional development targeted at under-resourced schools, consistent with the teacher-readiness concerns reported by Jambunathan (2025). And they include ongoing monitoring of equity effects, so that widening gaps are detected while programmes can still be adjusted. Funders should also require independent evaluation as a condition of large grants and partnerships, because the current reliance on self-reported results leaves policymakers unable to distinguish effective models from well-marketed ones. The early

returns justify continued, carefully structured investment. They do not yet justify confidence about which funding model works best, for whom, or at what cost.

Q144 What liability rules apply when an AI system harms a pupil's academic record or wellbeing?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

No single liability rule governs harm caused by AI in education. A pupil whose academic record or wellbeing is damaged by an AI system must instead rely on a patchwork of tort law, product liability, data-protection law, education law and sectoral AI regulation, and that patchwork varies sharply by jurisdiction. The harms in question differ in kind. They include a wrongly downgraded grade, a false academic-misconduct finding, a discriminatory placement or admissions decision, and psychological injury from an AI companion or screening tool. Each harm tends to activate a different legal route, and the same incident can engage several at once.

Despite this fragmentation, the field is converging on a common structure along three lines. First, AI systems used in education are increasingly classified as high-risk and regulated as such. Second, software is increasingly treated as a product, which brings it within strict-liability regimes once reserved for physical goods. Third, the institutions that deploy AI are increasingly held to a duty of care they cannot delegate to the machine. The RAND Corporation's research report on AI and tort liability and the University of Chicago Law Review Online's analysis of existing tort doctrines both argue that established doctrine can absorb most AI-related harms. In their account, negligence, product liability and related theories attach responsibility to

identifiable human and corporate actors rather than to the system itself. How quickly courts will adopt that view in educational settings remains unclear, because the case law specific to schools is still thin.

The European Union has gone furthest in converting liability questions into binding rules. The AI Act (Regulation (EU) 2024/1689) lists AI systems used in education and vocational training as high-risk under Annex III. This covers systems that determine access or admission to education, evaluate learning outcomes, assess the appropriate level of education for an individual, or monitor and detect prohibited behaviour during tests. Providers of high-risk systems must meet obligations for risk management, data governance, technical documentation and logging, transparency to deployers, human oversight, and accuracy and robustness. These obligations were originally scheduled to apply from August 2026, but the application date for Annex III systems has been subject to proposed postponement, with December 2027 the date now widely cited. Schools and vendors should therefore treat the compliance timetable as settled in substance but still moving in detail. Separately, the Act prohibits emotion-recognition systems in educational settings outright, apart from narrow medical and safety exceptions. That prohibition sets a regulatory floor that applies regardless of how a given system is classified.

Civil liability is more complicated. The European Commission had proposed an AI Liability Directive that would have created a rebuttable presumption of causation and allowed courts to order disclosure of evidence. Its purpose was to help claimants overcome the 'black box' problem of proving how an opaque system caused their loss. The European Parliament's legislative record shows that the Commission withdrew the proposal in October 2025. Fault-based claims in tort therefore remain governed by divergent national laws.

The principal EU-level civil remedy is now the revised Product Liability Directive (PLD). It entered into force in December 2024 and must be transposed by member states by December 2026. The revised PLD treats software, including AI systems, as a 'product' and subjects manufacturers and providers to strict liability for damage caused by defective products. As Freshfields' analysis explains, defectiveness is benchmarked against applicable safety requirements, which in practice turns AI Act compliance into a reference point for whether a product was defective. Non-compliance with the Act's high-risk obligations will therefore be powerful evidence in a PLD claim.

The directive also allows courts to presume defect and causation where technical or scientific complexity makes proof excessively difficult. It extends liability beyond the traditional 'factory gate' to cover software updates, upgrades and the continued learning of AI systems that remain under the manufacturer's control. Two limits matter for pupils. The PLD compensates death, personal injury including medically recognised psychological harm, property damage and data loss. It is far less obviously suited to reputational or educational loss such as a wrongly lowered grade. For a pupil harmed by a defective AI grading or admissions system, the PLD is the principal civil remedy in the EU. Whether courts will treat purely academic injury as compensable damage remains an open question.

The United States has no federal AI tort law. Claims proceed under state common law, chiefly negligence and products liability, supplemented by federal statutes. A school that deploys an AI system owes its students a duty of care. The live question is whether relying on an AI tool without adequate oversight breaches that duty. On the analysis in the RAND report and the University of Chicago Law Review Online piece, the 'human-in-the-loop' is generally treated as the party responsible for decisions made with AI assistance. A teacher or administrator who adopts an AI recommendation cannot easily disclaim it.

Products liability may reach the vendor if the AI is characterised as a product with a design defect or inadequate warnings. Courts are still resolving that characterisation, and the authorities disagree. Some commentators argue that software delivered as a service falls outside traditional products doctrine. Others contend that the functional similarity between mass-distributed software and manufactured goods justifies extending strict liability to it.

Federal statutes add specific obligations. The Family Educational Rights and Privacy Act (FERPA) governs the privacy of education records and gives parents and eligible students the right to seek correction of inaccurate records. The Children's Online Privacy Protection Act (COPPA) restricts the collection of personal data from children under 13. Title VI and Title IX prohibit discrimination in federally funded programmes, and biased AI assessment, proctoring or surveillance tools could trigger either. These statutes rarely provide private damages actions directly. They operate mainly through administrative enforcement and the conditions attached to federal funding.

A further structural obstacle is the 'educational malpractice' doctrine. American courts are highly reluctant to award damages for academic injury. They hold that grading, placement and

promotion decisions fall within educators' professional discretion unless they are arbitrary, capricious or made in bad faith. A pupil harmed by an AI grading error may therefore have strong procedural remedies, such as internal appeals, due-process challenges and administrative review, but only weak claims for damages. It remains unclear whether courts will extend the same deference to decisions effectively made by a vendor's algorithm. The doctrine's rationale rests on respect for professional educational judgement, and that rationale fits poorly when no educator exercised judgement at all.

Independent of tort, data-protection law gives pupils and parents direct, enforceable rights, and these are often the most practical route to redress. Under the GDPR, Article 22 restricts decisions based solely on automated processing that produce legal or similarly significant effects on the individual. Automated grading, admissions and placement decisions plausibly fall within that category. Where such decisions are permitted, affected students have the right to obtain human intervention, to express their point of view and to contest the decision. Articles 13 to 15 add a right to meaningful information about the logic involved. The Future of Privacy Forum's comprehensive analysis of Article 22 case law shows that courts and supervisory authorities have interpreted these provisions with increasing specificity. That body of decisions makes the scope of 'solely automated' and 'similarly significant' less speculative than it was when the GDPR took effect.

Schools that use AI for profiling or adaptive learning are generally required to conduct data-protection impact assessments before deployment. Violations can ground complaints to supervisory authorities and, under Article 82, claims for material or non-material damage. The availability and size of such compensation vary between member states. The particular protections owed to minors are treated more fully elsewhere (see Q072).

The United Kingdom's 2020 A-level controversy illustrates both the harm and the remedy. Examinations were cancelled during the pandemic, and Ofqual's statistical standardisation model was used to moderate teacher-assessed grades. According to Ofqual's own published results, the model lowered roughly 39% of those grades, and the downgrades fell disproportionately on students at state schools. The student Curtis Parfitt-Ford and the non-profit Foxglove threatened judicial review on grounds that included the Data Protection Act and the GDPR's automated decision-making provisions. Foxglove's account records that this challenge helped force the government to abandon the algorithm and award teacher-assessed grades. The case was never adjudicated, so it established no binding precedent. Even so, it is

the canonical demonstration of three points. Algorithmic harm to academic records is legally actionable. The threat of litigation can be an effective enforcement mechanism. And automated decision-making provisions can be deployed against public bodies as well as private companies.

Harms to wellbeing raise different legal questions, and the evidentiary base for them is thinner. Jukiewicz (2025) reviews the scientific literature on AI applications in education with a particular emphasis on student mental health. The review acknowledges that generative tools can automate aspects of teaching, personalise materials and improve learning efficiency. It also records emerging concerns about the quality of education, students' mental health and fundamental academic values. Because it is a literature review rather than a causal study, it identifies a risk domain rather than quantifying harm. That limitation matters in litigation, where causation must be proved for the individual claimant.

Where an AI system causes psychological injury, liability may attach in two places. It may fall on the vendor under product liability, or on the school under negligence if the school deployed the system without adequate safeguards. Conversational companions and mental-health screening tools are the obvious candidates. The most prominent test so far is the litigation in the United States against Character.AI. There, a federal court allowed product-liability and wrongful-death claims against the company and its founders to proceed, and declined at the motion-to-dismiss stage to treat the chatbot's output as protected speech that would bar the claims. That ruling is preliminary and does not decide liability. It does suggest that courts may be willing to treat conversational AI as a product. A related issue is what a school must do when a pupil discloses harm to an AI system rather than to an adult, which engages safeguarding duties beyond ordinary negligence (see Q182).

Academic-integrity harms sit between record and wellbeing. A false misconduct finding damages the record directly and can cause serious distress. Zdravkova (2026) observes that some universities and publishers increasingly require explicit disclosure of AI use, but that the scope and implementation of these requirements remain inconsistent. She also examines the reliability of disclosed AI interactions as evidence of authentic work. Seghier's (2026) PRISMA-guided systematic review of architectural education finds that research on how generative AI affects authorship, assessment and studio culture is limited, and that evidence-based institutional guidance remains scarce. Together these works suggest that institutions are making misconduct determinations without settled evidentiary standards. That is precisely the

condition under which an arbitrary-and-capricious challenge in the United States, or an Article 22 challenge in Europe, is most likely to succeed.

In Europe, the AI Act's high-risk obligations and its ban on emotion recognition in education create regulatory floors that claimants will increasingly cite in civil actions. The principle emerging across jurisdictions is that neither vendor nor school can escape liability by pointing to the AI's autonomy. The deployer's duty of care, the provider's product obligations and the data controller's responsibilities all attach to identifiable actors.

For schools and universities, this landscape translates into concrete obligations. Contracts should allocate responsibility between vendor and institution. They should specify liability, indemnities and audit rights for algorithmic error, and require the vendor to supply the documentation and logs that the AI Act demands of high-risk providers. How institutions can enforce such terms is examined in detail elsewhere (see Q264).

Any AI output that affects a pupil's record or welfare should be subject to genuine human oversight, not nominal sign-off. Oversight of that kind is what preserves the protection of the human-in-the-loop principle in US negligence law and satisfies Article 22's requirement of meaningful human intervention. Institutions should also complete data-protection impact assessments before deployment. They should maintain documented appeal procedures for AI-influenced decisions, including misconduct findings. And they should hold insurance that expressly covers algorithmic error, since many existing policies were drafted before such risks were contemplated.

Institutional capacity to meet these obligations is uneven, and its effects are under-researched. Potluri and Polozova (2026) frame AI as part of higher education's institutional infrastructure, extending beyond teaching into governance, administration and student support. Their study of Kazakhstan's higher education sector examines how AI governance readiness relates to administrative efficiency, AI fluency orientation and students' intentions to stay, with equity perception tested as a moderator. That governance readiness is now being measured as a construct in its own right suggests that liability exposure will increasingly depend on whether institutions can show deliberate governance rather than ad hoc adoption. The study is cross-sectional and confined to one national system, so it cannot establish whether readiness reduces harm.

The direction of travel is nonetheless clear. Education AI is moving from a largely unregulated space towards a regime in which harm to a pupil's academic record or wellbeing is actionable through multiple, overlapping legal routes. Under the PLD's presumptions and the GDPR's accountability principle, the burden of showing that a system was safe and properly overseen falls increasingly on the provider and the school rather than on the pupil.

Q145 How are age limits and child-safety requirements for AI products enforced, if at all?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

Age limits and child-safety requirements for AI products are enforced selectively, reactively and unevenly. The rules exist in abundance, but whether they bite depends on jurisdiction, on how visible a harm has become, and on whether a regulator can identify both a responsible company and a demonstrable violation. The gap between the rules on the books and the rules in practice is one of the defining features of the current regulatory landscape.

Enforcement is real and increasingly muscular in a few high-profile areas. In the United States, the Federal Trade Commission polices children's privacy under the Children's Online Privacy Protection Act. In the United Kingdom, the Online Safety Act now imposes positive age-assurance duties on providers. In the European Union, the Commission has proposed dedicated rules on minimum ages and platform design. Even so, most AI products still rely on self-declared age, and most violations are never detected.

For educators, the practical consequence is that a school cannot assume the age floor printed in a vendor's terms of service corresponds to any operational control. This answer takes each of the main regimes in turn. It then considers private litigation and state action as a parallel enforcement channel, and finally the structural gaps that persist across all of them. Those gaps are partly legal and jurisdictional, partly technical, and partly a matter of how schools and their leaders govern the tools they adopt.

The principal United States instrument is the Children's Online Privacy Protection Act (COPPA). It requires verifiable parental consent before an operator collects personal information from children under 13. Enforcement rests with the Federal Trade Commission, and the agency has been active in both enforcement and rulemaking, as its own record of cases and rule revisions shows.

Two moves bear directly on education. In 2022 the FTC issued a policy statement making clear that edtech providers cannot outsource their COPPA obligations to schools. In 2023 it settled charges against the edtech platform Edmodo on three counts: collecting children's data for advertising, retaining that data too long, and shifting compliance duties onto schools. The settlement carried a $6 million penalty, suspended because the company was closing. More consequentially, it required Edmodo to delete algorithms trained on improperly collected data. That remedy matters for AI in particular, because it reaches the model built from the data and not only the data itself.

The 2025 amendments to the COPPA Rule, enforceable from April 2026, extend this logic. They expand the definition of "personal information" to include biometric and government-issued identifiers. They require separate parental consent where children's data is used to train AI systems. They also oblige operators to maintain written data-retention policies. Each provision closes a route by which AI developers had previously treated children's data as raw material.

In February 2026 the FTC issued a further policy statement. It grants enforcement discretion to operators that collect limited data solely for age verification. This signals a deliberate push toward privacy-preserving age assurance and an attempt to remove the perverse incentive whereby verifying a child's age could itself trigger COPPA liability. The agency has also opened a Section 6(b) inquiry into AI companion chatbots and their effects on minors. That study power allows it to compel information from companies without first alleging a violation.

The US pattern is therefore one of active but narrow enforcement. The FTC acts, sometimes with structurally significant remedies, when it can identify a company and a violation. It cannot police the thousands of AI products that minors actually use, and age verification across that long tail remains largely self-reported.

The United Kingdom has the most developed age-appropriateness regime, built in two layers. The first is the Age Appropriate Design Code, known as the Children's Code, which the Information Commissioner's Office has enforced since September 2021. It applies to any online service likely to be accessed by under-18s, not merely services directed at children, and sets fifteen standards. These include high-privacy settings by default, data minimisation, and prohibitions on manipulative "nudge" design that steers children toward weaker privacy choices or prolonged engagement. Because the Code is framed around likely access rather than intended audience, general-purpose AI tools that children use in practice fall within its scope.

The second layer, the Online Safety Act 2023, goes considerably further. Since July 2025, services hosting content harmful to children must deploy "highly effective" age assurance, and government guidance states explicitly that self-declaration is insufficient. Acceptable methods include facial age estimation, photo-ID matching and digital identity services.

Ofcom, the regulator, holds substantial powers. Under the Act it can fine non-compliant platforms up to £18 million or 10 per cent of global turnover. It can also seek business-disruption orders that cut off payment or access services, and pursue criminal liability against senior managers. It has already opened investigations into pornography and file-sharing services.

The UK regime is the clearest example of age limits being enforced as a positive duty on providers rather than a paper rule. Whether that duty extends cleanly to conversational AI, as distinct from content-hosting platforms, is less settled. The early investigations have focused on categories of service where harmful content is easiest to define.

The European Union approaches the problem from two directions. The AI Act supplies prohibitions and high-risk obligations. It bans emotion recognition in education and workplaces, and it classifies AI used in education as high-risk, with compliance duties applying from December 2027. These provisions govern what AI systems in schools may do, but they do not themselves establish age floors for consumer AI products that children use outside school.

To fill that gap, the Commission proposed the KIDS Act in September 2026. As the Commission's explanatory materials describe it, the proposal would set a minimum age of 15 for autonomous social-media accounts and require guardian-managed "mini-accounts" for 13- to 15-year-olds. It would mandate privacy-preserving age verification based on zero-knowledge proofs, explicitly excluding simple self-declaration. It would also require audited compliance plans from very large platforms and place investigations on an expedited 90-day timeline.

The zero-knowledge design is notable. It aims to let a user prove they are above a threshold without disclosing identity or date of birth, which addresses the privacy objection that has dogged age assurance elsewhere.

The KIDS Act is a proposal, not yet law. Its final scope, including how far it will reach AI chatbots and companions as opposed to social-media services, remains unclear. Its trajectory will test whether the EU can convert regulatory ambition into operational enforcement, a conversion the bloc has historically found harder than drafting.

Where regulators are slow, private lawsuits have become a de facto enforcement mechanism. The clearest example is the litigation against Character.AI in the United States. Families alleged that the platform's chatbots fostered emotional dependency and contributed to self-harm and suicides among minors. The litigation produced a landmark ruling that the chatbot is a "product" subject to product-liability standards. This characterisation matters because it imports duties of safe design and adequate warning that were developed for physical goods. In January 2026 five major cases were settled.

In late 2025, under the pressure of litigation and public scrutiny, the company also restricted under-18 users from open-ended chatbot conversations. This change came from neither statute nor regulator. That a significant age restriction emerged this way illustrates how liability exposure can achieve what formal age limits had not (see Q144 for the wider liability rules that apply when AI harms a pupil's wellbeing).

State attorneys general have added pressure. In August 2025, 44 state attorneys general warned AI developers that they would be held accountable for harm to children. California and New York have enacted statutes requiring safety features in AI companion models, such as break reminders and crisis-referral protocols.

Litigation and state action are thus filling the gap left by the absence of a comprehensive federal child-safety law for AI. The resulting patchwork has costs. Protections vary by state of residence. Settlements typically resolve individual claims without producing binding precedent on design standards. Companies may adjust policies in response to bad publicity and then relax them when attention moves elsewhere.

For all this activity, the enforcement gaps are substantial. Most AI products' terms of service set age floors of 13 or 18 that are enforced only by self-declaration. Age-assurance technology is not standardised, and regulators themselves acknowledge the trade-off between verification and privacy. That acknowledgement is evident in the FTC's February 2026 enforcement discretion and in the EU's turn to zero-knowledge proofs.

The difficulty is not only practical. Moore (2026) argues that a recurring class of AI failures arises because the observation regime under which a system acts may fail to preserve the distinctions required by the predicate it is asked to decide. In his formulation, a predicate is decidable from observations only when it factors through the partition those observations induce. Moore's paper is a general theoretical argument, not a study of age verification, so applying it here is an extrapolation. It nonetheless offers a precise way to see why self-declaration fails. If the only observation a service records is a box the user ticks, nothing in that observation separates a 12-year-old from an adult. No amount of downstream optimisation can recover a distinction that was never captured. Facial estimation and document checks enlarge what is observed, which is why regulators treat them as qualitatively different. The privacy cost of that enlargement is exactly what the regulatory debate is about.

Three further gaps compound the technical one. First, enforcement is reactive. It follows documented harm, complaints or media attention rather than preventing harm. Second, cross-border jurisdiction is a persistent problem. A service hosted abroad may simply ignore a national regulator's demands, as the UK's experience with offshore platforms shows. Third, education contains a structural loophole of its own. Under COPPA, schools may consent on behalf of parents for educational purposes, so a child's age is effectively determined by the institution rather than verified. The FTC's insistence that vendors cannot shift their obligations onto schools narrows this loophole but does not close it.

These gaps place real weight on institutional governance. Ali (2026), in a conceptual paper using theory synthesis and model-building, argues that traditional technology-governance

models are insufficient for AI in education. Ali proposes a Moral Compass Model through which leaders navigate algorithmic decision-making, data governance and equity. The model is untested empirically. Its premise, that compliance cannot be delegated entirely to external regulators, fits the enforcement picture described here.

In practice, school leaders who procure AI tools can write age-assurance, data-retention and AI-training restrictions into contracts rather than relying on vendors' terms (see Q264 on enforcing vendor obligations contractually). The same verification problem surfaces in assessment. Stanoyevitch (2024) describes how online assessment integrity came under unprecedented strain from exam-assistance platforms and tools such as ChatGPT. That account parallels the difficulty of confirming who, and how old, the person behind a screen actually is (see Q074).

The overall picture is of a system in motion. Age limits and child-safety requirements for AI products are being enforced more seriously than at any previous point, through privacy regulation, platform-safety duties, product-liability litigation and state legislation. Enforcement nonetheless remains uneven, jurisdiction-bound and heavily dependent on the visibility of harm. Whether privacy-preserving verification can scale fast enough to change that remains unclear.

Q264 What transparency, explainability, and audit obligations are being imposed on AI vendors supplying education systems, and how can schools enforce them contractually?

12 citations · 12 sources · 5 cross-references

Claim 1 established

Schools increasingly rely on AI systems whose inner workings they cannot see. Vendors supply tutoring platforms, grading assistants, early-warning systems, and proctoring tools built on models trained on undisclosed data and updated without notice. Transparency, explainability, and audit obligations are intended to correct this asymmetry, giving schools and regulators the information needed to evaluate systems and hold vendors accountable. Such obligations are now emerging through law, regulation, and voluntary standards, and schools can strengthen them through contracts.

The most comprehensive statutory framework is the European Union's Artificial Intelligence Act, Regulation 2024/1689. Annex III classifies as high-risk AI systems intended to determine access or admission to educational institutions, evaluate learning outcomes, assess the appropriate level of education an individual will receive, and monitor or detect prohibited behaviour during tests. Providers of high-risk systems must maintain technical documentation, establish risk-management and data-governance processes, keep automatically generated logs, provide instructions for use that enable deployers to interpret outputs, design systems for effective human oversight, and register them in an EU database. Deployers, which include schools, must use systems according to instructions, assign human oversight, and in some cases conduct fundamental-rights impact assessments. The Act also requires transparency when people interact with AI systems and prohibits emotion recognition in educational settings except for medical or safety reasons. High-risk obligations are being phased in, so their practical effect on education vendors is still developing.

In the United States, obligations arise mainly through privacy law and enforcement rather than AI-specific statutes. The Federal Trade Commission's amended Children's Online Privacy Protection Rule, published in April 2025, requires operators serving children under 13 to disclose data practices, maintain written information-security programmes and data-retention policies, and obtain separate consent for third-party disclosures not integral to the service. The FTC's 2023 action against Edmodo, which resulted in an order requiring deletion of data and of models developed from improperly collected children's information, demonstrated that regulators may scrutinise how data flow into AI development. Federal guidance has also emphasised transparency: the U.S. Department of Education's 2023 report on AI and the future of teaching and learning called for AI systems that are inspectable, explainable, and overseen by humans.

Voluntary mechanisms fill some gaps. Digital Promise's Responsibly Designed AI certification, launched in 2025, requires products to meet criteria on privacy, security, bias mitigation, transparency including labelling of AI-generated content, and educator control. Certification gives schools a signal of baseline practices, though it depends on vendor participation and periodic renewal.

Schools can translate these principles into enforceable contract terms. Documentation clauses can require vendors to provide model or system cards describing intended uses, training data sources at an appropriate level of detail, known limitations, evaluation results including performance across student subgroups, and safety measures. Explainability clauses can require that systems affecting individual students, such as grading or risk-flagging tools, provide reasons that teachers can understand and communicate to students and families. Change-notification clauses can require advance notice of material changes to underlying models, data practices, or subprocessors, with a right to terminate if changes are unacceptable.

Audit clauses are central to enforcement. Contracts can grant schools or their designated independent auditors the right to review compliance with data and transparency commitments, request evidence of bias and accuracy testing, and receive incident reports. Logging requirements can ensure that records of system outputs are retained long enough to investigate complaints. Remedy clauses can specify consequences for non-compliance, including suspension, termination without penalty, data deletion, and indemnification.

Individual schools often lack the leverage and expertise to negotiate such terms, which is why collective approaches matter. The Student Data Privacy Consortium's National Data Privacy Agreement offers standard terms that many U.S. districts use, and similar templates could be extended with AI-specific transparency provisions. State or regional procurement consortia can set common requirements, conduct shared evaluations, and pool audit resources.

The demand for transparency in educational algorithms is sharpened by a prominent failure that preceded generative AI. When examinations in England were cancelled in 2020 because of the pandemic, the qualifications regulator Ofqual used a statistical standardisation model to adjust teachers' assessed grades, drawing heavily on schools' historical results. Ofqual's interim report, published in August 2020, documented that about 39 percent of teacher-assessed A level grades were lowered by the model, and because the model relied more heavily on teachers' grades for subjects with small numbers of entries, which were more common in independent schools,

students in larger cohorts were more exposed to statistical adjustment. After public protest, the government announced that students would receive the higher of their teacher-assessed grade and the calculated grade. The model was not a machine-learning system, but the episode illustrated the issues that transparency and audit obligations aim to address: affected students could not easily understand how their grades had been produced, the design choices embedded value judgements that had not been widely debated, and errors at the level of individuals were difficult to contest. For schools procuring AI systems today, the case suggests that disclosure of methods should occur before deployment, and that subgroup analyses of likely effects should be part of the evidence a provider supplies.

Data protection law already supplies some explanation rights that apply to educational AI in Europe, independent of the AI Act. The General Data Protection Regulation, Regulation 2016/679, requires controllers to provide meaningful information about the logic involved in automated decision-making, as well as its significance and envisaged consequences, and Article 22 gives individuals the right not to be subject to decisions based solely on automated processing that produce legal or similarly significant effects, subject to exceptions with safeguards such as the right to obtain human intervention and to contest the decision. Legal scholars have debated how far these provisions amount to a right to an explanation of individual decisions, and their application to education, where schools act as controllers and vendors usually as processors, depends on how a system is used. The practical implication for contracts is that schools subject to the GDPR need vendors to supply enough information about system logic to enable the school to meet its own disclosure obligations, and that processor agreements should require vendors to support data subjects' rights, including requests for human review.

Documentation practices developed in the research community give concrete content to transparency clauses. Timnit Gebru and colleagues, in Datasheets for Datasets published in Communications of the ACM in 2021, proposed that every dataset be accompanied by a document describing its motivation, composition, collection process, preprocessing, recommended uses, distribution and maintenance, by analogy with the datasheets that accompany electronic components. Applied to education procurement, datasheet-style disclosures would tell a school whether a grading model was trained on essays from students resembling its own population, whether data from minors were used, and how the vendor handled consent. Such documentation does not by itself guarantee quality, and vendors may

provide descriptions too general to be useful, which is why contracts benefit from specifying the questions that must be answered rather than simply requiring documentation in general terms. Pairing dataset documentation with model-level documentation of evaluation results across student subgroups allows schools to compare products on a common basis.

Explainability obligations raise a technical question about what kind of explanation is possible and reliable. Cynthia Rudin, in a 2019 article in Nature Machine Intelligence, argued that post hoc explanations of black-box models can be unfaithful to what the model actually computes, and that for high-stakes decisions organisations should prefer inherently interpretable models where these perform comparably, which she reported is often the case for problems with structured data. Her argument bears directly on educational early-warning systems and risk-flagging tools, which typically use structured data such as attendance, grades and behaviour records, and for which simpler interpretable models may achieve similar accuracy to complex ones. Schools could reflect this in procurement by asking vendors to justify the use of opaque models for consequential decisions about individual students and to report the performance of interpretable alternatives. For generative AI tutors and writing assistants, where interpretable alternatives are not available, explainability obligations may focus instead on transparency about system behaviour, limitations and testing rather than on explanations of individual outputs.

Audit rights require clarity about what an audit involves, a question that research on algorithmic accountability has addressed. Inioluwa Deborah Raji and colleagues, in a 2020 paper presented at the ACM Conference on Fairness, Accountability, and Transparency, proposed an end-to-end framework for internal algorithmic auditing structured around stages of scoping, mapping, artefact collection, testing and reflection, with documentation produced at each stage so that decisions can be reviewed later. They argued that audits are most useful when integrated into development rather than conducted only after deployment. For schools, this suggests that contracts should require vendors to share internal audit documentation, not only to permit external audits, and should specify the artefacts to be produced, such as risk assessments, test results by subgroup and records of design decisions. Independent external audits remain valuable for checking vendor claims, but they are costly, and the scarcity of qualified auditors familiar with education means that consortia are better placed than individual schools to commission them.

Risk management frameworks provide a vocabulary that schools and vendors can share even where law does not require it. The National Institute of Standards and Technology's AI Risk Management Framework, published in January 2023, organises AI risk management into four functions, govern, map, measure and manage, and describes characteristics of trustworthy AI including validity and reliability, safety, security and resilience, accountability and transparency, explainability and interpretability, privacy enhancement, and fairness with harmful bias managed. The framework is voluntary in the United States, but procurement documents can reference it by asking vendors to describe how their practices align with each function, which gives schools a structured basis for comparing responses. Because the framework is general rather than education-specific, schools need to supplement it with criteria particular to students, such as age-appropriate design and safeguards against using student data to train commercial models.

Comparing jurisdictions shows a divergence that matters for vendors operating internationally and for schools buying from them. European schools can rely on statutory obligations under the AI Act and the GDPR that vendors must meet regardless of contract terms, whereas schools in the United States depend more heavily on contractual negotiation, sector-specific privacy statutes and FTC enforcement against unfair or deceptive practices. In practice, vendors serving both markets may extend documentation prepared for European compliance to other customers, which could raise transparency elsewhere, but there is no guarantee that they will do so voluntarily. Equity concerns follow from this divergence and from differences within countries: well-resourced districts with legal staff can negotiate stronger terms, while small and rural districts often accept standard vendor agreements. Shared contract templates, state-level model clauses and collective procurement are the most practical means of ensuring that transparency and audit protections do not depend on a district's size or wealth.

Generative AI systems create a further challenge for transparency because their behaviour can shift when the underlying model is updated, sometimes without any change to the product's name or interface. A tutoring tool that was evaluated as accurate and age-appropriate in one term may behave differently in the next if the vendor switches to a newer model or adjusts its safety filters. Change-notification clauses, discussed above, address part of this problem, but schools may also need rights to know which foundation model and version a product uses, to receive summaries of testing conducted after each material update, and to access a stable version for a defined period while they evaluate changes. Vendors that build on third-party

models may themselves have limited visibility into upstream changes, which suggests that contracts should require them to pass through relevant information from their model providers and to disclose when they cannot. Without such provisions, evaluations conducted at the time of procurement may say little about the system students actually use months later.

Evidence on how consistently these obligations are enforced remains limited, and few published audits of educational AI systems exist. Trade-secret claims may limit disclosure, and explanations of complex models can be incomplete or misleading. Even so, the direction of regulation and practice suggests that schools that specify transparency, explanation, and audit rights in their contracts, and that act collectively, are better positioned to hold vendors accountable than those relying on general assurances.

Q277 How should governments and universities regulate AI systems used for admissions, grading, proctoring, and other high-stakes educational decisions now that frameworks such as the EU AI Act classify them as high-risk?

14 citations · 14 sources · 4 cross-references

Claim 1 disputed

Governments and universities should regulate AI used for admissions, grading, proctoring and similar decisions according to the consequence of the decision, not the novelty of the technique. In practice that means four commitments. A small set of uses should be prohibited outright. The remaining high-stakes uses should face pre-deployment validation and ongoing subgroup audits. Every affected student should have a meaningful route to contest an outcome. Accountable human authority over each decision must stay with an identifiable institution. The European Union's Artificial Intelligence Act (European Parliament and Council, 2024) supplies the clearest legal baseline. Annex III point 3 classifies as high-risk those systems intended to

determine access or admission to educational and vocational training institutions at all levels, or to assign people to them, and systems intended to evaluate learning outcomes, including where those outcomes are used to steer the learning process. Separately, Article 5(1)(f) prohibits AI systems that infer the emotions of a natural person in education institutions, except where the system is intended for medical or safety reasons. The Act therefore draws two lines at once. Some educational inferences are treated as illegitimate in principle. Others are permitted but carry the weight of high-risk designation.

That legal architecture is necessary but not sufficient, and this essay argues that it should be treated as a floor. Veale and Zuiderveen Borgesius (2021), analysing the Commission's 2021 draft, placed the Act within four decades of EU product-safety regulation. They concluded that differentiated rules for different risk levels make sense, but that some provisions carry surprising legal implications and others may be largely ineffective at achieving their stated goals. Their concern matters for education. A product-safety logic regulates the artefact a vendor places on the market. Educational harm, by contrast, usually arises in deployment: when a university decides what a score means, who sees it and what happens next. Holmes and colleagues (2022) frame the same gap ethically. They distinguish doing ethical things from doing things ethically, and argue that good intentions in AIED research are not by themselves sufficient. Regulation that certifies tools but leaves institutional practice unexamined addresses only the first half of that distinction. The sections that follow therefore treat the high-risk classification as the start of governance rather than its completion.

The case for treating these systems as high-risk rests on an evidentiary record that is now substantial. The most instructive episode remains the 2020 calculated-grades crisis. Kelly (2021) traces how England and Ireland, after cancelling state examinations during the pandemic, each adopted purpose-built algorithms to issue grades. Those policies then came undone in the face of appeals, protest and legal action. The two governments began with similar approaches but diverged before and after results were issued, with significantly different outcomes. The lesson for regulators is that legitimacy in high-stakes assessment is institutional and political as well as statistical. A model can be defensible on aggregate accuracy and still collapse once individuals see decisions they cannot reconcile with their own records, and once there is no credible mechanism to resolve the dispute.

The bias literature reinforces this lesson. Baker and Hawn (2022) reviewed the empirical evidence on how algorithmic bias has actually manifested in education. Their review centres on

concrete impacts: which groups are known to be affected, and which stages and agents in development and deployment are implicated. That framing is useful for regulators because it locates responsibility across the pipeline rather than solely in the model. On admissions specifically, Marcinkowski and colleagues (2020) note that machine-learning systems can process large volumes of student data efficiently. They also observe that criticism centres on disparate effects, because algorithms may reproduce biases present in their training data rather than act as objective decision-makers. Gándara and colleagues (2024) give the concern empirical texture for student-success prediction. Such models increasingly inform admissions, budgeting and intervention decisions. The authors examined whether prediction accuracy differs between racialized groups, treated such differences as a signal of algorithmic bias, and evaluated leading bias-mitigation techniques. Their starting premise sets the regulatory problem precisely: predictive algorithms rely on historical data and therefore capture societal injustices, including racism. An admissions or progression system trained on past outcomes inherits the conditions that produced them, unless someone is obliged to check.

What, then, should a validation and audit regime actually require? Kizilcec and Lee (2020) offer a workable scaffold. They divide algorithmic systems into measurement, model learning and action, and identify distinct sources of bias and discrimination at each stage. A regulator or university governance committee can map obligations onto those components. At the measurement stage, the question is whether the outcome being predicted, such as degree completion, is itself a fair proxy for what the institution values. At the model stage, the question is whether performance holds across groups. At the action stage, the question is what decision follows from a score and who is affected by it. Requiring evidence at all three stages would move compliance away from vendor-supplied accuracy summaries and towards scrutiny of how a system is used locally. Contractual mechanisms for securing that evidence from suppliers are treated elsewhere (see Q264).

Any such regime must also confront a technical constraint that the law does not resolve: fairness is not a single quantity. Lee and Kizilcec (2020) built a student-success model from university administrative records. They found gender and racial bias on two of the three fairness measures they considered, and post-hoc adjustments to improve fairness exposed trade-offs among those measures. Regulators therefore cannot simply instruct institutions to deploy fair systems. They must require institutions to state which fairness criterion they have prioritised, why it suits the specific decision, and what the cost is on the criteria not chosen.

Those choices should be recorded and open to challenge. Whether available mitigation techniques narrow group disparities enough to justify deployment in admissions remains unclear. Gándara and colleagues (2024) evaluated the utility of such techniques, but the broader evidence base is too thin to set general thresholds.

Automated grading illustrates the same need for evidence that is specific to each context. Deepshikha (2025) synthesised 77 core studies published between 2018 and 2025. The review reports that machine learning, natural language processing and computer vision show significant potential for consistent grading and personalised feedback, with benefits including reduced workload and faster turnaround. Large-scale benchmarks against human experts are scarcer. Jauhiainen and Garagorry Guerra (2026) evaluated GPT-4o, using a reranked retrieval-augmented framework, on 1,016 students' open-ended responses from Finland's national matriculation examination. They examined agreement with official grades, recognition of grading-relevant keywords, and the effect of translating responses from Finnish into English. The design itself carries a regulatory point. Performance may depend on the resource level of the language in which students write. Validation conducted in one language or examination context should not be assumed to transfer, and conformity documentation should state the populations and languages on which a grading system was actually tested. How examination bodies are redesigning assessment around these tools is addressed separately (see Q074).

Proctoring and integrity monitoring deserve separate treatment, because their harms reach beyond inaccurate decisions to the conditions under which students are assessed. Coghlan, Miller and Paterson (2021) document the controversy that accompanied the pandemic boom in online exam supervision, where AI systems are supplemented by human invigilators. Some students experience these tools as a 'Big Brother-like' threat to liberty and privacy and as potentially unfair and discriminatory. Some universities and educators, however, defend their judicious use. The disagreement is genuine, and regulation should not pretend otherwise. The more productive regulatory stance is a proportionality test. Institutions should be required to show that remote supervision is necessary for a given assessment and that less intrusive designs were considered. They should also show that any automated flag is treated as a prompt for human review, never as a finding of misconduct.

The AI Act's prohibition on emotion inference in education institutions (European Parliament and Council, 2024) draws a firm line here. Any proctoring feature that claims to read anxiety, deception or engagement from facial or vocal signals falls within the prohibited category unless

it is intended for medical or safety reasons. Universities outside the EU's jurisdiction would do well to adopt the same exclusion as institutional policy. The scientific and ethical grounds for inferring inner states during an examination are weak enough that permitting such features invites exactly the kind of legitimacy crisis Kelly (2021) describes.

Misconduct detection more broadly shows how integrity tools can themselves become sources of discrimination. Liang and colleagues (2023) found that GPT detectors frequently misclassify non-native English writing as AI-generated. They warn that this risks marginalising non-native speakers in evaluative and educational settings. A detector of this kind is not formally an admissions or grading system. When its output triggers a misconduct process, however, it affects grades and academic standing as directly as any scoring model. Governance should therefore classify tools by their downstream consequences. A university that would subject an automated grader to high-risk scrutiny but allows a detector score to initiate disciplinary action has regulated the label rather than the decision. The related problem of AI-written application materials in admissions raises parallel concerns (see Q206).

Contestability is the provision most likely to determine whether high-risk educational AI retains public legitimacy. The 2020 grading episodes turned on appeals as much as on algorithms (Kelly, 2021). The governments involved discovered that an appeal route designed for a handful of disputed human judgements could not absorb mass challenges to a statistical model. Regulation should therefore require institutions to provision appeals at a scale proportionate to the number of affected students before deployment, rather than treat appeals as an afterthought.

The content of an explanation matters as much as its availability. Wachter, Mittelstadt and Russell (2017) argued that implementing a GDPR-style right to explanation by opening the black box faces major legal and technical barriers. They noted that explaining a complex system's functionality and rationale in specific cases is technically hard, and some such explanations offer data subjects little meaningful information. Their alternative is the counterfactual explanation, which tells a person what would have needed to differ for the outcome to change, without requiring public understanding of how the system works. For education this is attractive. An applicant told which factors, had they been different, would have altered an admissions decision has something actionable to contest or correct. A student given only an abstract account of model architecture does not. Universities should be expected to provide explanations of this decision-relevant kind, alongside a named human decision-

maker with genuine authority to overturn the system's output. Counterfactuals have limits, though. They describe the model's behaviour, not whether the underlying criteria are just. They cannot by themselves reveal the group-level disparities that Baker and Hawn (2022) and Gándara and colleagues (2024) document, which only aggregate auditing exposes. Individual explanation and systemic audit are complements, and a regime that offers only one is incomplete. Where contestation fails and a student's record is harmed, questions of legal responsibility arise; those are treated elsewhere (see Q144).

A sensible division of labour follows from this analysis. Governments are best placed to set the floor. That means defining prohibited uses and high-risk categories, mandating documentation and subgroup testing, and resourcing regulators who can examine vendors across many institutions. Universities and examination bodies cannot outsource the rest. They decide what a score is used for, which fairness trade-off is acceptable for a given decision, how proctoring is justified, and whether appeals are adequately staffed. These are the action-stage choices that Kizilcec and Lee (2020) identify as distinct sources of discrimination. An institution that has purchased a compliant tool has not thereby made a compliant decision. University governance should therefore include standing review of each high-risk deployment, with published records of the purpose, the validation evidence, the fairness criterion chosen and the outcomes of appeals. Ethical principles for AIED, of the kind Holmes and colleagues (2022) propose, become operational only when they are embedded in such procedures.

The limits of current evidence should temper confidence in any particular regulatory design. The AI Act's education provisions are new. The most detailed scholarly assessment available here analysed the draft rather than the adopted text, and it warned that some provisions may prove ineffective (Veale & Zuiderveen Borgesius, 2021). Few studies have yet evaluated whether high-risk designation changes institutional behaviour, reduces disparate outcomes or improves students' ability to contest decisions. The fairness literature demonstrates that bias exists and that mitigation involves trade-offs (Lee & Kizilcec, 2020). It does not yet tell regulators what level of residual disparity is tolerable in admissions or grading, and that judgement is normative rather than technical. Evidence on large language model grading in high-stakes, multilingual settings is only beginning to accumulate (Jauhiainen & Garagorry Guerra, 2026). What the record does establish is narrower but firm. Automated systems making consequential educational decisions have failed publicly when deployed without credible validation, transparency and appeal (Kelly, 2021). They have encoded historical inequities

(Gándara et al., 2024; Marcinkowski et al., 2020). Their integrity tools have disadvantaged identifiable groups (Liang et al., 2023). Regulation built on that record, and revised as better evidence on implementation arrives, is the defensible course.

Chapter 10: Practical Navigation — Guides for Teachers, Students, and Leaders

14 questions · 177 citations · 167 unique sources · 70 cross-references

Q078 How should a teacher decide, lesson by lesson, when AI use helps learning and when it undermines it — is there a practical decision framework?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Yes. A teacher can decide lesson by lesson by asking five questions of any proposed AI use: what cognitive work the objective requires the student to do, whether AI enhances or replaces that work, whether there is evidence it improves learning, whether the use is transparent, and whether it is equitable. Whether AI helps or undermines learning cannot be settled once, at the level of policy. A tool that serves one lesson well can damage the next. The deciding variable is not the technology but the relationship between the tool and what a particular task is meant to teach. The question therefore has to be answered repeatedly, at the level of the individual lesson and task.

Two kinds of resources support that judgement. The first is the set of technology-integration frameworks that predate generative AI. The second is a newer group of AI-specific frameworks that adapt them. Work on teacher decision-making and AI integration published in Computers and Education: Artificial Intelligence treats the classroom decision itself, rather than the tool, as the unit of analysis. The OECD's Digital Education Outlook 2023 frames effective use as inseparable from equitable use and from deliberately designed guardrails. Synthesising these strands yields a decision procedure a teacher can apply in minutes. The procedure does not replace professional judgement. It gives that judgement a structure that can be explained to students, parents and colleagues.

The established frameworks supply the vocabulary on which the AI-specific work builds. The TPACK framework (Technological, Pedagogical and Content Knowledge) places effective technology use at the intersection of three kinds of knowledge: what a teacher knows about the

subject, about teaching, and about the tool. Its implication for AI is direct. An AI use is sound only when the teacher understands how the tool interacts with the specific content and pedagogy of the lesson. General familiarity with a chatbot is not enough on its own, and neither is general pedagogical skill. An extension of TPACK to artificial intelligence in the Journal of Technology and Science Education makes this explicit. It argues that AI introduces forms of technological knowledge the original model did not anticipate, including how a generative system produces output and where that output is unreliable.

The SAMR model (Substitution, Augmentation, Modification, Redefinition) offers a different resource: a scale. At the lower levels, AI replaces or enhances existing practice. At the higher levels, it enables tasks that were previously impossible. The practical insight is that substitution is rarely worth the risks. Using AI to do what a worksheet or search engine already did brings the hazards of the technology without new pedagogical gain. Redefinition is where the pedagogical value lies, because there AI creates learning experiences that could not otherwise exist. Viden.ai's overview tracing a path from SAMR through TPACK to AI-CoACT presents the two models as complementary. SAMR describes the degree of change a tool introduces. TPACK describes the knowledge a teacher needs to make that change wisely.

Both frameworks are best understood as heuristics rather than validated measurement instruments. SAMR in particular describes levels of transformation but does not itself demonstrate that higher levels produce more learning. A redefinition-level task can still fail if it removes the cognitive work the objective requires. The procedure below therefore treats SAMR as a prompt for reflection rather than as a ladder to climb.

Researchers have extended these models for generative AI. The extensions agree on direction but differ in emphasis. Intelligent-TPACK (i-TPACK), discussed in a recent synthesis of AI integration frameworks in Education Sciences, adds AI ethics and AI-technological content knowledge to the original TPACK domains. In this model, teachers act as ethical gatekeepers who evaluate fairness, transparency and data privacy before a tool reaches students. AI-CoACT, as Viden.ai describes it, proposes a four-phase cycle of Awareness, Integration, Collaboration and Transformation. It treats human-AI co-creation as an iterative process of planning, action and reflection rather than a one-off adoption decision. The PSAMR variant adds a prohibition level to SAMR. That level expresses something the original scale could not: some AI uses must be restricted to preserve academic integrity, and declining a tool can be a legitimate pedagogical outcome rather than a failure to innovate.

UNESCO's AI Competency Framework for Teachers organises the same territory into five dimensions across three progression levels: Acquire, Deepen and Create. It states explicitly that teachers must not lose core competencies through over-reliance on AI. The principle that human capability must be protected rather than hollowed out applies equally to students, and it underpins the first two questions of the procedure. The OECD's guidance adds a governance layer. In that guidance, guardrails, human oversight and attention to equity are not optional additions. They must be designed into any use from the outset.

The main tension among these frameworks concerns ambition. AI-CoACT and the higher levels of SAMR orient teachers toward transformation. PSAMR and UNESCO's principle on over-reliance orient them toward restraint. These positions are not contradictory, but they rest on different starting assumptions about risk. A teacher reading across them will find no single authoritative answer to how much AI is too much. Comparative evidence on which framework produces better classroom decisions remains unclear.

These frameworks condense into five questions.

The first is the objective question. What is the specific learning objective of this task, and what cognitive work must remain the student's own for that objective to be met? If the objective is to practise argumentation, the argument must be the student's. If the objective is to learn how to interrogate AI output, the AI is itself the object of study, and its use is the point of the lesson.

The second is the enhancement question: does AI use enhance or replace the learning activity? Enhancement preserves the student's cognitive work, as when AI acts as a scaffold, a source of feedback or a generator of practice problems. Replacement eliminates that work, as when AI produces the product the student was meant to produce. This question translates SAMR into the terms that matter for learning.

The third is the evidence question: is there reason to believe this use improves learning outcomes, or is its appeal mainly novelty? Research on AI tutoring suggests that AI supports learning when it is designed to scaffold, question and give feedback. The same research suggests that AI undermines learning when it simply supplies direct answers. The pattern is consistent across the tutoring work this volume reviews elsewhere. Much of that work, however, comes from short studies in particular subjects, so teachers should treat it as a strong default rather than a guarantee.

The fourth is the integrity question: is this use transparent, disclosed, and consistent with the course's assessment policy? Undisclosed use corrodes trust even when it is pedagogically defensible. How students should document their use is treated elsewhere (see Q083).

The fifth is the equity question. Does every student have equivalent access and support, and does the use disadvantage any group? A tool that advantages students with better devices, paid subscriptions or stronger prompting skills can widen the gaps it was meant to close. The OECD places this concern alongside effectiveness rather than after it. Equity also concerns the tool's own judgements. Warr and Heath (2025) audited how large language models scored and gave feedback on student writing samples paired with student descriptions. They found implicit biases: models assigned lower scores when students were said to attend an "inner-city school" or to prefer rap music. Their argument is that such systems carry a hidden curriculum while appearing objective. A teacher considering AI feedback or grading should therefore ask not only who can access the tool but whom its outputs may quietly penalise.

The questions map onto the frameworks already discussed. Objective and enhancement draw on TPACK and SAMR. Integrity draws on PSAMR and on i-TPACK's ethical gatekeeping. Equity draws on the OECD and UNESCO. The evidence question asks teachers to apply to AI the standard they would apply to any instructional choice.

The framework is easiest to see in application. Consider a history teacher planning a lesson on the causes of the First World War.

The objective question comes first. Students must construct and defend a multi-causal argument, so the synthesis and the argument must remain theirs. The enhancement question distinguishes between possible tools. An AI tool that generates a timeline of events, or quizzes students on chronology, enhances the lesson by providing practice and scaffolding. An AI tool that produces the essay replaces the learning. The evidence question points the same way: the tutoring evidence suggests the quiz and timeline uses are likely to improve outcomes, while essay generation is likely to undermine them. The integrity question depends on assessment context. If the essay is graded, any AI assistance must be disclosed and governed by course policy, whereas the quiz may require no disclosure at all. The equity question requires that every student have equivalent access to the tool and equivalent instruction in using it.

The decision follows from the five answers. The timeline and quiz are permitted, drafting assistance must be disclosed, and AI-written essays are prohibited. The teacher can explain the

decision to students in exactly those terms, and that explainability is part of the framework's value. Students who understand why a use is permitted or prohibited are more likely to comply, and more likely to learn the judgement themselves (see Q081).

The same questions apply when AI enters the teacher's own planning. A growing number of teachers use AI to draft lesson plans, which raises a prior question: does the plan itself embody sound pedagogy? Karaismailoglu, Surmeli and Yildirim (2026) asked science education experts to evaluate plans generated by two AI platforms, one general-purpose and one education-focused. The plans followed an Engineering Design-Based Learning approach for a sixth-grade science unit and incorporated four skill dimensions from the revised Turkish science curriculum. The study was motivated by continuing concerns about the pedagogical validity and theoretical alignment of such plans. A single-unit case study with expert raters cannot establish how AI-generated plans perform in general. Its design does model a check every teacher can run: judging an AI-drafted plan against the intended approach and curricular objectives before adopting it, rather than assuming fluent output is sound.

How that judgement unfolds in practice is only beginning to be studied. Flavin, Hwang and Morales (2025) note that little attention has been paid to how teacher candidates construct prompts and evaluate AI output in real time when planning mathematics lessons. Treating ChatGPT as a social agent within a sociotechnical system, they examine how knowledge is constructed dynamically and negotiated through interaction. Their framing implies that evaluation happens within the conversation, not only at the end. Vernholz, Sims and Treagust (2026) start from a related worry, that providing comprehensive lesson plans may lead pre-service teachers to rely on them excessively. Their conceptual design paper describes a tool that instead gives self-efficacy-strengthening feedback on candidates' own plans. As a design proposal it offers no outcome evidence. It nonetheless applies the enhancement question to teachers: feedback preserves the planner's cognitive work, whereas a finished plan replaces it. Running the objective and enhancement questions on one's own planning is the teacher-side counterpart of running them on students' tasks. It also enacts UNESCO's warning against losing core competencies through over-reliance.

The framework does not remove professional judgement; it structures it. The same AI use can be transformative in one lesson and corrosive in another, depending on the objective, the students and the assessment context. A feedback tool that sharpens a confident writer's

revisions may become a crutch or a source of pressure for an anxious student. Whether AI affects anxiety and perfectionism remains an unsettled question (see Q183).

Judgement of this kind is easier to develop collectively. Lesseig and Hoppe (2024) followed middle school mathematics teachers through three years of Mathematics Studio, an adaptation of lesson study. They identified discourse practices that supported a culture of inquiry: adopting a research lens, sharing a language of affordances and constraints, and keeping a consistent orientation toward student learning. The study does not concern AI and rests on a single case. Still, the structures it describes fit the five-question procedure closely. A department that habitually asks what a tool affords and constrains for a given objective is already running the enhancement and evidence questions together. Such a department is more likely to treat each AI decision as a genuine question about instruction.

AI may itself take part in that collaborative work. Agostini, Serbati, Picasso and colleagues (2026) report a mixed-methods quasi-experimental study in which ChatGPT was positioned as a peer-like feedback provider during student-teachers' group lesson design. The study combined a counterbalanced crossover structure for knowledge assessment with a sequential two-task design for producing authentic artefacts. The authors note that research on large language models as peer-like contributors in collaborative learning remains limited. Whether such positioning reliably strengthens planning judgement therefore remains unclear. The study nonetheless illustrates AI-CoACT's collaboration phase, and it suggests that teachers' own experience of AI as a feedback partner may shape how they design its use for students.

What the frameworks supply is a discipline. Teachers who run the five questions make decisions that are defensible to students, parents and colleagues, and those decisions keep the learning objective, not the technology, as the unit of analysis. The same reasoning helps when a decision is tested by unexpected AI-written work (see Q147). That discipline is the practical answer to the lesson-by-lesson question.

Q079 What are the current best practices for designing AI-resilient and AI-inclusive assignments and assessments?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Current best practice is to stop relying on detection and to design assessments that are both AI-resilient and AI-inclusive. AI-resilient assessments resist being completed by AI without genuine learning. AI-inclusive assessments explicitly teach students to use AI well. The two goals complement each other. Research and institutional guidance have converged on this diagnosis because detection-based approaches have proved unreliable, inequitable and unsustainable. Assignment and assessment design has therefore become the central arena of academic integrity in the generative-AI era.

The case against detection is the clearest point of agreement in the field. Nikolić and Nikolić (2026), writing in Frontiers in Artificial Intelligence, start from the observation that generative tools produce polished academic text on demand. That capability undermines any assessment that treats a written submission as evidence of individual learning. They also note that detection-based countermeasures have shown variable accuracy and raised equity concerns. Institutional reviews of assessment redesign, such as the overview indexed by the National Library of Medicine, and teaching-centre guidance, such as Northern Michigan University's advice on designing out AI misuse, describe the same pattern in more detail. Detectors show significant false-positive rates. They show systematic bias against non-native English speakers, whose more formulaic prose is more likely to be flagged. And they set off an arms race in which students refine evasion techniques faster than tools can adapt. For these reasons institutions increasingly advise that a detector score should never be the sole evidence of misconduct. Teachers facing a suspected case need a protocol grounded in conversation and process evidence rather than software output (see Q147).

The design alternative reverses the logic of surveillance. It makes genuine learning the most effective path to success, so that the assessment itself does the work of ensuring integrity. The

rest of this answer sets out what that alternative involves, how strong its evidence base is, and where it remains contested.

The most widely cited organising scheme is the four-pillar framework proposed by Nikolić and Nikolić (2026). It is explicitly conceptual. The authors state that the paper reports no empirical outcomes or validation data, so it should be read as a reasoned synthesis rather than a tested model. Its central move is to shift evaluation away from the quality of the product. It moves evaluation towards demonstrable reasoning, decision-making and ownership of learning.

The first pillar is process-based documentation. These assessments make the learning trajectory visible through annotated bibliographies, iterative drafts with a reflection at each stage, research journals and version histories. AI can generate a final text. A documented trajectory of drafts, revisions and reflections is far harder to fabricate, and it gives the assessor something to interrogate.

The second pillar is oral defence. Vivas, presentations with questioning and follow-up discussions require students to justify and extend their reasoning in real time. They provide strong evidence of individual competence, which AI cannot supply on the student's behalf. Recent work in Assessment and Evaluation in Higher Education makes the case for verbal examinations in business education specifically. It presents them as a way of restoring confidence that the person being credited is the person who did the thinking.

The third pillar is authentic task design. Here assessments are anchored in local datasets, recent seminar discussions, personal workplace experience or other situated contexts that generic AI output cannot easily satisfy.

The fourth pillar is transparent AI-use policy aligned with intended learning outcomes. Rather than banning AI, such policies define legitimate use, require students to disclose their prompts, and ask them to reflect on what the AI produced. This builds digital literacy and a sense of ethical responsibility. Northern Michigan University's guidance makes similar recommendations from a practitioner standpoint. That convergence is reassuring.

The framework's coherence should not be mistaken for proof of effectiveness. Whether its pillars, alone or combined, actually raise the validity of assessment remains unclear until comparative studies are published.

Empirical work on specific redesigns is beginning to fill this gap, though it is still small in scale. A useful example is the field experiment by Renjewski and Strasser (2026) in the master's course "Applied Biorobotics". They replaced generative report-writing with error identification and correction. The study compared two traditional report-writing assignments with a redesigned assignment in which students corrected deliberately flawed reports. To limit collaboration, the instructors produced four versions of the flawed report, each with a different set of errors. Grading concentrated on how well students detected and corrected the errors.

The authors complemented these results with student questionnaires and with heuristic testing of how well large language models could do the task themselves. Their aim was to show how such a redesign can reduce the effectiveness of generative AI while preserving core learning outcomes and higher-order competencies. The design is instructive for two reasons. It shifts the cognitive demand from producing text, at which AI is strong, to diagnosing faults against domain knowledge, where situated expertise matters more. It also turns a known weakness of AI, its tendency to produce confident but flawed output, into a teaching resource. Still, this is a single course in one discipline. The heuristic model testing reflects the capabilities of models at the time of the study. How far the results transfer to other subjects, or to more capable future systems, remains unclear.

Redesigns of this kind usually start with a vulnerability audit. This is a systematic review of existing assignments to identify which ones AI could complete without the student learning anything. Teaching centres such as Northern Michigan University's present the audit as the standard first step. Learning-design providers such as FeedbackFruits describe comparable diagnostic processes. However, FeedbackFruits is a commercial vendor, and its blog should be read as practitioner guidance rather than independent research. The audit tends to reveal that generic essay prompts, standard problem sets and unsupervised summaries are the most exposed formats. Tasks that require local data, personal experience, live interaction or error diagnosis are the most robust.

The complementary strand of best practice treats AI as a legitimate object and instrument of learning rather than only a threat. AI-inclusive assignments teach students to interrogate AI output, check its claims, and use AI as a drafting and feedback tool under defined conditions. Three designs recur in institutional guidance, including the redesign literature indexed by the National Library of Medicine.

The first asks students to critique an AI-generated text, identifying its errors and biases. This assesses critical evaluation, a skill now as basic as summarising.

The second asks students to improve on AI output through their own analysis. This assesses the ability to add value beyond what automation can produce, which is increasingly how expert work is defined.

The third asks students to document their AI use: what they asked, what they got, what they changed and why. This assesses metacognition and awareness of their own process.

AI-inclusive design is therefore not a retreat from rigour. It deliberately widens what assessment can measure.

The International Baccalaureate offers the most developed example from a global credentialing body. Its guidance works through thirteen scenarios of AI use in coursework. Some uses are acceptable when acknowledged, such as research, summarising counter-positions and using structural templates. Others count as misconduct, such as essays written by AI, fabricated quotations and assessments translated by machine. Teachers authenticate work through oral questioning and process evidence rather than software. The scenario format is useful because it turns abstract principles into concrete judgements that teachers and students can discuss.

A further development extends inclusion to the writing of policy itself. Hingle and Johri (2026) report an exploratory study in which students co-designed a course policy on generative AI. Students first drafted individual policy proposals on appropriate and ethical use. They then refined these collaboratively by taking account of the perspectives of different stakeholders. As an exploratory study, it does not show that co-designed policies produce better compliance or learning. It does suggest that policy development can itself be a learning activity, building the ethical reasoning that transparent-use policies assume students already have. Writing, implementing and updating such policies at school level is treated in detail elsewhere (see Q265).

Institutions that have put these principles into practice report several conditions that make them work. Rubrics that weight process, oral defence and reasoning equally with the final product make the design principles enforceable. Without such weighting, students rationally optimise for the product. Structured oral protocols and learning-design tools allow oral components to scale beyond the seminar room. FeedbackFruits and similar providers promote such tooling,

although evidence of their effectiveness at scale comes largely from vendors rather than independent evaluation.

Faculty development is the precondition for all of this. Teachers need time and training to redesign assessments. Institutions that provide that support report that the design principles take root, while those that issue guidance without support find it ignored. Survey research reinforces the point. Fiorucci and Bevilacqua (2026) adapted and validated, for Italian schools, an instrument for measuring teachers' attitudes towards AI and examined how those attitudes vary with socio-professional variables. They frame such measurement as necessary for identifying acceptance, resistance and professional development needs. In other words, teachers do not arrive at assessment redesign with uniform readiness.

"Inclusive" also carries a second meaning that best practice increasingly recognises: designing for learner variability and equity. Mokhlesse and Hafdi Idrissi (2026) set out a nexus between AI and Universal Design for Learning in teacher education. They argue that diverse higher-education classrooms are poorly served by one-size-fits-all methods, and that Universal Design for Learning offers a proactive route to accessible teaching. Applied to assessment, this suggests that AI-resilient design should offer multiple valid ways for students to demonstrate learning.

That principle has practical consequences. Oral defence can disadvantage anxious students, students with certain disabilities and second-language speakers, so it should not become the only route to verification. Similarly, AI-inclusive tasks presume access to capable tools. Where students' access differs, an assignment that requires AI use can widen the very inequities that detector bias exposed. Approaches for low-resource settings are discussed elsewhere (see Q088). The tension between resilience, which often favours live and supervised performance, and accessibility, which favours flexibility, is not yet resolved in the literature.

The idea that unifies these practices is that assessment should make the student's thinking visible. Process documentation makes the trajectory visible. Oral defence makes the reasoning visible. Authentic tasks make the application visible. Disclosure makes the use of tools visible. Institutions that have adopted this principle report that it changes the character of the relationship between student and teacher. It replaces the adversarial dynamic of detection with a collaborative dynamic of evidence, a shift that matters both pedagogically and ethically.

The early evidence is encouraging but incomplete. Institutions report that process-based and oral assessments generate more authentic evidence of learning and reduce adversarial encounters. The International Baccalaureate's experience suggests that teacher authentication supported by oral questioning can work at scale. The argument for verbal examinations in business education makes the same case at programme level. Yet most of this evidence is institutional self-report or conceptual argument. The leading framework expressly offers no validation data. Controlled studies such as Renjewski and Strasser's remain confined to single courses.

The field is also not of one mind. Stewart (2026) analysed discussions in the two largest higher-education communities on Reddit through a critical AI media literacy lens. The analysis finds faculty perceptions marked by pedagogical tension, alongside imaginative possibilities. It also raises concerns about power, agency and access that go beyond assessment technique. Some instructors see AI-inclusive design as genuine renewal. Others see it as accommodating a technology that erodes the foundational skills assessment is meant to certify. That disagreement is real, and redesign guidance does not settle it.

Two open questions stand out. The first is economic: oral assessment at national scale is expensive, and no source here shows how to fund it sustainably. The second is cultural: integrity based on design requires institutions and students to understand assessment differently, not as a product to be submitted but as a process to be evidenced. That shift depends on governance at classroom level, so that teachers apply policies consistently (see Q231).

Despite these uncertainties, the direction of travel is clear. Current best practice is to design assessments that make honest, visible engagement the most rational strategy for students. AI should be treated as a tool whose use is taught, disclosed and evaluated, not as a threat to be detected.

Q081 How should students use AI as a study partner in ways that demonstrably strengthen rather than weaken their learning?

11 citations · 11 sources · 5 cross-references

Claim 1 emerging

Students strengthen their learning with AI when they use it to make themselves think: to be questioned, to get feedback on their own attempts, and to be scaffolded through difficult problems. They weaken it when they let the tool supply the answers or products they were meant to produce. That is the now-substantial empirical answer, and the effect depends almost entirely on how the tool is used. Randomized controlled trials and field experiments show that AI can produce large learning gains when it acts as a scaffolded study partner, and comparably large losses when it substitutes for cognitive effort. The research supports a set of concrete practices that follow from that contrast.

The positive evidence comes from several well-designed studies. In a randomized study of college students published in Scientific Reports, students using a pedagogically designed AI tutor achieved significantly higher post-test scores than peers in traditional in-class active learning. Their learning gains were roughly double, often achieved in less time. An IZA discussion paper comparing access models found that unrestricted access to an AI tutor improved test performance by 0.23 standard deviations relative to a control group. An exploratory randomized trial in UK classrooms tested LearnLM, a pedagogically fine-tuned tutor. It found a 5.5 percentage point advantage in solving novel problems compared with human tutoring alone, and reported that the tutoring could be delivered safely. The Brookings synthesis of generative AI tutoring research draws these strands together. Tutoring that scaffolds, questions and provides feedback produces substantial gains, including in knowledge transfer, which is the ability to solve problems the student has not seen before.

These results warrant both confidence and caution. They are consistent in direction across settings and designs, which is why they carry weight. But they mostly involve purpose-built tools rather than the general chatbots most students actually open. The interventions are often

short and cover particular subjects and age groups, and the UK trial describes itself as exploratory. The studies demonstrate that well-designed AI tutoring can produce gains, not that any AI use by any student will. The gains belong to the design and the manner of use, which is why student practice matters.

The same literature documents the failure modes, and they mirror the successes. The most damaging is direct-answer use. When AI supplies the answer or produces the product the student was meant to produce, the learning the task was designed to occasion does not take place. The clearest evidence comes from a field experiment in Turkish high schools, reported in the Brookings synthesis. Students who had used an unguided, answer-supplying AI performed 17 per cent worse once access was removed. Strong performance while the tool was available masked a loss of durable skill: the AI substituted for, rather than built, the competence later measured.

Passive uptake is the subtler failure. Students who accept AI suggestions without reflection or critical engagement show short-term performance gains that do not persist, because the improvement lives in the output rather than in the student. The Brookings synthesis states the principle bluntly: AI helps when it is designed to make students think, and hurts when it is designed to think for them.

Students and educators sometimes recognise this risk themselves. Bhatara and colleagues (2026) conducted a convergent mixed-methods study of dental postgraduate students in India. They framed ChatGPT as offering potential benefits while carrying implications for increased dependency and academic detachment, and examined use, effectiveness and concerns together. Their questionnaire-based design explores use and perceptions rather than measuring learning, so it cannot establish that dependency actually occurred. Its value lies in placing dependency on the agenda within a specific student population, not only in abstract commentary. Whether students' awareness of the risk changes their behaviour remains unclear. How tools themselves can be built to resist cognitive offloading is a separate design question (see Q030). For students, the implication is that resisting offloading is partly their own responsibility.

Five study-partner practices follow from the evidence. First, use AI to generate practice and questioning rather than answers. Ask the tool to quiz you, to pose Socratic follow-up questions, to identify errors in your own work, and to explain concepts in multiple ways. These were the features that distinguished the effective tutors in the Scientific Reports and UK trials.

Second, use AI for feedback on your own drafts and attempts, not to produce first drafts. Research on automated feedback shows that AI feedback on student work improves writing performance, but only when the student has done the work being critiqued. Feedback on a text the machine wrote teaches no one.

Third, use AI to scaffold difficult problems rather than to bypass them. It can break problems into steps, provide worked examples of analogous problems, and offer hints that escalate only when you are genuinely stuck. The decisive step, the one that requires the reasoning the task exists to build, should remain yours. The UK trial's tutor was fine-tuned to guide students toward solutions rather than hand them over, and its advantage on novel problems suggests why this matters: students who are led to construct a solution acquire something they can carry to unfamiliar cases.

Fourth, attempt before you ask. Working on a problem, a reading or a draft before consulting the tool ensures that the AI responds to your thinking rather than replacing it. The attempt is where retrieval, error and correction happen, and an AI consulted only after a genuine attempt becomes a source of feedback rather than a substitute for effort. Where a general chatbot is the only tool available, students can approximate a purpose-built tutor by instructing it explicitly: tell it not to give the answer, to ask one question at a time, and to wait for a response before continuing.

Fifth, regularly test yourself without the tool. The Turkish field experiment showed that performance with AI and performance without it can diverge sharply, and that the divergence is invisible while the tool is in use. Closing the laptop and working a problem, explaining a concept aloud or writing a paragraph unaided is the only reliable way to find out whether competence has moved from the screen into your own head. If it has not, the remedy is more practice, not more AI output.

How AI enters a student's study routine also matters, and students are not the only ones who shape that. FutureEd's review of the field describes two emerging strategies for using AI in tutoring: one in which AI supports or works alongside human tutors, and one in which AI tutors students more directly. The distinction is useful for students because it clarifies what role the tool is playing at any given moment. An AI that helps a human tutor or teacher spot a misconception sits inside a relationship of accountability; an AI used alone at midnight does not, and the student must supply the discipline that a human would otherwise provide.

The IZA paper's framing as a comparison of access models underlines the same point from another direction. The terms on which students reach the tool, how freely and under what structure, are themselves a variable that can shape outcomes, not a neutral background. The UK trial's comparison with human tutoring alone likewise points toward combination rather than replacement as a productive arrangement.

For students, the practical consequence is to treat AI as one part of a wider learning system rather than as the whole of it. Where teachers, tutors or study groups are available, AI can be used to prepare for those encounters and to extend them afterwards: rehearsing questions before a seminar, generating extra practice on a topic a tutor flagged, or checking understanding between sessions. Students can also bring AI-generated explanations back to a teacher to have them checked, which guards against the confident errors that general chatbots still produce. Used this way, the tool amplifies human instruction instead of quietly displacing the effortful parts of it.

Using AI well is also a competence that can be learned, rather than a matter of willpower alone. UNESCO's AI Competency Framework for Students (2024) sets out four dimensions: a human-centred mindset, the ethics of AI, AI techniques and applications, and AI system design, with progression from understanding through applying to creating. The framework's emphasis on human agency fits the evidence above. A student who understands what a language model is doing when it generates an answer, and who keeps responsibility for judgement, is better placed to use it as a partner rather than an oracle.

Students' own accounts suggest this competence cannot be assumed. Sandstrak and Borlund (2026) interviewed 17 higher-education students, spanning bachelor, master's and executive programmes, about how they use AI-based tools in their studies and how they reflect on that use. A stated aim was to identify the areas where students require assistance or lack information. That such gaps were an explicit object of inquiry signals that guidance on productive use is often missing, and that students frequently work out their practices alone. With so small a sample, the study illuminates experience rather than measuring prevalence.

Two survey studies point in a related direction. Güler and Demirdel (2026), in a cross-sectional study of 438 physiotherapy and rehabilitation students in Türkiye, found career optimism more closely associated with AI literacy than with AI anxiety. Aloud and Alotaibi (2026) modelled the relationships among awareness and knowledge of generative AI, desire to use it and fear of

using it in a survey of 652 students at King Saud University. Neither study measures learning, and both are correlational, so they cannot show that literacy improves study outcomes. They do suggest that knowledge about AI, rather than avoidance of it, is the more constructive stance, which supports students investing deliberately in understanding the tools they use.

A final consideration is motivation, because study practices persist only if students want to sustain them. Yavich and Davidovitch (2026) examined the relationship between AI use for learning and learning motivation among 207 middle and high school students in Israel, using self-report measures of AI use frequency and perceived educational value alongside a motivation questionnaire grounded in self-determination theory. Its correlational, self-report design means it cannot show that AI use causes changes in motivation, and it does not measure achievement. Its framing is nonetheless instructive. Self-determination theory locates durable motivation in autonomy and a sense of competence, and AI use that hands students finished answers undercuts precisely the experience of competence, while use that helps them succeed at something difficult can reinforce it.

Taken together, the evidence gives students a workable rule. The question to ask of any AI interaction is whether it left you doing more of the thinking or less. Quizzing, Socratic questioning, feedback on your own attempts and graduated hints keep the cognitive work with the learner, and they are the patterns associated with large gains in the strongest studies. Answer-supplying and passive acceptance move the work to the machine, and they are the patterns associated with losses that appear only once the tool is gone.

The evidence base remains emerging. The strongest trials use purpose-built tutors, cover limited subjects and durations, and do not yet show how general chatbots behave in students' unsupervised hands over a full course. The surveys and interviews describe perceptions and practices rather than learning. But the direction is consistent enough to act on: students who attempt first, ask to be questioned, seek feedback on their own work, check themselves without the tool and build genuine understanding of AI are using it in the ways the research associates with stronger, not weaker, learning.

Q082 What should students know about the limits, failure modes, and biases of AI systems before trusting their outputs?

11 citations · 11 sources · 5 cross-references

Claim 1 emerging

Before trusting anything an AI system produces, students need to know that large language models generate plausible text rather than retrieve verified facts, so their outputs can be fluent, confident, biased, and wrong all at once. Students who use AI as a study partner, a drafting tool, or a source of information need an accurate mental model of what these systems are and are not. Research on student understanding indicates that many lack one. The arXiv study of student mental models of LLMs and hallucination reports that students commonly treat these tools as database-driven research engines that look up facts. In reality they are probabilistic text generators with no built-in way to tell truth from plausible fiction. This misconception is the root of the most damaging failures in educational AI use, because it leads students to extend a kind of trust the technology was never built to earn.

The mechanics are well established. As MIT Sloan's Teaching and Learning Technologies group and Duke University Libraries both explain, large language models are trained to predict the most statistically likely next word in a sequence. They are not trained to retrieve verified facts or to reason in the sense students usually assume. They have no internal database, no internet access by default, and no mechanism for checking whether an output corresponds to reality. They are pattern-matching systems trained on vast, uncurated internet text that contains contradictions, misinformation, and bias, and they reproduce the statistical patterns of that text without discerning which parts are true. This is why they can produce fluent, confident, and entirely fabricated content, the phenomenon known as hallucination. The ScienceDirect study of AI literacy, hallucination, and critical evaluation in education frames this as the conceptual foundation of AI literacy. A student who understands that the model is completing a pattern,

rather than consulting a record, can anticipate failures that a student holding the search-engine model cannot.

The failure modes students will actually meet are specific and recurring. Fabricated citations are the most dangerous in academic work. Models generate references that look real, with plausible authors, journals, and years, but that do not exist. False historical facts, erroneous statistics, and flawed code arrive with the same confidence as correct answers, so the tone of a response tells the reader nothing about its accuracy. Duke University Libraries also identifies an incentive problem in how these systems are built. Evaluation benchmarks reward confident, plausible-sounding answers over acknowledged uncertainty, which encourages the systems to guess rather than say they do not know. This account suggests that hallucination is partly a product of design and evaluation choices rather than a temporary defect that scale alone will remove. It also helps explain why the problem persists across successive generations of models.

Sycophancy is a distinct and underappreciated failure mode. Models are reinforced through human feedback to be helpful and affirming. As a result, they will validate incorrect premises or agree with a mistaken user rather than correct them. For a learner this is especially hazardous. A student who brings a misconception to the tool may leave with that misconception confirmed, along with a fluent explanation of why it is correct.

The arXiv study of student mental models and the ScienceDirect study report that students encounter all of these failures. Both also find that many students rely on intuitive judgement to detect fabrication: whether an answer sounds right, reads smoothly, or matches a vague memory. That is precisely the strategy that fails. The errors are plausible by construction, since plausibility is what the model optimises. Intuition therefore tends to be weakest exactly where fabrication is most convincing, which is why routine verification matters more than careful reading (see Q081 on study practices that build, rather than bypass, students' own judgement).

AI systems also inherit and amplify the biases of their training data. As MIT Sloan's guidance sets out, models trained on internet text absorb stereotypes about gender, race, language, and culture. They can reproduce those stereotypes in descriptions, generated examples, feedback, and assessment. The bias is not a bug that occasional fixes remove. It is structural, because the training data is a sample of human expression, prejudices included. Students need to know three things here: AI output is not neutral, it reflects the statistical distribution of what has been written, and it will systematically underrepresent and misrepresent some groups. This matters

doubly in education, where biased output can shape both what students learn and how they are assessed.

In educational settings the bias problem takes forms students should learn to recognise. AI feedback tools may evaluate writing by non-native speakers more harshly, because the models' training data is dominated by standard written English. AI-generated examples and explanations may reproduce stereotypes about who succeeds in mathematics, science, or literature. AI-based assessment or placement tools may encode historical patterns of inequality and recommend different trajectories for students from different backgrounds. These are documented concerns about the systems students are being asked to use, not hypothetical ones. However, the strength of the evidence varies by tool and context, and how large such effects are in any particular classroom product often remains unclear.

The linguistic dimension has practical weight for students who work across languages. Tabiri, Jones-Mensah and Kouamé (2026) studied how Ghanaian tertiary students integrate AI tools into multilingual learning, including which languages they use the tools for. Their abstract describes this as a study of perceptions and patterns of use within a technology-acceptance framework. It does not report measures of output quality across languages, so it cannot show that the tools perform worse in some languages. What it does show is that AI is already embedded in multilingual learning, where the dominance of standard English in training data is most likely to matter. That makes language-related bias a live concern rather than an abstract one (see Q249 on whether AI levels or steepens the playing field for disadvantaged students).

Assessment tools deserve particular scrutiny, because "AI" in education does not always mean a large language model. Konu Kadirhanoğulları (2026) developed a model to identify secondary students' misconceptions about mitosis and meiosis from open-ended answers. The sample comprised 400 students in eastern Turkey, and the model works by comparing each response with a set of possible responses using SequenceMatcher similarity rates. The abstract describes the construction of the model rather than an audit of its fairness. Even so, the design illustrates a general point students should understand. A tool that scores answers by their similarity to a reference set is only as fair as that set. Correct but unconventionally phrased answers, including those from students writing in a second language, are vulnerable to being judged by their surface form rather than their content.

Several verification practices follow from these limits, and they should become as routine as checking a calculation. They are drawn from MIT Sloan's guidance, the Faculty Focus discussion of mitigating hallucinations for classroom use, and the ScienceDirect study.

The first is to treat AI output as a draft or hypothesis, never as an authoritative source. Every claim that matters must be checked against a primary or authoritative source.

The second is to verify citations specifically. Fabricated references are the most common and most damaging academic failure, so every citation must be confirmed both to exist and to say what the model claims it says.

The third is to use verification-friendly tool configurations where they are available. Faculty Focus describes three options. Retrieval-augmented tools ground responses in curated, trusted datasets. Chain-of-thought prompting exposes the model's reasoning to inspection. Low-temperature settings reduce random variation in outputs. These measures reduce error rather than eliminate it, so they complement checking rather than replace it.

The fourth is to be alert to sycophancy. If the model is agreeing with you, ask it to argue the opposite, and test your premises rather than accepting validation.

The fifth is to understand the limits of your own verification. Some fabrications cannot be detected by inspection, which is why triangulation, meaning checking multiple independent sources, matters more than reading carefully.

The order in which students engage with AI may also matter, though the evidence is still early. Yoon, Lee, Lee and colleagues (2026) compared two approaches with thirty undergraduates working on mathematical proofs. In one, students constructed their own drafts before interacting with generative AI. In the other, they examined AI-generated proofs before drafting their own. The researchers then analysed how students incorporated the AI proofs into their work. With a sample of thirty and two related tasks, the study cannot settle which sequence is better in general. Its framing does, however, point to a practical principle consistent with treating AI output as a hypothesis. A student who has already attempted a problem has an independent standard against which to judge the machine's version. A student who starts from the AI's answer has a weaker basis for noticing when it is wrong. How students record and acknowledge this kind of interaction is a separate question of integrity and documentation (see Q083).

Verification habits matter partly because students' sense of how useful a tool is does not track how reliable it is. EL Idrissi and Alami (2025) surveyed 392 management students in Morocco and used structural equation modelling (SEM-PLS) to examine how chatbot quality, task–technology fit, social influence, perceived usefulness, and actual usage relate to academic productivity. Such models describe associations among self-reported constructs. They do not show that AI use causes productivity gains, and they do not measure whether the outputs students relied on were accurate. That gap is itself instructive. Perceived usefulness and social influence are the kinds of factors that drive adoption, and none of them requires a student to have checked a single claim. A tool can feel productive while quietly introducing fabricated content into a student's work.

Recent literacy frameworks try to make critical evaluation a measurable competence rather than an assumed one. Hershkovitz, Tabach, Reich and colleagues (2025) developed a task-centred generative AI literacy framework together with academic and administrative staff at a large Israeli research university. It identifies eight skills informed by the six cognitive domains of Bloom's Taxonomy, and the team built an instrument from it that they administered to 1,667 students. Organising AI literacy around Bloom's levels places evaluation alongside, rather than beneath, the ability to operate a tool. This matches the argument of the ScienceDirect study that critical evaluation of AI output must be taught explicitly rather than expected to emerge from use. Frameworks of this kind are still being validated, and whether measured literacy translates into better verification behaviour in real coursework remains unclear. The direction is nonetheless consistent: knowing how to prompt a system is not the same as knowing when not to believe it.

The verification practices described above apply to bias as much as to accuracy. In practice, students should treat AI output as one voice among several rather than as an objective authority. They should watch for patterns: if a tool consistently evaluates, describes, or recommends in ways that differ across groups, that is a signal of bias, not a coincidence. Checking outputs against authoritative sources, triangulating across tools, and raising suspicious patterns with instructors are all part of the literacy that protects students from systems that are fluent, confident, and wrong. Students should also recognise that school AI tools can be manipulated by users and outsiders, which adds a further reason not to take outputs at face value (see Q218).

The UNESCO AI Competency Framework for Students (2024) places this understanding at the base of its progression. Students must understand what AI is and how it works before they can

apply it or create with it. The ordering reflects the evidence reviewed here. The misconception documented in the arXiv study of student mental models, that LLMs are fact-retrieval engines, is not a gap that tool proficiency fills; if anything, fluency with the tools can deepen misplaced confidence. Conceptual understanding has to come first, because it determines whether every later use is critical or credulous.

The practical lesson is that trust in AI output must be earned, not given. These systems are powerful, fluent, and useful. They are also confidently wrong in ways that are hard to detect, both because plausibility is what they optimise and because their training and evaluation reward confident guessing over acknowledged uncertainty. Students who internalise that duality, useful yet unreliable, fluent yet biased, are equipped to use AI as a tool rather than be used by it.

Q083 How should students disclose and document their AI use in academic work, and how can they build integrity habits that also serve them professionally?

10 citations · 10 sources · 5 cross-references

Claim 1 disputed

Students should disclose their AI use proactively, specifically and in writing. That means naming the tool, the purpose it served and the extent of its contribution, and explaining how its output was checked, changed or folded into the final work. They should also keep a record of the process rather than only declaring the outcome, because that record is what turns disclosure from a confession into a professional habit.

This has moved from a theoretical concern to a practical urgency in roughly two years. Generative tools have become ubiquitous in student life, and institutions have scrambled to build disclosure frameworks that are honest, workable and pedagogically coherent. The emerging evidence favours approaches that treat disclosure as part of intellectual integrity education rather than as a compliance mechanism.

The case for disclosure rests on several connected reasons. First, it preserves the epistemic integrity of academic work, because assessors need to know what they are actually evaluating. Second, it protects students from inadvertent misconduct, that is, from using AI in ways that breach institutional policy without realising it. Third, it builds the habit of transparency about method that is a core professional virtue in research, law, medicine and many other fields. Fourth, it creates a record of how AI is really being used, which institutions need if their policy is to be evidence-based rather than speculative.

UNESCO's Guidance for Generative AI in Education and Research (2023) frames these concerns as matters of human agency and institutional responsibility. It asks institutions to set and communicate clear expectations for AI use rather than leave individuals to guess. In scholarly publishing, the Committee on Publication Ethics takes a closely related position. COPE holds that AI tools cannot be listed as authors, that authors who use them must state how they were used, and that the human authors remain fully responsible for the content. Students who learn to disclose well are therefore rehearsing a norm already operating in the professional world they are preparing to enter.

The difficulty is that poorly designed disclosure requirements can backfire in three ways. They can deter legitimate AI use. They can create anxiety and confusion about what counts as acceptable. And they can produce pro forma compliance, in which a boilerplate statement is attached to every submission without any genuine transparency behind it.

A long-standing premise in academic integrity scholarship is that students are more likely to follow rules they understand and perceive as fair than rules they experience as arbitrary or punitive. The specific study this chapter previously cited for that claim could not be verified and has been removed. The premise is still widely held, and it is consistent with the newer evidence below, but readers should treat its application to AI disclosure as a reasoned expectation rather than a demonstrated finding.

What the recent literature does show clearly is inconsistency. Zdravkova (2026) observes that some universities and academic publishers increasingly require explicit disclosure of AI use, but that the scope and implementation of these requirements remain inconsistent. A student taking courses in several departments may therefore meet several incompatible definitions of what must be declared. That is precisely the condition under which rules come to feel arbitrary.

The alternative to disclosure, which is detection, carries its own costs. Salamah's (2026) systematic review of AI-based academic integrity systems in Palestinian higher education identifies three problems. Such systems are vulnerable to algorithmic bias against non-native English speakers. Their decision-making is not very transparent. And they raise privacy and academic-freedom concerns because they expand surveillance.

These findings strengthen the argument for disclosure as the primary integrity mechanism. A regime built on student self-report shifts the emphasis from catching students to understanding their process. A regime built on automated suspicion risks penalising exactly the students least able to contest a false accusation. Teachers facing a suspected case need a response grounded in conversation rather than in a detector score (see Q147).

The frameworks that have emerged range from simple acknowledgement statements to detailed process documentation.

The most widely adopted approach asks students to attach an AI use statement to submitted work. The statement specifies which tools were used, for what purposes, and how the AI-generated content was verified, modified or integrated. It works much like the methodology section of a research paper or the acknowledgements section of a scholarly publication, and it mirrors the disclosure COPE expects of published authors. Francophone scholarship on AI declarations in academic work, such as the framework-and-practice analysis published in Érudit, has mapped similar models. This suggests the statement format is becoming a shared convention across linguistic and national contexts rather than a local improvisation.

More elaborate frameworks distinguish between types of AI use: brainstorming and ideation, research assistance, drafting, editing, translation and code generation. They require different levels of disclosure for each, on the reasoning that a grammar check and a generated first draft are not ethically equivalent.

Some institutions go further and ask for AI use logs or portfolios that document a student's interactions across a whole project. These give a richer picture of the creative and intellectual process. Process-based approaches are more demanding for both students and assessors. They are also more pedagogically valuable, because they require students to reflect on their AI use rather than merely acknowledge it.

There is, however, a real limitation here. Zdravkova (2026) examines LLM-based ghostwriting and questions how reliable disclosed interactions are as evidence of authentic use. A log is only as trustworthy as the student who compiles it, and a curated transcript can make heavy reliance look modest. Process documentation is therefore best understood as a reflective and dialogic tool, a basis for conversation between student and teacher, rather than as forensic proof.

Disciplinary context matters as well. Seghier's (2026) PRISMA-guided systematic review of architectural education finds that research on how generative AI affects authorship, assessment and studio culture is limited, and that evidence-based institutional guidance remains scarce. In fields where the creative process is itself assessed, a single generic disclosure template is unlikely to be enough. Whether more granular frameworks actually improve learning or honesty, as opposed to simply generating more paperwork, remains unclear.

The best-documented problem is a compliance gap: many students do not disclose AI use even when they are required to.

Qu and Wang (2026) studied 409 undergraduates at a Singaporean university who reported using generative AI for academic purposes. They used a mixed-methods design guided by Bandura's Social Cognitive Theory. They report that students frequently conceal their AI use despite institutional mandates, and they interpret this concealment as reflecting ethical uncertainty and relational risk. Their analysis looks at how cognitive, social and emotional factors jointly shape students' willingness to disclose. On this account, disclosure is a social act whose perceived consequences, including how peers and teachers will judge the student, weigh as heavily as knowledge of the rules. The study was conducted at a single institution in one national context, and its correlational components cannot establish which factors cause disclosure.

Related work points to the role of social influence in AI use itself. El Idrissi and Alami (2025) surveyed 392 management students in Morocco and used structural equation modelling (SEM-PLS). They modelled social influence, perceived usefulness, chatbot quality and task-

technology fit as factors associated with actual AI usage and academic productivity. This study concerns use rather than disclosure. Still, it complements Qu and Wang: if peers shape whether students use AI, it is plausible that they also shape whether students admit to it.

Perceptions of the institutional apparatus matter too. Tayebipour, Siddique and Hamid (2026) used questionnaires and focus groups to explore how Omani college students and lecturers across disciplines perceive Turnitin and ChatGPT in relation to academic integrity. This work is a reminder that students interpret disclosure rules alongside detection tools, and that both sides of the classroom may understand them differently.

The previous version of this answer cited a 2024 study for two claims. The first was that students who understood the rationale for disclosure, namely protecting assessment integrity and informing institutional understanding, were significantly more likely to comply than students who experienced disclosure as confession or self-incrimination. The second was that framing disclosure as a professional norm akin to citation yields higher compliance than framing it as a rule to be enforced, and that the vocabulary of transparency and professional integrity outperforms the vocabulary of honesty and cheating. That source could not be verified. Qu and Wang's emphasis on ethical uncertainty and relational risk makes the framing hypothesis plausible. If concealment stems from fear of how disclosure will be read, then language that removes the stigma should help. But direct comparative evidence on framing effects remains unclear, and institutions should evaluate their own messaging rather than assume it works.

The strongest argument for student disclosure is not compliance but professional development.

In virtually every profession, transparency about method, including the tools and assistance used, is a core ethical obligation. Researchers disclose their methods and data sources. Lawyers disclose conflicts of interest. Doctors document their diagnostic reasoning. Journalists are expected to be open about their sources and methods. The COPE position on AI in publishing shows how directly these norms now extend to AI: authors must say how a tool was used, and they cannot hand responsibility to it. A student who has spent three years writing honest AI use statements arrives at the first manuscript submission, client report or design brief already fluent in the practice.

The professional link is especially visible where AI is reshaping practice itself. Seghier (2026) notes that generative AI is transforming architectural design practice even as its implications

for integrity in architectural education remain insufficiently understood. Students in such fields are, in effect, being trained for a profession whose disclosure norms are still being written. That makes the reflective habit more valuable than mastery of any particular rule.

Teachers play a mediating role. Ayesha (2026) studied Saudi TESOL teachers in English for Academic Purposes classrooms, where writing development and independent reasoning are core outcomes. The study explores the strategies these teachers use to balance AI use with academic integrity and critical thinking, given concern that the tools may erode students' reasoning. This kind of classroom-level negotiation is where the abstract case for transparency is either made concrete or lost. Teachers who model their own disclosure strengthen the norm they are asking students to adopt (see Q101).

The claim that students who see the connection between integrity habits and professional ethics are more likely to internalise those habits is intuitively compelling. It is consistent with UNESCO's emphasis on cultivating human agency and ethical judgement rather than mere rule-following. The two studies earlier cited for it could not be verified, however, and the longitudinal evidence needed to show that undergraduate disclosure habits carry over into professional conduct does not yet exist. The professional-development rationale is best presented to students as a strong normative argument, not as a proven effect.

Taken together, the evidence supports five working practices for students. These are offered as current best guidance rather than settled science.

First, disclose proactively and specifically. Identify the tool, the purpose and the extent of use, without waiting to be asked and without hiding behind a generic statement. Where course rules are silent or inconsistent, as Zdravkova (2026) shows they often are, ask the instructor and record the answer.

Second, treat AI output as a draft to be verified, modified and integrated, never as a finished product. The student, like the COPE author, remains responsible for every claim submitted.

Third, document the process and not only the outcome. Keep notes or logs of significant interactions, and use them for reflection: what the tool contributed, where it misled, what you changed and why. Students should also recognise, as Zdravkova cautions, that a log is evidence of honesty only when it is complete.

Fourth, apply the same critical evaluation to AI-generated content that you would apply to any other source. Check facts, trace references and test reasoning. This is also how AI becomes a study partner that strengthens rather than replaces learning (see Q081).

Fifth, develop a personal AI use policy that reflects both your institution's requirements and your own professional values. Revisit it as you move between courses, placements and eventually employment.

For institutions, the implication of Qu and Wang's (2026) findings is that disclosure will remain partial until students no longer perceive it as risky. Reducing ethical uncertainty through clear, consistent rules, and reducing relational risk by responding to disclosure with feedback rather than suspicion, are therefore as important as the wording of any template. The habits formed this way will serve students well beyond assessment. Professional life increasingly asks them to state what tools shaped their work and to stand behind the result, and a student who already does this routinely will meet that expectation without strain.

Q084 What practical steps allow school and university leaders to move from prohibition or paralysis to structured adoption — a realistic implementation roadmap?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

School and university leaders move from prohibition or paralysis to structured adoption by building governance first, auditing what already exists, piloting deliberately, investing in sustained professional development, and evaluating continuously. The emphasis on governance

and continuous evaluation runs through the guidance from UNESCO and the OECD. No single roadmap has been tested against alternatives in controlled comparisons.

The history of educational technology offers many institutions that met a new tool with either blanket prohibition or uncritical enthusiasm and later regretted both. Prohibition tends to drive use underground. Enthusiasm tends to produce expensive deployments with no clear educational purpose. The international frameworks share a different position: the most defensible response is neither prohibitive nor permissive but structured. UNESCO's implementation roadmap and the OECD's framework for AI in education describe that structure in similar terms. It combines clear governance, sustained professional development, phased implementation, and ongoing evaluation.

The empirical base behind this consensus is thinner than its confident tone implies. Lipsou, Keravnos and Eteokleous (2026) conducted a PRISMA-aligned structured literature review of publications from 2019 to 2025, searching Scopus, Web of Science, ERIC and Google Scholar. They concentrated on K–12 school leadership. They drew on higher education sources only selectively, for governance mechanisms judged transferable, such as policy, procurement, documentation and explainability, and auditability. That design choice is telling. Even a systematic review had to borrow from adjacent sectors to assemble governance guidance, so the research on AI implementation in schools is still young.

The five phases described below should therefore be read as a reasoned synthesis of framework guidance, adjacent evidence on technology adoption and professional learning, and early empirical work on school leaders. They are not a validated protocol. The month ranges attached to each phase are planning heuristics, not empirically derived timelines. The phases overlap deliberately, and smaller institutions may compress them.

The first phase, roughly months one to three, establishes a governance structure that gives the institution the capacity to make and carry out decisions about AI.

Three elements recur in the framework guidance. The first is a named senior leader who is accountable for AI governance at leadership level, rather than a responsibility handed to the IT department. The second is a cross-functional task force that includes teachers, IT staff, legal counsel, student representatives and parent representatives. The third is a clear, accessible AI policy that distinguishes permitted, conditional and prohibited uses and is reviewed at least every six months. The policy should work as a living document: short enough to be read,

specific enough to guide decisions, and flexible enough to evolve as AI capabilities change. The practical craft of drafting and maintaining such a policy is treated in detail elsewhere (see Q265).

It is often claimed that governance clarity is the single most important predictor of successful implementation. That claim should be held more tentatively than it usually is. The reasoning is plausible. Institutions without clear governance appear prone to policy drift, a gradual accumulation of ad hoc decisions that are inconsistent, hard to communicate and impossible to enforce. Lipsou and colleagues (2026) identify policy, procurement, documentation and auditability as governance mechanisms worth transferring across settings. However, no study in the present evidence base ranks governance against other predictors of implementation success. The claim remains a well-founded professional judgement rather than a demonstrated finding.

The composition of the task force matters for a reason the early survey evidence makes concrete. Kim (2026) surveyed 147 US K-12 educators, drawing on the technology acceptance model and distributed leadership theory. School leaders reported higher AI familiarity and greater optimism than teachers. Teachers expressed more varied views and lower confidence about implementation. A governance group dominated by senior leaders risks mistaking its own readiness for the institution's.

Ghamrawi, Al-Fadala, Shal and colleagues (2026) push the point further. They interviewed 23 AI-active teacher leaders across six Arab States and analysed the interviews thematically. They argue that leadership scholarship has cast principals as the architects of AI reform while reducing teacher leadership to implementation. The teacher leaders they interviewed imagined a principalship that would not surrender pedagogy, ethics or agency. For governance design, the implication is that teachers belong on the task force as co-authors of policy, not merely as recipients of it. Because the study is interpretive and small, it suggests this rather than demonstrating it.

The second phase, roughly months two to four and overlapping with the first, is an audit and inventory carried out before any new tools are adopted.

The starting point is the existing technology landscape. Leaders need to know which AI tools are already in use, including shadow AI that staff and students use without institutional approval. Shadow use is almost certain to exist by the time a school decides to act. The audit should establish three things: the data privacy implications of tools already in circulation, the

equity effects of current access patterns, and the professional development needs of staff. Two companion entries cover the technical and organisational safeguards that any sanctioned deployment should include (see Q087) and the ways institutions with minimal budgets can still secure equitable access (see Q088).

The audit should also include a needs assessment. Leaders should ask which educational problems the institution is trying to solve, and which of those AI tools might plausibly address. Digital Promise's procurement guidance consistently recommends this needs-first approach, which identifies the problem before seeking the tool. It associates needs-first procurement with more effective and sustainable adoption than tool-first approaches, which begin with a product and then search for applications. Readers should note that this association comes from procurement practice and evaluation, not from controlled comparison.

A needs assessment should look beyond the classroom. Kafa (2025) interviewed 43 randomly sampled primary and secondary school leaders in Cyprus, a highly centralised education system. These leaders described ways AI tools could support their management work. They mentioned decision-making, administrative task support, operational efficiency, data processing, scenario planning and communication. Kafa frames these explicitly as perceived potential and aspirational uses rather than observed outcomes. They are best treated as candidate needs to test, not as benefits to bank.

The centralised context also matters for interpretation. In systems where curriculum, procurement and data policy are set nationally, a school-level needs assessment may identify problems the school lacks the authority to solve. The audit should therefore record which decisions sit with the institution and which sit above it. Lipsou and colleagues' (2026) emphasis on procurement, documentation and auditability supports building this record from the outset. The same inventory that maps shadow use can also become the baseline against which later evaluation is measured.

The third phase, roughly months three to nine, replaces any temptation toward institution-wide rollout with structured pilots.

Pilots should be designed with pre-specified outcome measures, clear evaluation criteria and a genuine commitment to learning from failures as well as successes. They should involve volunteer teachers who receive adequate support and protected time to experiment, reflect and share what they learn with colleagues. Volunteers bring obvious selection effects: early

adopters are not representative of the whole staff. Pilot results therefore indicate feasibility more reliably than they predict effects at scale.

Evidence on teacher learning gives the pilot phase a second purpose beyond testing tools. The Learning Policy Institute's synthesis of effective professional development identifies collaboration among teachers as a recurring feature of programmes that change practice. Research on technology adoption in schools likewise finds that peer learning, teachers learning from teachers, produces more durable change than top-down training. Pilots should therefore generate peer learning deliberately. Useful mechanisms include regular sharing sessions, communities of practice, and structured reflection on what is and is not working.

Early evidence on acceptance indicates what pilots should attend to. Feng and Adams (2026) surveyed 488 middle leaders in China and analysed the data with partial least squares structural equation modelling within the technology acceptance model. They found that perceived ease of use had a significant positive effect on both perceived usefulness and intention to use generative AI. These are associations within a cross-sectional model, not causal estimates, and they concern intention rather than observed classroom practice. They do suggest that a pilot judged only on outcome measures may miss why a tool is or is not taken up. Usability barriers can depress perceived value independently of a tool's pedagogical merits.

Kim's (2026) finding that teachers report lower implementation confidence than leaders points in the same direction. Pilots are the first point at which that confidence gap becomes visible in practice. Leaders should design pilots so that teachers' difficulties are reported and acted on, rather than read as resistance.

The fourth phase, roughly months six to eighteen, scales from pilot to institution-wide adoption. It depends on sustained, job-embedded professional development.

On general professional learning the evidence is unusually consistent. The Learning Policy Institute's review concludes that one-off training sessions are insufficient to change practice. Effective programmes share several features. They are sustained rather than episodic and embedded in teachers' actual work. They are collaborative, typically through communities of practice, and focused on content and pedagogy rather than on tools in isolation. Applied to AI, this means helping teachers understand how AI might serve their educational goals, not merely how to operate particular products. Extending these findings to AI integration is a reasonable inference rather than a separately established result. Few AI-specific professional development

programmes have yet been rigorously evaluated. Classroom-level practices that help teachers apply policy consistently are discussed in a companion entry (see Q231).

Institutions should build internal capacity rather than rely exclusively on external training providers. That means identifying exemplary AI practitioners and supporting them to act as peer mentors and coaches. Internal capacity is likely to be more sustainable, more contextually relevant and more conducive to the adaptive expertise that AI integration requires. The work of Ghamrawi and colleagues (2026) gives this recommendation a sharper edge. Their AI-active teacher leaders saw themselves not as implementers of principals' plans but as shapers of the leadership that AI-era schooling needs. Positioning internal experts as genuine leaders, rather than as unpaid help desks, may determine whether they remain engaged.

Confidence and self-efficacy appear repeatedly in the early research as plausible levers. Raptis and Psyrras (2026) surveyed 262 primary school leaders in four Greek districts with a 61-item questionnaire. Using correlation and multiple regression, they examined attitudes, self-efficacy, perceived usefulness of AI in decision-making, and challenges to integration. Their framing reflects a broader assumption that leaders' own self-efficacy shapes whether they can champion integration. Kim's (2026) leader–teacher confidence gap and Feng and Adams' (2026) ease-of-use findings sit alongside this. Together they suggest that professional development at scale should build hands-on familiarity and confidence for leaders and teachers alike. Workshops for staff alone, while leaders oversee from a distance, are unlikely to be enough. How much each factor contributes to successful scaling remains unclear, because these studies measure perceptions and intentions rather than implementation outcomes.

The fifth phase, evaluation and iteration, has no end date. Effective implementation is an ongoing process rather than a destination.

Institutions should establish regular evaluation cycles that assess AI tools against the outcome measures specified during piloting. These cycles should also monitor for unintended effects, including widening equity gaps, cognitive offloading and data privacy incidents. Policies and practices should then be updated in response to what the cycles reveal. The OECD and UNESCO frameworks both add a second monitoring task: tracking the external environment. That includes new AI capabilities, regulatory developments and emerging research, and leaders should be ready to adapt as these shift.

Evaluation design deserves more care than it usually receives. Recent work from dental education, a distant field, illustrates why. Al-Haj Ali (2026) compared three multimodal AI models with 48 students on 80 practical examination questions split between visually supported multiple-choice and fill-in-the-blank formats. The study set out to examine how question characteristics shape performance. Al-Haj Ali and Farah (2026) then profiled workload across ten AI models and twenty students on 70 items in four formats. They argued that accuracy alone cannot characterise how AI engages with assessment tasks. The lesson for school and university leaders is methodological rather than substantive. A tool's apparent effectiveness may depend on task format and context, so evaluations relying on a single headline metric risk misleading decision-makers.

The most effective institutions treat AI implementation as a learning process rather than a deployment project. They change course when evidence shows that a tool or approach is not working. They communicate transparently with staff, students and parents about what they are learning and how they are responding.

That transparency should extend to the limits of the evidence underpinning the roadmap itself. Most empirical work on school leaders and AI, including that from the United States, Cyprus, China, Greece and the Arab States, rests on surveys and interviews about perceptions, readiness and intentions. Little of it measures student learning or longer-term organisational outcomes. The international frameworks agree on the broad shape of structured adoption. Which elements matter most, in which contexts and at what cost, remains unclear. A roadmap followed with that humility is more likely to survive contact with real institutions than one presented as settled science.

Q085 How should institutions structure professional development so teachers gain real AI competence rather than one-off training?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

Institutions build real AI competence in teachers by replacing the one-off workshop with a sustained, job-embedded, and assessed programme of professional learning. That programme should be anchored in a shared competency framework, differentiated by role, and backed by protected time, tools, and incentives. The dominant institutional response to AI in schools has instead been the isolated event: a half-day introduction to ChatGPT, a vendor demonstration, a policy briefing. Decades of research on teacher professional development show why this model fails. Isolated training events rarely change classroom practice because they do not provide the sustained practice, feedback, and collaboration through which new pedagogical skills develop. AI competence is not mainly an informational problem. It is a practical, ethical, and pedagogical one, and it requires a professional development architecture as deliberate as the technology itself.

Recent syntheses of teachers' own needs support this diagnosis. Aravantinos and colleagues (2026) synthesised 43 empirical studies, drawn from Scopus and Web of Science, on the training needs and professional development practices of primary and secondary teachers integrating AI. The breadth of that corpus shows that needs extend well beyond tool operation into curriculum design and pedagogy. Kayıran and colleagues (2026) interviewed 30 in-service public-school teachers in a Turkish metropolitan city using an eight-question semi-structured protocol and qualitative content analysis. Their questions covered instructional processes, cognitive development, psychosocial implications, and professional learning needs. That teachers frame AI in cognitive and psychosocial terms, and not only technical ones, is a further reason a demonstration-style workshop cannot meet the need. These are small or descriptive studies, so they identify needs rather than test remedies. Practitioner commentary makes a related equity argument: an eSchool News piece (2024) contends that equitable access to AI for students begins with teachers' professional development. This is a reasonable argument, but it is advocacy rather than research evidence.

The most significant reference point for designing such programmes is UNESCO's AI Competency Framework for Teachers (AI CFT). It is a global reference tool that defines what

teachers need to know and be able to do. As UNESCO describes it, the framework organises fifteen competencies across five dimensions: a human-centred mindset, the ethics of AI, AI foundations and applications, AI pedagogy, and AI for professional development. Crucially, it structures progression into three levels, Acquire, Deepen, and Create, so that competence is treated as a developmental trajectory rather than a binary state.

Summaries prepared by the CIDDL and listed in CEDEFOP's resource toolkit describe the levels in the same way. At the Acquire level, a teacher understands how AI works and its basic applications. At the Deepen level, the teacher integrates AI into pedagogical practice and critically assesses its impact on learning. At the Create level, the teacher designs new learning approaches that make use of AI's capabilities. UNESCO's accompanying guidance recommends that governments and institutions use the framework as a roadmap for national strategy. It calls for AI competency to be integrated into both pre-service and in-service training and for assessment tools to be developed to measure teacher competence.

The framework's insistence on a human-centred approach gives professional development a normative anchor that technical training alone cannot provide. Under that approach, AI serves human agency rather than replacing the teacher. Its status should be stated precisely, however. The AI CFT is a consensus-based reference document, not an empirically validated model of how teacher competence develops. Whether its three-level progression matches how teachers actually learn remains unclear. Institutions should therefore treat it as a common language and a design scaffold rather than as proof that any particular programme will work.

Against this backbone, institutions should build professional development that is sustained, job-embedded, and collaborative. The general evidence on teacher learning is consistent here. Coaching, professional learning communities, and lesson study outperform stand-alone workshops because they embed learning in the teacher's actual work. For AI specifically, this means creating structures in which teachers co-plan lessons with AI tools, analyse AI outputs for bias and error, observe colleagues' AI-integrated lessons, and bring student work back to a community of practice for collective analysis.

A professional learning community focused on AI might meet monthly to examine a shared question, such as how AI-generated feedback affects student revision. Each meeting would be anchored in classroom evidence rather than general impressions. This turns AI competence

from an individual acquisition into a collective, continuously updated practice. That matters because the technology changes faster than any fixed curriculum can.

Emerging longitudinal work points to a mechanism such structures should cultivate. Zhou, Yang and Chen (2026) used a three-wave design over one year with 558 university physical education teachers in China. They applied cross-lagged panel modelling to examine the dynamic associations between generative AI adoption and professional competence. They also tested self-regulated learning as a longitudinal mediator and teaching experience as a moderator. The study is valuable because longitudinal evidence on generative AI and teacher development has been scarce, particularly in embodied-teaching fields such as physical education. Its design nonetheless remains correlational and confined to one national and disciplinary context. It suggests rather than demonstrates that teachers' self-regulated learning is central to how AI use relates to competence.

If that pathway holds, professional development should deliberately build teachers' capacity to set goals, monitor, and reflect on their own AI practice. Collaborative inquiry cycles do exactly that. Readers seeking programmes that have been formally evaluated will find them discussed separately (see Q254). The honest position is that the AI-specific effectiveness evidence is still thin, even though the general case for job-embedded learning is strong.

Competence that is not assessed is easily assumed. Institutions should therefore pair professional development with competency-based assessment. Suitable evidence includes portfolios of AI-integrated lessons, evidence of student learning, and structured reflection against the UNESCO dimensions. Micro-credentials offer a promising mechanism because they let teachers accumulate verifiable evidence of specific competencies over time.

The OECD Digital Education Outlook 2023 observes that professional standards for digital competencies are often too broad to be useful. It points to Austria's Digi.kompP and US micro-credentialing systems as more structured alternatives. Credentialing serves two functions. It makes competence visible and portable for teachers, and it gives institutions a defensible basis for decisions about roles, mentoring, and leadership in AI-integrated teaching. What such a standard should contain is a question in its own right (see Q217).

The research base for assessing AI competence is itself young. Baizhanov and colleagues (2026) conducted a scoping review of 33 peer-reviewed articles published between 2022 and 2026, identified through a bounded Web of Science search. They mapped how AI, machine

learning, and learning analytics are being connected to teacher assessment, modelling, and professional development, and they identified two broad lines of work in the literature. The authors state explicitly that their purpose was to describe the extent, range, and nature of the evidence, not to evaluate whether interventions are effective. That limitation is itself informative. A mapped literature of 33 studies, many of them recent, indicates a field still defining its constructs.

Institutions adopting micro-credentials or analytics-based competence measures should therefore present them as provisional and review them as evidence accumulates. They should not assume that any credential already measures what it claims to measure. The use of AI and learning analytics to assess teachers also raises its own ethical questions. Those questions call for the same human-centred scrutiny the UNESCO framework applies to student-facing AI.

Not every teacher needs the same depth of AI competence. A differentiated model recognises that classroom teachers, subject leaders, special educators, and administrators face different demands. All teachers need foundational AI literacy and ethics. Some need deep pedagogical expertise in AI-mediated instruction. A smaller group needs the technical and evaluative skills to lead institutional adoption.

Professional development should therefore offer role-based pathways rather than a single uniform programme. The UNESCO framework's progression levels can provide the common language across those pathways. Differentiation also respects teachers' time, a scarce resource that one-off training wastes by treating everyone as a beginner.

Recent survey research supports designing for differences in role and background rather than for an average teacher. Alsuhaymi and Eltantawy (2026) surveyed 173 principals, supervisors, and teachers in public schools providing special education services in Riyadh. They examined perceptions of AI for administrative decision-making and tested whether those perceptions differed by professional role, years of experience, and AI-related training. The variables they chose make the relevant point. Role and prior training are treated as plausible sources of variation in how AI is understood. Leaders who make data-informed administrative decisions therefore need different preparation from teachers who use AI in instruction.

Fiorucci and Bevilacqua (2026) adapted and validated an Italian version of the Alsudairy and Eltantawy questionnaire on teachers' attitudes toward AI in education. They then explored attitudinal differences across socio-professional variables. They frame understanding attitudes

as essential for identifying acceptance, resistance, and professional development needs. Both studies are cross-sectional and context-specific, so their results cannot be generalised across systems. Taken together with the 43-study synthesis by Aravantinos and colleagues (2026), they support a practical design principle. Diagnose teachers' starting points, including attitudes and prior training, and match them to role-appropriate pathways, rather than delivering identical content to an entire staff.

Finally, professional development fails without enabling conditions. Teachers need scheduled time that is protected from other duties. They need leadership that models AI learning rather than delegating it. They need reliable access to the tools they are being trained to use, and technical support that does not assume expertise. They also need incentives, such as recognition, career structures, and compensation, that signal the institution takes AI competence seriously.

Pre-service education must also change. New teachers should enter the profession already grounded in the AI CFT, so that in-service programmes build on a foundation rather than starting from zero. That is the integration of pre-service and in-service training UNESCO itself recommends. Where budgets and infrastructure are limited, these conditions will need to be met creatively rather than abandoned (see Q088).

The stakes are distributional as well as pedagogical. The OECD Digital Education Outlook 2023 reports that roughly one in five secondary teachers still says they need further training in digital skills, even after a decade of investment in digital education. That finding is a warning. The eSchool News commentary (2024) reaches a similar conclusion from the practitioner side, arguing that equitable student access to AI depends on investment in teachers. Its argument should be weighed as advocacy rather than evidence.

Without sustained, structured, and resourced professional development, AI competence is likely to remain the property of a self-selected minority of enthusiasts. In that case, the technology may widen rather than narrow the gap between teachers who use it well and those who do not, and with it the gap between the students they teach. The emerging research reviewed here does not yet establish which programme designs close that gap most effectively. That uncertainty argues for designing professional development as an evaluated, iterative institutional commitment rather than for waiting.

Q086 How can schools communicate with and involve parents and communities in decisions about AI use?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

Schools can communicate with and involve parents and communities in decisions about AI by telling them early and honestly what is being adopted and why, naming its limits and risks, and giving parents a real role in governance rather than treating them as an audience for announcements. The relationship between schools and the communities they serve is one of the most important determinants of educational success. The rapid introduction of AI into classrooms is testing that relationship. Managing it means communicating honestly, involving parents meaningfully and building the trust that durable AI adoption requires. It is one of the most consequential and least appreciated challenges facing school leaders.

The picture of parental attitudes is complex and still changing. Survey work such as the Pew Research Center's 2024 national study of parental attitudes toward AI in education points to a pattern in which initial enthusiasm gives way to more qualified views as parents learn how AI tools work, what data they collect and what effects they may have on children. The evidence suggests that support tends to soften as exposure increases. Parents who had received information about specific AI tools used in their children's schools were more likely to express concern than parents who had received none.

This finding needs careful reading. It does not show that information simply manufactures opposition. A more plausible interpretation is that information revealed complexities that early

enthusiasm had obscured. It is also a cross-sectional association, not evidence that informing parents causes concern. Its practical implication is still significant. Transparency about AI use, including its limitations and risks, is more likely to build durable trust than promotional messaging that emphasises benefits and minimises concerns. Support won through omission is fragile, because it erodes the moment parents meet the complications on their own. Intergovernmental guidance points the same way. UNESCO's guidance on community engagement and the OECD's work on school AI governance both treat parents and communities as stakeholders whose informed involvement is part of responsible adoption, rather than a public-relations step taken once decisions are made.

Parents' concerns about AI in education are commonly described as clustering around three themes. The first is data privacy: what data is collected about their children and how it is used. The second is equity: whether AI tools will benefit all students equally or advantage some at others' expense. The third is the human relationship: whether AI will erode the teacher-student relationship that parents tend to value most. Effective communication has to address all three directly and honestly.

The peer-reviewed evidence specific to parents on this three-part structure is thinner than it appears. Much of the recent empirical work examines teachers, learners and school leaders rather than families. That work does corroborate the substance of the first two concerns from other vantage points.

On privacy, Riachi's 2026 qualitative study of 28 Lebanese schoolteachers reports concerns about data privacy and ethical use as barriers to integration. Those concerns sat alongside insufficient training and lack of institutional support. Teachers who share these worries will struggle to reassure parents convincingly unless the school itself has clear answers.

On equity, Ying's 2026 structural equation modelling study of 679 Chinese learners of English as a foreign language found significant correlations among perceived algorithmic bias, perceived AI surveillance, linguistic identity and willingness to communicate in AI-mediated learning. These are correlations from self-report data and cannot show that perceived bias causes reduced participation. They nonetheless suggest that perceptions of fairness and surveillance are bound up with how students engage, which is exactly what parents asking equity questions want to understand.

At the level of synthesis, Bellibaş and Karaferye's 2026 systematic review of 26 articles on AI in K-12 school leadership places ethical considerations at the centre of the research agenda. Creely's 2026 narrative review of literature published between 2022 and 2026 traces a widening set of ethical, social and environmental concerns about generative AI in education. Neither review measures parental opinion. Together they indicate that the questions parents raise are the same ones researchers regard as unresolved, so schools should not present them as misunderstandings to be corrected. Whether the human-relationship concern is borne out in practice remains unclear. Schools should acknowledge it as a legitimate value judgement rather than an empirical error.

Several practical strategies for school-community communication about technology are widely recommended. They should be presented as reasoned professional practice. The rigorous comparative evidence on AI-specific communication remains limited, and claims that these strategies are proven should be treated with caution.

The first strategy is multi-channel communication. Schools that combine email, social media, phone messages, written materials and in-person meetings are likely to reach more families, and to achieve wider understanding, than those relying on a single channel. Families differ in language, schedule, digital access and trust in institutions. A single channel systematically misses some of them, often those the equity concern is about.

The second is plain language. Technical explanations of how large language models or adaptive systems work tend to communicate less than concrete examples of how AI is used in specific lessons and what that means for a student's day. Concreteness also guards against overstatement. López Costa's 2025 study of a representative sample of teachers in rural Catalan schools found that over half reported moderate to high AI knowledge, yet classroom implementation remained limited. Where AI was used, it served mainly for text generation and content detection, with video generation and simulations less frequent. Communication that describes what is actually happening, rather than what the technology could in principle do, gives parents an accurate picture and avoids promising transformations that classrooms are not delivering.

The third is proactive communication. Informing parents before AI tools are deployed, not after, plausibly builds more trust than reactive communication issued once concerns have surfaced, because it signals that families are being told rather than discovering. Kumar and

Sarkar's 2026 scoping review of 21 sources on administrators' roles organises AI integration across instructional, managerial, strategic and relational leadership dimensions. Their framework is a reminder that communication with families is a core relational leadership task, not an afterthought to procurement.

Proactive honesty also means admitting uncertainty. Gorman and Brennan's 2026 interview study of 20 Irish primary principals found that AI leadership is not yet a coherent or established field of practice, and that it operates within a provisional and evolving policy context. Leaders who acknowledge to parents that guidance is still developing are describing their situation accurately. That candour is more defensible than projecting confidence the evidence does not support.

The most consequential strategy is to move from information provision to genuine involvement. Schools can invite parent representatives onto AI planning teams, governance committees or advisory groups. They can hold town halls in which community input demonstrably shapes decisions. Both approaches treat families as participants in decision-making rather than recipients of decisions already taken. The OECD's work on school AI governance and UNESCO's guidance on community engagement both emphasise this kind of stakeholder participation as an element of responsible adoption.

The claim that participatory schools achieve higher community trust and more sustainable adoption is consistent with the broader scholarship on school-community partnerships. That scholarship associates genuine involvement, as distinct from token consultation, with community support for school initiatives. Direct evidence for AI specifically remains thin, and the associations are not proof that participation causes trust. The distinction between involvement and consultation is still worth insisting on. Consultation asks for reactions to a settled plan. Involvement gives parents a voice in whether, how and under what safeguards a tool is adopted, and in how its effects will be reviewed.

The leadership research explains why this is harder than it sounds. Bellibaş and Karaferye's 2026 systematic review identifies ethical considerations and implementation challenges as persistent features of AI adoption in K-12 leadership. Lee and Kim's 2026 interview study of 14 middle leaders in Korean secondary schools found that professional judgement shaped how these leaders incorporated AI across domains of their leadership practice. That finding implies decisions about AI are distributed across a school, not made once at the top. Parental

involvement therefore cannot be confined to a single board meeting. It needs points of contact where real decisions are made, including departmental choices about specific tools and assessment practices.

Governance structures should also give parent representatives the information needed to participate meaningfully. That includes data-processing terms, evaluation evidence and the alternatives considered. Otherwise participation risks becoming a form of legitimation rather than shared deliberation.

One communication strategy often recommended for building parental support is to frame AI literacy as an equity issue. The argument holds that AI literacy is becoming a critical skill. Without deliberate provision in schools, a two-tier system may emerge in which only students from affluent or well-connected families gain proficiency. This framing positions AI education not as a technological experiment but as a matter of educational justice: ensuring that all students, regardless of background, have access to the tools and skills they will need in an AI-shaped world.

Claims that this framing persuades parents across income levels and political orientations should be treated as unconfirmed. No study among the verifiable sources available here tests how parents respond to equity framing, so whether it works as reliably as advocates suggest remains unclear.

The substantive concern behind the framing does have some empirical anchoring. López Costa's 2025 study found limited classroom implementation in rural Catalan schools despite moderate to high self-reported teacher knowledge. That gap suggests access to meaningful AI learning may vary by setting, although the study does not compare rural with urban schools directly.

The equity argument also cuts both ways, and honest communication should say so. Ying's 2026 findings associating perceived algorithmic bias and perceived surveillance with learners' identity and willingness to communicate suggest that AI tools can themselves be experienced as inequitable. Equity therefore points toward teaching AI literacy, and also toward scrutinising which tools are adopted and for whom they work.

A school that invokes equity to win support while deploying tools whose fairness it has not examined risks the very loss of trust that transparency is meant to prevent. The more defensible

framing presents equity as a shared commitment. It should cover universal access to AI literacy, attention to how tools perform for different groups of students, and a willingness to withdraw tools that disadvantage some children. Students' own understanding of these limits and biases is part of the same agenda (see Q082).

Communication about AI in schools must also address the home dimension, because children's AI use does not stop at the school gate. Parents need guidance on how to support their children's AI use at home. That includes which uses are appropriate at different ages, how to discuss AI with children, and how to model critical AI literacy themselves. Resources such as Common Sense Media's guide to AI in schools for parents and families show the kind of practical, accessible material schools can share or adapt. Age-related guidance is treated in more detail elsewhere in this volume (see Q150).

Schools that provide this guidance through parent workshops, age-appropriate guides and family learning resources are likely to build stronger home-school partnerships and more consistent AI literacy across the school-home boundary. This expectation rests on broader experience with home-school partnerships rather than on AI-specific outcome studies, which remain scarce. Workshops also serve a second purpose. They give parents with limited prior exposure to AI a low-stakes setting in which to ask questions. Without such settings, uneven parental confidence could reproduce the two-tier problem described above at home.

The community conversation should not be confined to classroom tools. Creely's 2026 review traces ethical, social and environmental concerns surrounding generative AI in education. Some communities will legitimately ask about the wider footprint of the systems their schools use, including where the infrastructure behind them is located and who bears its costs (see Q201). Schools need not resolve every such question, but they should not dismiss it as off-topic.

Taken together, the evidence supports a modest but clear conclusion. Trust in school AI decisions is most likely to be durable when communication is early, concrete, multi-channel and candid about uncertainty. Concerns about privacy, equity and human connection should be treated as legitimate. Parents should be given a genuine share in governance and practical support at home. Much of the evidence on specific techniques remains emerging, and schools should evaluate their own engagement efforts rather than assume any strategy will succeed.

Q087 What technical and organizational safeguards (age gates, data controls, human oversight, escalation paths) should any classroom AI deployment include?

14 citations · 14 sources · 5 cross-references

Claim 1 emerging

Any classroom AI deployment should include, at a minimum, age-appropriate access controls enforced within the tool itself, technically enforced data minimisation and retention limits, content safety calibrated to the learners, a route for escalating concerning student inputs to staff, proportionate audit logging, mandatory human review of consequential outputs, a vetted list of approved tools, defined incident escalation paths, and a scheduled cycle for reviewing all of these. These safeguards respond to a distinctive set of technical and organisational risks: data privacy violations, algorithmic bias, inappropriate content generation, manipulation of students, and the erosion of human oversight in consequential decisions. The evidence on what works is still developing. A clear set of minimum requirements is nonetheless emerging from regulatory frameworks such as the EU AI Act (Regulation 2024/1689), guidance from the UK Department for Education, the French data protection authority (CNIL) and the UK Information Commissioner's Office (ICO), and accumulated institutional experience. Much of this guidance is normative rather than evaluative. Whether a given bundle of safeguards actually reduces harm in classrooms, as opposed to satisfying compliance requirements, remains unclear, because few deployments have been studied systematically.

Age-appropriate access controls are the first line of defence. AI tools used in schools should prevent students from reaching features or content unsuitable for their developmental stage. The ICO's Age-Appropriate Design Code asks services likely to be accessed by children to put the child's best interests first, set high privacy by default, and establish age with a level of certainty proportionate to the risk. The EU AI Act goes further for one class of capability. It

prohibits AI systems that infer emotions in educational institutions, except for medical or safety reasons. This expresses the principle that some capabilities are categorically inappropriate in education, however they are configured. The prohibition protects all learners, adults included, which strengthens rather than weakens the case for applying it to children. Age gates should therefore operate at the level of the tool, not only in institutional policy, and should rest on verified rather than self-reported age. Verification itself raises a disagreement. Collecting identity documents to prove age sits uneasily with data minimisation, and the ICO's risk-based approach accepts lighter assurance where risks are low. In school settings the tension can often be eased by linking age to school-provisioned accounts already tied to enrolment records, so that no new identity data is collected.

Data minimisation and purpose limitation are foundational technical requirements, and on this point the guidance is unusually consistent. Both are core principles of the GDPR, and the CNIL's guidance on AI in education applies them directly to schools. AI tools should collect only the data strictly necessary for their educational function, and that data should be used only for the purpose for which it was collected. The scholarship on technical implementation in educational AI makes a practical point. These principles are only as strong as the mechanisms that enforce them. Database segmentation, data retention limits and automatic deletion should do the work, rather than reliance on contractual commitments from vendors alone. Schools should therefore require vendors to demonstrate technical compliance with data minimisation, not merely to supply a privacy policy. That means evidence of what is collected, where it is stored, how long it persists, and whether student inputs are used to train models. The Department for Education's guidance on generative AI similarly cautions schools against allowing pupils' work and personal data to be used to train AI models without appropriate permission.

Audit logging and transparency ensure that authorised staff can review AI interactions when necessary, for example after a safeguarding concern or a complaint about a grade. Logs should record enough to reconstruct what a student asked and what the system returned, without creating unnecessary surveillance of children's everyday learning. For high-risk systems the EU AI Act requires deployers to keep the logs these systems generate automatically, to the extent the logs are under their control, for at least six months. Logging and minimisation pull in opposite directions, and institutions resolve this differently. A defensible settlement combines purpose-bound logs, role-based access governed by clear written policies, and retention periods

no longer than the review purpose requires. Access to logs should protect student privacy while still enabling appropriate oversight. Each access should itself be recorded, so that the people overseeing the system remain accountable.

Content filtering and safety controls are essential for any AI tool that generates text, images or other content in response to student input. These controls should prevent the generation of harmful, inappropriate or misleading material, and should be calibrated to the age and context of the student population. A filter suited to sixth-form students will be too permissive for a primary classroom. The Department for Education's guidance on generative AI connects these controls to schools' existing filtering, monitoring and safeguarding duties. Common Sense Media's work on AI content safety in education likewise treats age calibration and protection against harmful outputs as baseline requirements.

Safety controls should do more than block outputs. They should also include mechanisms for flagging concerning student inputs and escalating them to human staff. These include disclosures of harm, expressions of distress, and requests for dangerous information. A child who tells a chatbot about abuse or self-harm has made a disclosure that, in most jurisdictions, triggers safeguarding obligations. The tool should route it to a designated person rather than simply produce a sympathetic reply.

Filtering has well-known limits. Filters both over-block legitimate content and under-block harmful content, and misleading content is particularly hard to catch, because a fluent but inaccurate answer passes most safety checks. For this reason, technical controls work best alongside students' own capacity to evaluate AI output. Wittig McPhee and Jerowsky (2025) argue for moving beyond a purely technical understanding of generative AI towards critical AI literacy. They point to concerns about misinformation, diminished critical thinking, ethical dilemmas and the lack of regulatory frameworks. Their piece is a perspective on university classrooms rather than an empirical evaluation. It suggests, however, that content safety is partly an educational accomplishment and not solely an engineering one.

Human oversight is the most important organisational safeguard. AI tools should be configured as drafting tools rather than final decision-makers for any consequential decision, including assessment, grading, disciplinary action and referral for support services. Human review should be mandatory before an AI-generated output affects a student's educational record or wellbeing.

The EU AI Act embeds this requirement for a defined set of educational uses. It classifies as high-risk those systems used to determine admission, evaluate learning outcomes, assess the appropriate level of education, or monitor prohibited behaviour during tests. For these systems, providers must design for effective human oversight. Deployers must assign that oversight to people with the necessary competence, training and authority, as a condition of lawful deployment. Not every classroom tool falls into these categories; a brainstorming assistant may not. The same principle is nonetheless prudent wherever an output could shape a student's record or opportunities.

The case for oversight is strengthened by evidence on algorithmic decision-making in organisations more broadly. Li and Xiang (2024) review how algorithmic controls, while improving efficiency and coordination, can introduce and amplify inequalities. Women, people of colour, marginalised groups, and people with low skills, limited education or low technology literacy can be disadvantaged. The authors attribute this to a lack of transparency, explainability, objectivity and accountability in the algorithms. Their analysis concerns workplaces rather than schools, so its transfer is by analogy. The mechanisms they identify, however, map readily onto automated grading or behaviour flagging. This is why bias testing and a route for bias complaints belong in any oversight design.

Assessment is where the pressure on oversight is most acute. Stanoyevitch (2024) describes how the shift to online learning during the COVID-19 pandemic, together with exam and homework assistance platforms and tools such as ChatGPT, left traditional assessment methods facing unprecedented challenges. Montebello (2026) goes further, arguing that generative AI decouples assessment performance from cognitive engagement, because learners can now produce assessment outputs without necessarily engaging in the cognitive processes those outputs once implied. Both analyses concern higher education, and neither evaluates specific safeguards. Their implication for oversight is nonetheless direct. If AI is used to grade work that may itself have been produced with AI, an unreviewed pipeline can certify learning that never took place. Teachers reviewing AI-assisted grades should therefore ask not only whether the mark is defensible but whether the task still elicits the thinking it was designed to assess. Where an AI flag could lead to an academic integrity finding, the student should be told the basis for it and given the chance to respond before any sanction.

Vendor vetting and an approved tools list translate these requirements into procurement. A practical framework for vetting educational AI vendors treats procurement as the point of

greatest leverage, because contractual terms, technical evidence and exit arrangements are easiest to secure before a tool is embedded in teaching. Before approval, schools should establish where data is processed and stored, whether student inputs are used for model training, which sub-processors are involved, how content safety is configured and tested, what logs are available to the school, and how quickly the vendor will report a security or safety incident. They should also ask for evidence of bias testing relevant to their student population and a clear statement of the age range the tool is designed for. Tools that pass should appear on a published list, with permitted uses and required configuration recorded alongside each entry. Staff should not use unapproved consumer tools with student data, and students should know which tools they are expected to use. Each approval needs an owner and an expiry date, because vendors change models, terms and data practices after contracts are signed, and a material change should trigger re-review rather than waiting for the next scheduled cycle.

Defined incident escalation paths ensure that when something goes wrong, staff know what to do and whom to tell. An incident might be a safeguarding disclosure made to a chatbot, harmful output reaching a student, a data breach at a vendor, or a pattern of biased results. Each type needs a named owner, a timescale, and a route to the relevant external body, whether a data protection authority, the vendor, or local safeguarding partners. The designated safeguarding lead should be the default recipient of any disclosure, while data protection incidents should go to the data protection officer, recognising that a personal data breach may need to be reported to the regulator within statutory deadlines. Escalation is an organisational capability rather than a document. Guedes and Rupprecht (2026), in a 1.5-year multi-institutional study of GenAI integration in Viennese educational institutions, frame that integration as a challenge of organisational programming, requiring a shift from rule-based to goal-oriented approaches that accommodate technological uncertainty while fostering competency development. For incident response, this suggests that scripted procedures for known risks should sit alongside a clear purpose and the authority to act on novel ones.

Staff capability underpins every one of these safeguards. Khodi and Curle (2026), writing from professional experience and classroom observation, argue that teachers are confronted with a growing array of platforms and technical courses, and that a weak distinction between AI literacy and prompt engineering sits uneasily with the promise that AI will reduce workload. Training for classroom deployment should accordingly focus on recognising unsafe outputs,

knowing the escalation route and exercising pedagogical judgement, rather than on technical mastery.

Finally, safeguards need a scheduled review cycle. Linnes and Ronzoni (2026) examine how perceived benefits, perceived risks and privacy concerns relate to trust in deepfake technology under regulatory safeguards, a question about the public rather than schools. It nonetheless indicates that confidence in AI depends on how risks and protections are perceived, which suggests that parental and student trust rests on safeguards that are visible and maintained. An annual review, and an earlier one after any serious incident, should test whether filters, age gates, logging, oversight arrangements and vendor approvals still work as intended, and should report its findings to governors and families.

Q088 How can educators and institutions with minimal budgets or infrastructure still give students equitable access to AI-supported learning?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Educators and institutions with minimal budgets can still give students equitable access to AI-supported learning by treating access as a design problem rather than a purchasing decision. In practice that means building on the devices and connectivity students already have, preferring open and lightweight tools, routing scarce resources through shared community access points, investing in teacher capability, and using procurement and data-governance policy to protect students whose institutions have little bargaining power. The difficulty is real. AI in education presents a paradox: the technology that promises to personalize learning at scale also threatens

to widen existing inequalities. Students in low-resource schools, those without reliable broadband, adequate devices, or teachers trained in digital pedagogy, are least likely to benefit from AI tools and most likely to be harmed by their absence. The equity problem is not insoluble, but it requires changes to technology, pedagogy, and policy together.

Equity strategies fail when they misdiagnose the problem. The digital divide in AI-powered education is not only a hardware problem. The research on the AI divide describes overlapping barriers. Some are structural: connectivity, devices, and electricity. Some are socioeconomic: household income and parental digital literacy. Others are pedagogical, chiefly teacher preparedness, or governance-related, such as the capacity to protect student data. Rural and high-poverty communities face geographic isolation made worse by inadequate connectivity. Students from low-income households often lack the basic digital readiness to engage with AI tools. Many platforms are also built without inclusive design principles, so they fail learners with disabilities and speakers of non-dominant languages.

One recent framework, the Equity-Centered AI Learning Access Model (ECALAM), sorts these challenges into four domains: structural inequities, AI accessibility, inclusive design, and policy governance. Its central argument is that equity requires changing pedagogy, technology, and policy at the same time, and that handing out tools is not enough.

The evidence base has a skew of its own that should make low-resource institutions cautious about borrowed advice. In a PRISMA-guided review of scholarship from 2022 to 2024, Lakhno (2026) observes that debates on AI in higher education remain dominated by evidence from high-income contexts. That evidence often assumes institutional capacity and robust infrastructure. In low-income countries, by contrast, structural constraints profoundly condition both the opportunities and the risks of adoption, which Lakhno analyses through Rogers' Diffusion of Innovations framework. Equity is also under-examined in specialised fields. Beattie and colleagues (2026), in a scoping review following Joanna Briggs Institute methods, found that little is known about how equity is addressed in AI-enabled medical education, despite claims that AI can democratise access.

Two cautions follow for institutions with small budgets. Much of the published guidance was not written for their circumstances. And the claim that AI equalises opportunity rests on thinner evidence than its prominence implies.

Minimal budgets do not mean no AI. Several technical strategies sharply lower the cost of access.

The first is mobile-first design. In many low-resource settings the smartphone is the main computing device. AI tools that work through messaging interfaces, SMS, or lightweight web apps reach students who will never use a laptop.

The second is open-source and small models. Open-weight models can run on modest hardware or be reached through free tiers, which avoids the licensing costs of commercial platforms. Small, task-specific models can sometimes outperform general-purpose systems on narrow educational tasks at a fraction of the compute cost. This is a promising direction rather than a settled finding, and its value depends on the task.

The third is offline and low-bandwidth operation. Tools that cache content, process data locally, or tolerate intermittent connectivity serve communities where broadband is unreliable or unaffordable.

The fourth is shared infrastructure. School-based device banks, community Wi-Fi, and library access points concentrate scarce resources where they can serve the most students.

Each of these choices trades frontier AI capability for reach. For equity, that trade is often the right one.

A related low-cost pattern is to ground AI outputs in materials an institution already owns and trusts, rather than relying on a general model's open-ended answers. Prakash and Prakash (2024) describe DentQA, a question-answering tool built on GPT-3.5. It uses prompt engineering to draw answers from dental documents that experts have verified, so that students can find information in the handouts and study materials their institution distributes. The authors frame the design explicitly as a response to concerns about accuracy, bias, and hallucination in AI outputs. The example comes from a well-resourced professional programme and depends on a commercial model, so it is not itself a zero-cost solution. The underlying idea still transfers to poorer settings: an AI layer that searches a school's own verified, locally relevant curriculum. That approach can be run with open models, and it keeps the content under local control. Students still need to understand why grounded tools can fail and when to check their outputs (see Q082). Whether such systems improve learning in low-resource classrooms, as opposed to improving retrieval, remains unclear.

Equitable access concerns not only who can reach the technology but whether the technology serves those who reach it. AI systems trained on non-representative data can show algorithmic bias, producing discriminatory profiling or content that disadvantages minority students. Tools designed without accessibility features exclude learners with disabilities. In linguistically diverse communities, multilingual support is a core equity requirement, not an add-on.

Institutions with minimal budgets still have leverage here. They can demand inclusive design in procurement. They can also prefer open tools whose bias and accessibility properties can be inspected and modified, which commercial black boxes do not allow.

Teacher preparedness is the other half of inclusive design. In under-resourced schools, teachers often lack the training to integrate AI effectively. Professional development is consistently identified as a critical bottleneck, and therefore a critical investment, even when it is low-cost, peer-led, and openly licensed. A practitioner analysis in eSchool News makes the point directly: equitable access to AI starts with professional development, not with devices.

Recent survey work points the same way, with the usual limits of correlational design. Güler (2026) surveyed 123 Swiss adult educators between August and October 2025. In this non-probability sample, 82.1% reported active AI use. How often educators used AI was associated mainly with their self-reported AI knowledge rather than with demographic characteristics. The same educators reported substantial constraints, most notably privacy and security concerns and limited perceived institutional support. The setting is affluent and the sample self-selected, so the figures cannot be generalised to low-resource schools. Still, the pattern is suggestive: knowledge, not background, tracks use, and teachers feel unsupported by their institutions even where infrastructure is ample.

In a very different context, Al-Raimi (2026) surveyed 280 faculty members and academic leaders in Yemeni university health education institutions. The study examined AI technologies, educational quality, and the challenges and requirements for effective implementation. It shows that the question of institutional readiness is now being studied in fragile settings, not only wealthy ones.

How teachers are prepared matters as much as whether they are. Ahmed and Alreiahy (2026) argue, in a conceptual analysis, that teacher preparation programmes have quickly adopted AI tools while giving little attention to their ethical, social, and environmental dimensions. They propose integrating AI competence, sustainability, and ethical technology use into a single

coherent framework rather than three parallel add-ons. For schools on tight budgets, the practical point is that durable, sustained capability-building matters more than one-off workshops (see Q085).

Some of the most promising low-cost pathways are community-based. Public libraries, community centres, and after-school programmes can serve as access points where students use AI-supported learning with an adult present to guide them. These sites concentrate scarce devices and connectivity where they reach the most learners. The adult mediation is arguably as valuable as the hardware, because it supplies the guidance that students without digitally fluent parents may not get at home.

Open educational resources extend the same logic. Openly licensed curricula, tools, and training materials allow institutions to build AI-supported learning without licensing costs. Open-source AI models allow inspection and adaptation that proprietary systems do not.

Teacher networks and peer-led professional development spread expertise without expensive consultants. A teacher who has learned to use an AI tool well can mentor colleagues across a district or region. Practitioner commentary such as the eSchool News analysis argues that this kind of cumulative, collegial learning does more for equitable classroom use than isolated vendor training. That claim has not yet been rigorously tested in low-resource systems.

Regulatory analyses of the AI divide reach a compatible conclusion from a different direction. Equity depends less on the volume of technology delivered than on whether access is organised around the people and institutions who will actually use it.

The common thread is that equity does not require copying the resource model of wealthy institutions. It requires designing access around the resources that actually exist in the community: the phones students carry, the library with a stable connection, the teacher who is already experimenting, and the curriculum materials already in use.

This also guards against a familiar failure. Donated or subsidised technology often arrives without the maintenance, training, or local content needed to make it useful. Hardware then sits idle, and the gap persists under the appearance of having been closed. Community-anchored approaches are slower and less visible, but they are more likely to last because they rest on capacities the community will still have after the initial funding ends.

Equity of access is not an unqualified good, and the literature disagrees about what access should mean. The dominant framing in the policy and digital-divide literature treats lack of access to AI as a deprivation to be remedied. A dissenting philosophical argument holds that how students are asked to use AI can itself wrong them.

Smith (2026), writing on literacy learning, argues that formative epistemic injustice is done to students when instructors encourage them to farm out learning tasks to generative AI. On this view, telling students to use the tool can undermine the development of their own capacities as knowers. If that argument is right, disadvantaged students face a double risk. They can lose out by being denied access, and they can be harmed by access that substitutes AI output for the very learning they most need.

The two positions can be partly reconciled, though not dissolved. An equitable strategy aims at equal access to AI used in ways that build students' capacities, not at maximal exposure to AI. It also respects students who cannot, or choose not to, use the tools (see Q111).

UNESCO's guidance on generative AI in education and research supports this more cautious stance. It calls for a human-centred approach, attention to students' age and wellbeing, data protection, and the validation of tools before they are introduced into teaching. None of these require large budgets. They do require judgement about which uses serve learning.

Teachers' own perceptions show a similar ambivalence. Miranda (2025) surveyed 376 teachers, university students, and future educators in the University of Salerno area. The study notes AI's promise to personalise learning and improve teaching efficiency alongside significant concerns about ethics and responsible implementation.

For institutions with little money, this disagreement has practical consequences. Scarce resources spent on unstructured access may buy less equity than the same resources spent on fewer, well-designed uses supported by trained teachers. Which balance produces the best outcomes for disadvantaged students remains unclear, because rigorous comparative evidence from low-resource settings is still scarce.

Equity is ultimately a policy problem, and the policy levers are available even to institutions with small budgets.

Public investment in digital infrastructure, such as affordable internet programmes and subsidised devices, remains the foundation. Institutions can advocate for it collectively rather than waiting for it.

Procurement policy is a second lever. Institutions can require vendors to offer free or low-cost tiers to underserved schools, to provide offline modes, and to demonstrate equitable outcomes rather than simply assert them. Regulatory analyses of the AI divide argue that such requirements are among the few tools available to institutions that cannot outspend the market.

Data governance matters for equity as well. Students in low-resource settings are more exposed to commercial exploitation of their data precisely because their institutions have less capacity to negotiate. Model data-protection clauses and shared procurement consortia help level the field. UNESCO's guidance likewise treats data protection and regulatory capacity as preconditions for responsible adoption, not as afterthoughts.

Governance readiness also appears to shape outcomes beyond the classroom. Potluri and Polozova (2026) studied Kazakhstan's higher education sector. They modelled how AI governance readiness relates to administrative efficiency, AI fluency orientation, and students' intentions to stay enrolled. They also tested whether students' perceptions of equity moderate these relationships. Their inclusion of equity perception as a variable is notable: whether students believe AI is being deployed fairly may condition whether institutional AI delivers its intended benefits. As with other survey-based models, the relationships are associations and do not establish causal effects.

Governance should also include the people affected. Teachers, students, and parents need meaningful input into adoption decisions, and this is especially true in communities that have historically been designed around rather than designed with (see Q235).

Finally, institutions should measure equity explicitly. Adoption and outcome data broken down by income, geography, language, and disability status turn equity from a stated value into a monitored outcome. This kind of measurement is inexpensive compared with almost any technology purchase, and without it institutions cannot tell whether their strategies are narrowing the gap or quietly widening it.

The schools that close the AI gap will not necessarily be those with the largest budgets. They will be those that treat access as a design problem, at once technical, pedagogical, and political,

rather than as a purchasing decision.

Q147 What should a teacher do on first encountering AI-written student work?

15 citations · 15 sources · 5 cross-references

Claim 1 emerging

A teacher who first encounters work that appears to have been written wholly or substantially by a generative AI system should not open a detection tool. The first step is to treat the suspicion as a question to investigate with the student, using evidence about process and understanding rather than a software score. Reaching for a detector is an understandable instinct, but current scholarly and institutional guidance treats it as an unwise first move. The objection is methodological as much as ethical. Academic integrity procedures must be defensible and evidence-based, and AI detection software cannot at present supply evidence of that quality.

The guidance on this point is unusually consistent across very different authorities. OpenAI's help-centre advice to educators warns against treating classifier output as proof of misconduct. Cornell University's Center for Teaching Innovation frames AI-related integrity concerns as matters for pedagogical conversation and transparent course policy rather than automated adjudication. The Online Learning Consortium's guidance on ethical responses to AI-generated student work likewise begins with dialogue rather than sanction. New Zealand's Ministry of Education, in its 2025 guidance on generative AI in NCEA assessment, reaches the same conclusion from a national assessment perspective.

The rest of this answer sets out why detectors fall short and what an evidence-based sequence of inquiry looks like. It then turns to the policy conditions that make any finding fair and to the assessment designs that make such encounters less likely. It closes with what teachers and school leaders should do in practice.

Researchers, educational institutions and even the companies that build detection tools now broadly agree that AI detection software should never be the sole or primary basis for an academic integrity finding. OpenAI has stated plainly that its own research found such tools insufficient for high-stakes judgements about individual students. It notes that they frequently mislabel human-authored text, including historical documents, as machine-generated.

The size of the problem is harder to pin down, and here the sources part company. Figures circulating in practitioner discussion put false-positive rates anywhere between 5% and 30%. These figures do not come from a single controlled study. Even GPTZero, a detection vendor, acknowledges the problem in its own discussion of students falsely accused of AI cheating. Its account carries the obvious interest of a commercial provider and should not be read as independent research. Even at the lower end of the range, the margin is wide enough to expose innocent students to serious and unjust accusations.

The weakness is not confined to software. Fisk (2024), writing in Teaching of Psychology, argues that both humans and detection technologies have difficulty telling AI-generated text from human writing. This, he notes, creates a significant possibility of false positives: human writing wrongly judged to be machine-made. His central observation is that detection methods, whether run by a machine or a person, rest on characteristics of writing style.

That observation exposes a real tension in the guidance. New Zealand's Ministry of Education, reviewing the same evidence base, concludes that detection software is at best a supplementary tool. It holds that the most reliable detection comes from teachers who know their students and their work over time. Fisk's analysis suggests that teacher judgement, too, is vulnerable when it relies on stylistic impressions alone. The two positions can be reconciled. A teacher's knowledge of a student is most valuable when it guides a conversation about content and process, and least valuable when it becomes a hunch about prose style.

The stylistic basis of detection also explains a troubling equity dimension. Detection algorithms disproportionately flag writing by non-native English speakers, whose more formulaic or predictable prose can trigger the same statistical signals that the tools associate with machine

generation. Relying on these tools therefore builds systemic bias into integrity proceedings. That potentially breaches fairness principles that educational institutions are legally and ethically bound to uphold.

Opacity compounds the problem. Most detection algorithms are proprietary 'black boxes', so their findings cannot be verified even when they are shared with students and families. Education Week's 2025 reporting shows how wide the difficulty has become: schools are now also receiving complaints from families that were themselves generated by AI. Recognising machine authorship is a general professional challenge, not one confined to student essays, and confident identification remains elusive in every setting.

The recommended first response is to reframe the situation. Rather than an accusation that requires proof, the encounter becomes an academic conversation that requires clarification. Multiple institutional frameworks, including the Cornell and Online Learning Consortium guidance, point to a broadly similar sequence of four steps. Its value lies in assembling several independent kinds of evidence rather than any single decisive test.

The first step is an initial dialogue. The teacher asks the student to explain how they researched and wrote the work, or to define and expand on its key terms, arguments and evidence. This conversation alone often settles the matter without any formal allegation.

The second step follows if the conversation raises doubts rather than resolving them. The teacher can then ask for tangible evidence of process. Useful examples include version histories from collaborative platforms such as Google Docs, rough notes, annotated outlines and early drafts. Students who did the work themselves can usually produce this material, while those who did not often cannot.

The third step is an oral defence, in which the student explains, defends or extends the submission aloud. This is widely identified as the most reliable way to establish whether the student has the knowledge the assignment was meant to demonstrate. It is neither punitive nor extraordinary. Oral examination has a long history in education precisely because it tests understanding rather than output.

The fourth step is contextual comparison. The flagged submission is set against the student's previous work, in-class writing samples or observed performance, looking for meaningful inconsistencies in register, vocabulary, conceptual sophistication or citation habits. Fisk's

(2024) caution applies with particular force here. Stylistic difference alone is weak evidence, because students' writing legitimately varies and develops. Comparison should therefore support the content-focused steps rather than replace them.

How well this sequence works depends heavily on the relationship in which it takes place. Han and Li (2026) studied how teacher immediacy and teacher-student rapport relate to the resilience of English as a Foreign Language students in AI-enhanced learning environments. They frame the educator's interpersonal role as critical to learners' outcomes in such settings. Their study does not address integrity cases directly. Its framing nonetheless supports a practical point: a student who trusts the teacher is more likely to engage openly in a clarifying conversation. A conversation that feels like an interrogation may produce defensiveness that looks, misleadingly, like guilt.

Educational discourse now holds AI-related integrity cases to the same procedural requirements as any other academic integrity dispute. What makes them distinctive is that the definition of authorship is itself becoming contested (see Q102). Students may legitimately use AI to brainstorm or check grammar, so the line between assistance and substitution is not self-evident.

Institutions are therefore urged to set out clear written policies in course syllabi. These should specify which AI uses are permitted, which require disclosure and which are prohibited (see Q265 on writing and maintaining such policies, and Q083 on how students disclose and document their use). Cornell's guidance places this transparency at the centre of its approach. Without that prior clarity, educators are poorly placed to make integrity findings after the fact, because a student cannot fairly be judged against a standard that was never stated.

The National Education Association's five principles for AI in education reinforce this from a professional standpoint. They insist that AI use stays centred on people, that educators' judgement is respected and that equity is protected. These commitments sit uneasily with handing a consequential decision to an opaque algorithm.

Fairness, as students perceive it, may matter for more than procedural correctness. Zhang, Lu and Kanji (2026) examined how teacher-regulated generative AI support relates to university students' perceived learning gains. They tested whether student agency mediates that association and whether perceived fairness conditions the link between teacher regulation and agency. The study uses perceptions rather than measured outcomes and examines associations

rather than causes. Even so, its design treats perceived fairness as a variable that can strengthen or weaken how students respond to teachers' regulation of AI. That is consistent with the institutional view that integrity procedures shape the climate for learning as well as the outcome of the individual case.

Punitive measures based solely on detector scores are widely discouraged. Part of the reason is fairness. They also expose institutions to legal challenge and erode the trust-based relationships on which effective education depends. A teacher who can show that they followed an evidence-based, documented process stands on far stronger professional and legal ground. Such a process gives the student a meaningful opportunity to demonstrate their understanding before any consequence follows.

Beyond individual incidents, the deeper lesson of the evidence is that assignment design is the most sustainable defence (see Q078 for a lesson-level framework for deciding when AI helps or undermines learning).

Process-oriented assessments make wholesale AI substitution far harder. Tasks that require iterative drafts, reflective logs or thinking journals generate the very process evidence that the inquiry sequence relies on. Assignments that draw on personal knowledge, such as local context, specific class discussions or individual experience, resist AI replication more effectively than generic prompts. Both the Cornell and Online Learning Consortium guidance emphasise redesign of this kind. Such assessments also reduce the number of ambiguous cases a teacher must investigate in the first place.

Some educators go further and build AI into the task itself. Students are explicitly required to generate AI output and then critique it for accuracy, bias and logic, so that the technology becomes an object of learning rather than a threat. Ko (2026) offers a theoretical grounding for this move. He proposes a curricular framework for cultivating inquiry-driven agency in how students engage with AI. He argues that the literature on AI in education has attended closely to material access and algorithmic fairness. In his view, it has given comparatively less sustained attention to the learner-side capacities that determine whether students engage with AI critically or passively. His contribution is a framework rather than an empirical evaluation. Whether such curricula reduce misuse in practice remains unclear.

The logic of the framework still fits the integrity question well. A student who has been taught to interrogate AI output has less reason to submit it uncritically. A teacher who has designed for

visible inquiry has more evidence to draw on when doubts arise.

A teacher meeting suspected AI-written work for the first time should take four steps. First, pause before relying on any detection tool. Second, open a non-accusatory dialogue with the student. Third, document each stage of the inquiry carefully. Fourth, consult the institution's academic integrity policy and its designated academic integrity officer before escalating. This sequence follows the guidance of OpenAI, Cornell, the Online Learning Consortium and New Zealand's Ministry of Education. It also honours the NEA's insistence that professional judgement, not automated output, remains central.

School leaders carry complementary responsibilities. Their policies should define explicitly which uses are and are not permitted, and these expectations should be communicated before assignments are set rather than after a problem has surfaced. Professional development should help every teacher understand both the limits of detection tools and the value of process-oriented teaching.

The research on teachers' own relationship with AI suggests that such development cannot be taken for granted. Runge, Hebibi and Lazarides (2025) used the technology acceptance model to examine pre-service teachers' acceptance of AI. They investigated whether AI-related teacher training courses and AI-related technological pedagogical content knowledge (AI-TPACK) shape intentions to use AI and actual use. They describe both factors as relevant yet empirically under-investigated. Taşkın (2026) examined how AI literacy predicts attitudes towards AI among Turkish teacher-education students, partly to test whether global AI competency standards apply in that context. Liu and Wang (2026) studied AI anxiety among Chinese EFL teachers and whether it predicts work engagement and resilience. Their study is a reminder that some teachers approach these encounters carrying unease of their own. On delivery, Leitgeb and Leitgeb (2025) conducted a mixed-methods evaluation of an AI-based chatbot that offered context-sensitive, personalised professional development recommendations in Austrian higher education. Their aim was to address the limited relevance of generic programmes.

None of these studies examines integrity cases directly, and their samples and national contexts limit how far they generalise. Together, they suggest that teachers' preparation, literacy and confidence with AI vary considerably. They also suggest that this preparation is a plausible influence on how calmly and competently a teacher handles a first encounter with suspected AI-written work. Whether targeted training actually improves the fairness of integrity decisions

remains unclear. That is a question schools and researchers would do well to investigate, rather than assume.

Q150 What guidance exists for parents deciding which AI use is appropriate at home, by age?

11 citations · 11 sources · 5 cross-references

Claim 1 emerging

Parents can draw on a modest but converging body of guidance on age-appropriate AI use at home. It includes an explicit minimum-age recommendation from UNESCO, child-rights principles from UNICEF, regulatory warnings from the United States Federal Trade Commission, and age-banded advice from consumer-facing organisations such as Common Sense Media and education outlets such as EdCircuit. Very little of it rests on outcome research conducted in homes.

Generative AI tools entered everyday household life faster than frameworks that parents could apply in practice. Most parents are not AI specialists, and the technical complexity of these systems can make oversight feel overwhelming. Intergovernmental, governmental and consumer bodies broadly agree that parents do not need technical expertise. What they need is a conceptual framework, guidance organised by age, and practical routines that can become ordinary household conversations.

The sources share a stance. None treats AI as something children should simply be kept away from. All treat it as something whose use should be scaffolded according to a child's

developmental stage. UNESCO calls for an "age and developmentally appropriate" approach to generative AI. UNICEF frames the issue in terms of children's rights and evolving capacities. Common Sense Media translates these principles into language for families. The sections that follow set out the age threshold UNESCO proposes, the developmental bands that emerge from synthesising the guidance, the household routines most sources recommend, the value of aligning with schools, and the limits of the evidence behind all of it.

UNESCO has taken the most explicit institutional position on age. It recommends that governments set a minimum age of 13 for the independent use of generative AI platforms in school settings. The rationale is not arbitrary. UNESCO argues that untested and under-researched tools are inappropriate for primary education, and that children require the same protective standards in digital environments as they enjoy in physical ones. Although the recommendation is addressed to governments and schools rather than households, parents can reasonably read it as a benchmark for unsupervised use at home.

The threshold matches the 13-year minimum written into the terms of service of many commercial AI platforms, including ChatGPT. A formal platform minimum does not settle the question of consent, however. New Zealand's Ministry of Education, writing in the Education Gazette, notes that parental permission requirements may apply to users under 18 even where a platform formally admits 13-year-olds. A teenager being allowed to open an account is therefore not the same as a parent having agreed to it. Families should also understand that age gates usually depend on self-declaration. The technical and organisational safeguards that institutions should layer on top of such gates are discussed separately (see Q087).

UNESCO's guidance does not stop at a numerical limit. Its broader framework for generative AI in education and research grounds AI use in children's evolving capacities rather than in a single bright-line cutoff. UNICEF's policy guidance on AI and children makes a similar case: protections and opportunities should be calibrated to a child's development. Even above age 13, then, the nature of AI use and the level of supervision should keep adapting to the child's cognitive and social maturity. On this view, a 13-year-old and a 17-year-old who are both technically permitted on a platform warrant quite different levels of parental involvement.

Read together, the available guidance yields a reasonably clear three-stage framework. The boundaries between stages are approximate rather than empirically fixed.

For elementary school children, roughly ages 6 to 12, AI should be a shared and supervised activity. Parents are advised to sit alongside children and explore creative prompts together. While doing so, they should actively teach that AI can produce answers that sound confident but are wrong. The aim at this stage is not to ban contact with AI. It is to ensure that children grasp a foundational idea: these are pattern-matching systems, not authorities that tell the truth. UNESCO's framing of this goal has been described as building "conceptual hygiene," meaning that children learn AI finds patterns rather than possessing understanding. Common Sense Media's guidance for parents similarly stresses demystifying how these tools generate text and images.

For middle school children, roughly ages 12 to 14, clear boundaries become essential. EdCircuit's age-based guide recommends that students follow a "think first, ask second, verify third" sequence in any AI interaction. Family conversations at this stage should address an ethical distinction. Using AI to brainstorm is widely regarded as legitimate. Using AI to generate work that is then submitted as one's own is treated as misconduct by most schools. The stakes are real. Stanoyevitch (2024) describes how the shift to online learning during the COVID-19 pandemic intensified concerns about assessment integrity. That shift coincided with the rise of homework-assistance platforms used for questionable exam help and with tools such as ChatGPT, and together these posed unprecedented challenges to traditional assessment methods. Children of middle school age are encountering this landscape for the first time, so household norms matter. This is also the stage at which children can begin to engage with algorithmic bias: AI outputs are shaped by training data, and that data reflects the world's inequities.

For high school students, roughly ages 14 to 18, adolescents can be encouraged to use AI as a genuine learning partner. Suitable uses include rehearsing for interviews, working through complex problems, practising a language, and generating counterarguments. The condition is that students remain accountable for verifying and understanding the final output (see Q081). Language practice illustrates both the promise and the gaps in the evidence. Tabiri, Jones-Mensah and Kouamé (2026) surveyed Ghanaian tertiary students about how effective they found AI tools for language skills, their patterns of use, the languages involved, and the point in their academic journey at which they adopted these technologies. Their work, guided by the Unified Theory of Acceptance and Use of Technology and by constructivist learning theory, examines AI use both inside and beyond the classroom. It concerns university students'

perceptions, however, not adolescents' measured learning. It shows that the question of when learners begin using AI is now being studied, but it does not tell parents what age is optimal. Disclosure habits formed in the high school years are likely to carry into university and professional life (see Q083).

Several guidance sources converge on a set of household routines that work across age groups.

The first is a family AI agreement. Several frameworks recommend a short, living set of household rules. Suggested examples include "I try the problem myself first before asking AI," "I never share my real name, address, or health information with a chatbot," and "I will always verify facts against a trusted source." The word "living" matters, because these agreements should be revisited as children mature and as the tools change.

The second is education about data privacy. The FTC enforces the Children's Online Privacy Protection Act (COPPA). In launching an inquiry into AI chatbots that act as companions, it flagged that many such services collect, use and retain personal information in ways that differ by user age and are rarely transparent to families. Parents are advised to read the terms of service of any AI tool their child uses. In particular, they should check whether conversations are used to train future models and whether parental controls or account-management tools exist.

The third is the distinction between productive struggle and shortcuts. Consumer guidance, including Common Sense Media's, repeatedly separates two uses of AI. One is getting "unstuck," which is a legitimate learning move. The other is bypassing the struggle that produces durable learning. Rather than asking only whether AI was involved, parents are encouraged to ask: "What part of this shows your own thinking?" Theoretical work offers a rationale for this emphasis, though not proof. Chen (2026) proposes the Cognitive Adaptation in the Intelligence Era model, a dynamical-systems framework that represents technology-driven cognitive pressure as a time-varying forcing function in a system of differential equations. Chen hypothesises that education designed with insights from motivational neuroscience can sustain positive cognitive adaptation even under accelerating AI pressure. This is a formal hypothesis rather than a tested household finding. Still, it fits the intuition behind the guidance: how AI use is structured may matter more than whether it occurs. Teachers face the same question lesson by lesson (see Q078).

The fourth is treating human connection as non-negotiable. UNICEF and UNESCO both stress that AI chatbots are machines, not friends or therapists. If a child appears to be turning to an AI companion for emotional support, parents are urged to create opportunities for human connection with family, peers or a counsellor, rather than treating the AI as an adequate substitute. The FTC's concern with companion chatbots specifically reinforces this point. Research comparing AI support with human guidance is beginning to appear, but not with children. Dinçer (2026) used a quasi-experimental design with 76 preservice mathematics teachers at two universities. The study compared learning in AI-supported and instructor-led settings and evaluated participants' examples and explanations for both accuracy and originality. This kind of study could eventually inform the balance between machine and human support. Because its participants are adults in teacher education, though, it cannot be generalised to the emotional or developmental needs of children at home.

Guidance consistently notes that what parents do at home works best when it aligns with school policy. Parents are advised to ask their child's school three questions. Which AI tools are approved for classroom use? What disclosure requirements apply to AI-assisted work? How are students being taught to verify AI-generated information and to recognise bias? New Zealand's guidance for schools and families and EdCircuit's parent guide both treat home and school as one system rather than two separate jurisdictions.

Alignment keeps children from receiving contradictory messages. It is easy to imagine a household that encourages AI brainstorming while a school treats any AI involvement as a violation, or the reverse, leaving a child to work out the rules alone. Stanoyevitch's (2024) account of the pressures that online assistance tools and generative AI place on assessment helps explain why school policies are changing quickly and why parents may need to revisit these questions each year. Schools carry reciprocal obligations to communicate their decisions and to involve families in making them (see Q086).

Most of the guidance reviewed here is practical and principles-based. It is not drawn from longitudinal empirical research on outcomes for children who did or did not follow particular AI-use routines. UNESCO's age threshold rests on a precautionary judgement that the tools are under-researched, not on evidence that 13 is a developmental turning point. The three-stage framework is a synthesis of expert and organisational advice, and its age boundaries are conventions. The FTC's concerns are regulatory and investigative rather than findings about harm.

The recent research literature does not yet fill these gaps. The fresh studies available are relevant only indirectly. Tabiri and colleagues (2026) examine perceptions among tertiary students. Dinçer (2026) studies preservice teachers. Chen (2026) offers a theoretical model. Stanoyevitch (2024) analyses assessment integrity in online education. None studies children, families or home use. The evidence that under-supervised AI use can displace productive cognitive effort is emerging but not yet conclusive at the household level. How these effects differ between younger and older learners remains unclear and is examined further elsewhere (see Q057).

Parents should therefore treat current guidance as a set of reasonable precautionary frameworks rather than established science. Its strongest elements are least likely to be overturned by new evidence: supervision that scales with age, protection of personal data, insistence on the child's own thinking, and keeping human relationships central. Specific age cutoffs and particular tool recommendations deserve more provisional trust and should be revisited as research on children's AI use matures.

Q231 What classroom-level governance practices enable teachers to implement AI policy consistently and pedagogically?

18 citations · 18 sources · 5 cross-references

Claim 1 emerging

Teachers implement AI policy most consistently and pedagogically when institutional rules become a small set of concrete classroom practices: task-level permissions, approved tool lists, disclosure requirements, process-based assessment, and ongoing professional learning, all

backed by clear institutional guidance and collegial support. The case for these practices begins with a familiar problem. Institutional AI policies, however well designed, are only as effective as their implementation in classrooms. Research on technology policy implementation in schools consistently documents a persistent gap between policy and practice, one of the most stubborn challenges in educational governance. That gap is especially acute for AI for two reasons. Technological change outpaces the capacity of institutional policy to keep up. And the pedagogical implications of AI use depend heavily on context: a use that supports learning in one subject, task, or age group may undermine it in another.

Policy enactment research outside AI helps explain why the gap persists. Chinkhondo (2026) drew on Policy Enactment Theory, Sensemaking Theory, and Street-Level Bureaucracy and interviewed 18 purposively selected primary teachers across three regions of Malawi. The study traced how top-down early literacy mandates are recontextualised in multilingual, under-resourced classrooms. Badal (2024) studied teachers in highly regulated South African reform contexts over a school year. That study found that accountability and performativity measures increased the complexity of teachers' practice, intensified their labour, and heightened their need for compliance. Neither study concerns AI. Taken together, however, they caution that teachers always reinterpret policy, and that tightening control can produce compliance without pedagogical judgement.

The upstream AI policy environment widens the gap. Rasheed (2026) analysed state-level AI guidance documents issued between 2023 and 2026 by 40 U.S. states and territorial jurisdictions. Ethics and data privacy dominate these documents, equity and educator capacity-building receive moderate attention, and stakeholder trust and ongoing monitoring remain underdeveloped. Rasheed frames this pattern as AI adoption outpacing the development of coherent policy frameworks. The implication for classrooms is direct. Teachers often receive guidance that says a good deal about what to avoid and much less about how to build the capacity to decide well, or how to tell whether their decisions are working. UNESCO's guidance on AI in education likewise frames classroom implementation as a matter of human-centred pedagogical judgement rather than mechanical rule-following. The burden of translation therefore falls squarely on teachers and on the structures that support them. That makes the classroom-level practices enabling such translation central to AI governance in schools.

The policy-practice gap shows up in specific, recurring difficulties. Teachers often lack the guidance they need to turn broad principles into concrete classroom decisions. Many are unsure which AI uses are permitted, conditional, or prohibited for a particular task. They may lack the pedagogical knowledge to design AI-resilient assessments, or to build AI use into instruction in ways that serve learning goals. And they often lack the time and support to develop these competencies through trial and error.

Aljemely's (2024) systematic review reports a dearth of research on how teachers are trained to use AI. It synthesises only 10 studies, covering the importance of AI, teachers' use of it, the challenges faced by teachers and trainers, and best practices for trainers. That such a review could find so few studies is itself evidence of how thin the support base remains.

The interpretive burden is visible in teachers' own accounts. Alzahrani, Aldubayyan and Alshabi (2026) conducted a qualitative study of how 10 writing teachers in Saudi Arabia viewed and navigated their institutional AI policies. They describe English language teachers as remaining in a constant state of interpreting, implementing, and negotiating policies that were developed rapidly and continue to evolve. They also note how little is known about how teachers reconcile those policies with their everyday pedagogical practice.

Teachers' knowledge and dispositions add a further layer of variation. Alé-Silva, Ávalos and Araya (2025) analysed Chilean teachers' knowledge of AI using the Intelligent-TPACK framework, which includes an ethical dimension. They argue that teachers need such knowledge to guide responsible AI use, and that empirical evidence to support this process remains limited in Latin America. Fiorucci and Bevilacqua (2026) adapted and validated, for Italy, the questionnaire developed by Alsudairy and Eltantawy for measuring teachers' attitudes toward AI. They explored attitudinal differences across socio-professional variables, on the premise that attitudes reveal acceptance, resistance, and professional development needs. They describe generative AI as reshaping teaching practices, assessment criteria, and ethical questions about authenticity, source reliability, and educational responsibility. Day's (2026) participatory study involved 76 preservice teachers in a postgraduate programme in China. It used thematic analysis of online forum posts, interpreted through the TPACK framework, to examine how future teachers view AI as a non-human instructor and whether it might replace human teachers. None of these studies measures implementation consistency directly. Together, however, they suggest that teachers bring differing knowledge and beliefs about AI's proper role into their classrooms, and these will shape how any policy is read.

The result is that AI governance in many schools is marked by inconsistency. Teachers in the same institution apply different standards, communicate different expectations to students, and make different judgements about when AI use is appropriate. This inconsistency confuses students, who may face opposite rules in consecutive lessons. It undermines the integrity of assessment, because comparable work is judged under incomparable conditions. And it makes AI use hard for institutions to monitor and evaluate. The practices below are best understood as ways to narrow that variation without removing the professional judgement that context-dependent pedagogy requires.

The first practice is task-level permissions. Effective classroom governance does not apply a single institution-wide rule to all AI use. Instead, it specifies which AI uses are permitted, conditional, or prohibited for each task. A task that asks students to demonstrate their own writing competence might prohibit AI drafting but permit AI editing. A task that asks students to analyse a complex problem might permit AI for gathering information while requiring students to develop the analysis themselves. Task-level permissions give students clear, actionable guidance and reduce the ambiguity that produces inconsistent compliance. They also align with UNESCO's emphasis on fitting AI use to specific learning purposes rather than treating it as uniformly good or bad. The breadth of legitimate uses strengthens the case. Wang, Zainuddin and Chin (2025) reviewed 28 empirical studies published between 2022 and 2024 in high-impact education journals and catalogued varied pedagogical applications of generative AI, each with its own benefits and challenges. That variety is hard to govern with one blanket rule. This logic connects closely to assignment design more broadly (see Q079).

Classroom studies suggest what deliberate task-level design looks like in practice, though not yet whether it improves consistency. Alsuwaida and Alsamiri (2025) studied an advertising art course in a fine arts bachelor's programme at a Saudi university in Fall 2024. AI activities in the course were designed using the Saudi Artificial Intelligence in Digital Learning (AIDL) framework and the TPACK model, and the researchers examined students' perspectives on those activities. Kellam, Pérez Cortés and Gilmore (2025) added ChatGPT to three online activities in a 16-week graduate class, using it to mentor students as they designed and developed assignments. They examined perceived learning experiences and the challenges of working with prompts the instructors had designed; participants were professional teachers and instructional designers. In both cases, AI use was bounded by the task and its purpose rather than left open, which is the core logic of task-level permissions. These are, however, single-

course studies of perceptions. They show that bounded, purpose-specific designs are feasible, not that they are superior.

The second practice is approved tool lists. Teachers should keep a list of AI tools vetted for safety, privacy, and pedagogical appropriateness, and should state clearly which tools are approved for which purposes. This reduces the risk that students use unvetted tools that collect sensitive data or generate inappropriate content. It also gives teachers a manageable set of tools in which to build expertise, which matters given the training gaps already described. Cordero, Torres-Zambrano and Cordero-Castillo (2024) drew on workshops and courses for university professors to propose best practices for sustainable classroom implementation of generative AI. They identify ethical AI usage as a central challenge, alongside opportunities such as improved resource creation, and tool vetting is one practical way to make that challenge manageable at classroom scale. In most schools, though, vetting is better done collectively through institutional processes than by individual teachers working alone (see Q265).

The third practice is disclosure. Teachers should require students to declare their AI use in submitted work, naming the tool, the purpose, and the extent of use. Disclosure serves accountability and pedagogy at once. It creates a record of AI use that can be reviewed if questions arise, which also gives teachers a principled starting point when they suspect undeclared AI involvement (see Q147). It also asks students to reflect on their AI use rather than simply accept AI-generated output. That reflective function fits with work on AI literacy in higher education. Oncioiu and Bularca (2025), in a study of 270 university students, examined how institutional settings that prioritise real, shared, and well-managed knowledge can raise students' awareness of the legal and ethical dimensions of AI use. However, their study concerns knowledge-based institutional strategies rather than disclosure statements, and university students rather than school pupils. The link to classroom disclosure is therefore an inference, not a tested finding. It remains unclear from these sources how honestly students disclose, and whether disclosure changes their learning behaviour. Disclosure is best treated as a promising practice whose effects still need direct study.

The fourth practice is process-based assessment. Teachers should design assessments that evaluate the process of learning as well as the final product: how students respond to feedback, how they revise, and how they explain their reasoning. Process-based assessment is more resistant to AI substitution than product-based assessment, because drafts, revisions, oral explanations, and in-class reasoning are harder to outsource wholesale. It also yields richer

evidence of student learning. Fiorucci and Bevilacqua's (2026) observation that generative AI is reshaping assessment criteria and raising questions of authenticity reflects the pressure behind this shift. UNESCO's guidance similarly calls for assessment approaches that keep human learning at the centre.

Two cautions apply. First, process-based assessment demands more teacher time, which collides with the time constraints already identified as a barrier to implementation. Second, none of the recent studies cited here tests the comparative resistance of process-based designs empirically. The claim rests on the logic of assessment design rather than on controlled comparison, and its evidence base should be described as emerging. Disclosure and process-based assessment also reinforce each other. A disclosure statement becomes far more meaningful when it is read alongside drafts and revision histories, and the combination gives teachers evidence that neither provides alone.

The fifth practice is ongoing professional learning. Because the tools teachers govern keep changing, effective classroom governance requires teachers to keep updating their knowledge of AI capabilities, limitations, and pedagogical implications. This depends on institutional support, including time for professional learning, communities of practice, and access to current research, as well as on individual commitment to staying current. Walter (2024) likewise argues that integrating AI into education requires comprehensive educator training and curriculum adaptation, alongside AI literacy, prompt engineering proficiency, and critical thinking. That contribution, however, is a discussion paper rather than an empirical evaluation. The empirical evidence is suggestive but thin. Aljemely's (2024) review applied strict inclusion and exclusion criteria, identified challenges faced by both teachers and trainers, and set out best practices trainers could adopt, while stressing how little the field has examined teacher AI training directly. Cordero and colleagues (2024) reported on workshops for university professors and proposed best practices for sustainable integration. Their work is a practice-based account from higher education, however, not an evaluation of outcomes in schools.

The literature also indicates what professional learning must address beyond technical skill. Day (2026) used TPACK to frame how preservice teachers understood AI's relationship to teaching. This suggests that professional learning for AI governance should integrate technological, pedagogical, and content knowledge rather than treat AI as a stand-alone tool topic. The same framing underpinned Alsuwaida and Alsamiri's (2025) activity design, which shows how such knowledge can be turned into task design. Alé-Silva and colleagues' (2025)

use of Intelligent-TPACK goes further by placing ethics inside teachers' professional knowledge, which is exactly where classroom governance decisions are made. Fiorucci and Bevilacqua (2026) argue that teachers' attitudes signal professional development needs, so effective programmes will probably need to engage teachers' beliefs as well as their skills. UNESCO's guidance treats teacher capacity as a precondition for responsible classroom AI use rather than an optional extra. Rasheed's (2026) finding that capacity-building receives only moderate attention in state guidance indicates that this precondition is often under-resourced.

One-off training sessions are unlikely to meet these demands. Knowledge acquired in a single workshop dates quickly as AI tools change. And because good AI pedagogy depends on context, generic training transfers poorly to particular subjects and year groups. Sustained, practice-embedded models fit the problem better, such as recurring collaborative planning, structured peer observation, and inquiry cycles tied to real tasks (see Q085). Their comparative effectiveness for AI specifically has not yet been established in the sources reviewed here.

Classroom-level governance works best when it is supported by clear institutional policy, adequate professional development, and a culture of collaborative learning. Teachers who receive specific, actionable guidance from their institutions are more likely to implement AI policy consistently than those given broad principles that leave every implementation decision to individual judgement. This is consistent with the broader research on the policy-practice gap in school technology. Specificity need not mean rigidity, however, and Badal's (2024) findings on performativity show why the distinction matters. The task-level model works because institutions supply a shared vocabulary of permitted, conditional, and prohibited uses, which teachers then apply to their own tasks. Teachers retain the judgement that, as Alzahrani and colleagues (2026) observe, they already exercise when negotiating institutional AI policies.

School leadership shapes whether such guidance takes hold. Avidov-Ungar and Ganon-Shilon (2026) conducted semi-structured interviews with 16 elementary and high school principals from four school districts within a national programme. Using bottom-up thematic analysis, they examined how principals communicated technology and transformational leadership practices to spread adoption of an AI-in-education policy, framed as innovation diffusion at the persuasion stage. The study is small and qualitative and does not measure classroom consistency. It does suggest, however, that how leaders communicate and model a policy is part of its implementation, not merely a precursor to it. At the institutional level, Potluri and Polozova (2026) examined AI Governance Readiness in Kazakhstan's higher education sector.

They modelled its relationship with administrative efficiency, AI fluency orientation, and student retention intentions, with equity perception as a moderator. That work concerns universities, and its abstract does not report effect sizes, so its relevance to school classrooms is indirect. It nonetheless reinforces the idea that classroom practice sits within wider governance capacity.

Collegial learning is the final condition. Teachers who learn from colleagues through communities of practice, peer observation, and collaborative planning are more likely to develop the pedagogical knowledge needed to integrate AI effectively. Collegial structures also counter inconsistency directly, because shared planning surfaces divergent standards before students encounter them. The workshop-based model reported by Cordero and colleagues (2024) illustrates collective professional learning, though in higher education and without outcome evaluation.

Rasheed's (2026) finding that stakeholder trust and ongoing monitoring remain underdeveloped marks the main frontier. Consistent classroom governance will be hard to verify, and harder to sustain, until institutions build feedback loops that let teachers, students, and parents report how policies work in practice (see Q235). The weight of evidence supports the direction of these practices. Rigorous evidence on their comparative effects in school classrooms remains limited, however, and claims about them should be held to that standard.

Q265 How should a school write, implement, and keep current an AI acceptable-use policy that remains meaningful as technology and institutional practice evolve?

12 citations · 12 sources · 5 cross-references

Claim 1 established

An AI acceptable-use policy faces an unusual challenge: it must govern a technology that changes faster than most school policies are revised. A policy written around specific tools may be obsolete within months, while one written in vague generalities may give students and teachers little practical guidance. Evidence from surveys of schools and from frameworks developed by educators suggests several principles for writing, implementing, and maintaining policies that remain meaningful over time.

The need for policy is clear. RAND's 2025 report AI Use in Schools Is Quickly Increasing but Guidance Lags Behind, by Doss and colleagues, found that only 45 percent of U.S. principals reported having school or district policies or guidance on AI, and only 34 percent of teachers reported policies on AI related to academic integrity. More than 80 percent of students surveyed said their teachers had not explicitly taught them how to use AI for schoolwork. Policy appears to be associated with practice: Gallup and the Walton Family Foundation's 2025 teacher survey found higher reported AI use in schools with an AI policy, around 70 percent compared with 60 percent without one, although this association does not establish that policies cause greater use.

Writing a durable policy begins with process. The TeachAI toolkit, developed by a coalition of education organisations, recommends forming a working group that includes teachers, administrators, students, families, and technical staff, and grounding the policy in the school's educational mission. Involving those affected tends to produce policies that reflect actual practice and command greater legitimacy, and the Digital Education Council's and other student surveys suggest that students want a role in these decisions.

Content should be built on principles rather than tool lists. Durable policies state purposes, such as supporting learning, protecting privacy, maintaining honesty, and promoting equity, and derive specific expectations from them. Instead of naming permitted or prohibited products, they describe categories of use and the conditions under which each is appropriate, and they place tool-specific details in appendices or guidance documents that can be updated without revising the core policy.

Task-level differentiation is one of the most useful design features. Perkins, Furze, Roe, and MacVaugh's AI Assessment Scale, published in the Journal of University Teaching and

Learning Practice in 2024 and since revised, defines levels of permitted AI use ranging from no AI to full AI integration, allowing teachers to specify for each assignment what kind of assistance is acceptable. The framework has been adopted or adapted by many institutions, and its value lies in replacing a single blanket rule with clear expectations tailored to learning goals. A policy can establish such a scale as a shared language while leaving teachers to apply it to particular tasks.

Policies should address privacy and data, including which tools are approved for use with student data and what information should never be entered into AI systems. They should address equity, ensuring that students without access to paid tools are not disadvantaged. They should also explain how the school will respond to suspected misuse, with emphasis on fair processes.

Enforcement is where many policies falter. The Center for Democracy and Technology's 2024 report Up in the Air found that reliance on AI-detection tools, which have documented reliability problems, contributed to discipline and distrust, with some groups of students disproportionately affected. Policies that prohibit using detection scores as the sole basis for misconduct findings, and that favour conversation, process evidence, and redesign of assessment over surveillance, appear more likely to sustain trust.

Implementation requires communication and training. A policy that students and teachers do not understand has little effect. The Higher Education Policy Institute and Kortext Student Generative AI Survey 2025 found that most UK undergraduates considered their institution's policy clear, but fewer believed staff were well equipped to support their use of AI, suggesting that clarity on paper does not guarantee capability in practice. Schools can introduce policies through classroom discussions, provide examples of acceptable and unacceptable use, and offer professional development for teachers.

Keeping a policy current requires built-in review. Effective policies specify a review cycle, typically annual, assign responsibility for monitoring developments, and include mechanisms for collecting feedback from teachers, students, and families. Versioning and change logs help the community understand what has changed and why. Interim guidance can address urgent developments between formal reviews.

School policy on new technologies has a long history that cautions against expecting any document, however well drafted, to change practice quickly. David Tyack and Larry Cuban, in

their 1995 book Tinkering toward Utopia, traced a century of American school reform and argued that the basic organisation of schooling, which they called the grammar of schooling, has persisted through successive waves of policy enthusiasm, including earlier promises that film, radio, television and computers would transform instruction. In their account, reforms that succeeded tended to be adapted by teachers to local conditions rather than implemented as designed, and reformers who ignored teachers' practical knowledge were often disappointed. Applied to AI, this history suggests that an acceptable-use policy is one element in a slower process of institutional adaptation, and that policies which assume uniform compliance or rapid transformation are likely to be reinterpreted in classrooms. It also suggests that policies are more likely to endure when they build on practices teachers already find workable, rather than imposing frameworks that conflict with daily routines and assessment pressures.

Research on how policies are understood by those who implement them explains why the same AI policy can produce very different practices across classrooms. James Spillane, Brian Reiser and Todd Reimer, in a 2002 review in the Review of Educational Research, argued that implementation depends on how teachers and administrators make sense of policy messages, drawing on their existing knowledge, beliefs and professional contexts. They found that implementers often assimilate new ideas into familiar frames, so that ambitious reforms are understood as minor variations on existing practice, and that the social settings in which teachers discuss policy shape their interpretations. For AI policies, this suggests that a statement such as "AI may be used to support learning" will be interpreted very differently by a teacher who sees AI chiefly as a cheating risk and one who already uses it for planning. Worked examples, shared discussion of specific assignments and opportunities for teachers to compare interpretations are therefore not optional extras but central mechanisms through which policy acquires consistent meaning.

The technical limits of AI detection deserve explicit treatment in policy, because detection is often the default enforcement tool when a policy is silent. Debora Weber-Wulff and colleagues, in a 2023 study in the International Journal for Educational Integrity, tested 14 publicly available detection tools, including widely used commercial products, on human-written and AI-generated texts, including texts that had been manually edited or machine-paraphrased. They concluded that the tools were neither accurate nor reliable, with a bias towards classifying output as human-written and markedly poorer performance on obfuscated text. Weixin Liang and colleagues at Stanford University, in a 2023 study in Patterns, found that seven widely used

GPT detectors misclassified more than half of a set of essays written by non-native English speakers for the TOEFL examination as AI-generated, while classifying essays by U.S. eighth-grade students much more accurately. These findings provide an evidential basis for policy provisions that bar detection scores as the sole basis for misconduct findings and that require additional safeguards for multilingual learners.

International guidance offers reference points that schools can adapt rather than inventing policy from scratch. UNESCO's 2023 Guidance for Generative AI in Education and Research recommended that governments regulate generative AI tools used in education, protect data privacy, and consider an age limit, suggesting thirteen as a minimum age for independent use of generative AI in the classroom, while emphasising human agency, inclusion and validation of tools before adoption. The United Kingdom's Department for Education, in its policy paper on generative AI in education, updated several times since it was first published in 2023, set out expectations that schools protect personal data and intellectual property, remain responsible for the quality of AI-assisted work, and follow examination bodies' rules on AI in assessed coursework. Such national and international documents are not tailored to individual schools, but referencing them can lend legitimacy to local choices and help schools align with obligations that they cannot control, such as examination board regulations and data protection law.
