Empirical support for the claim that structured AI use can preserve or strengthen critical thinking comes mostly from other disciplines, and its evidential weight is modest. Liu, Sihes and Lu (2025) conducted a systematic review, following PRISMA guidelines, of studies from 2022 to 2025 on generative AI and critical thinking in English as a Foreign Language education. They argue that these tools must be integrated thoughtfully if they are to enhance learning without replacing learners' critical thinking. Abdelmagid, Jabli and Qahmash (2026) embedded AI assistants in a structured e-learning programme in a quasi-experimental study with 82 graduate students divided evenly into experimental and control groups, targeting higher-order problem-solving. Sun and Liu (2026) evaluated a bespoke AI Digital Teacher for foreign literature study. They note that AI's rapid spread in higher education has outpaced the rigorous evidence needed to guide its use, particularly in complex humanities subjects. Serra and Oliveira (2025), reviewing 166 studies, examine how prompting strategies can turn static materials into adaptive, interactive learning experiences. The common thread is structured design: AI was embedded in deliberate sequences rather than left to open use. That points to a

transferable principle rather than proven outcomes, and none of these studies examined image curation.

One further consideration is cognitive load. Culling thousands of frames is an exhausting task that makes heavy demands on sustained, effortful attention. Berman, Jonides and Kaplan (2008) frame directed attention as a resource that natural environments allow to replenish, whereas urban environments demand it continuously. Their work concerns environments, not screens, and it would be overreach to claim it governs editing sessions. The underlying model nonetheless offers a reason, worth testing, why automation is attractive at the point of fatigue. A tired editor is the one most likely to accept the machine's picks wholesale. Course design can respond by scheduling the blind cull early in a session, splitting large shoots across days, and reserving the comparison with AI output for when students are fresh enough to disagree with it.

None of this works unless instructors themselves understand the tools well enough to expose their limits. Traga Philippakos and Rocconi (2025) surveyed 242 teachers in grades 3 to 12 about their use of AI tools, their confidence, their professional development needs, and the challenges of integration. Their premise is that successful classroom use depends largely on teachers' understanding, confidence, and training. Huang and Lim (2026) review how AI might enable teacher professional development at scale while balancing equity, quality, and efficiency. They observe that a comprehensive understanding of AI's role in scaling such development remains lacking. Studies of student adoption point in a related direction. Salem's (2025) study of 301 medical students in Saudi Arabia models adoption intentions for AI language tools through an acceptance framework. Such intention models describe willingness to use a tool, not whether use is critical or competent, and that distinction matters in a DAM classroom. Students will readily adopt culling assistants. The pedagogical problem is ensuring that adoption does not become abdication. Photography and design faculty therefore need concrete preparation in how culling and tagging models fail, including which subjects, lighting conditions, and aesthetic choices they systematically misjudge. Without that knowledge, instructors cannot design disagreement exercises that reveal anything.

The gaps in the evidence should be stated plainly. Few studies have examined AI-assisted culling or tagging in educational settings at all. The memory research concerns taking photographs rather than selecting them. The homogenisation evidence concerns generative writing. The critical-thinking studies come from language, literature, and entrepreneurship education. What remains unclear is whether students who learn culling alongside AI develop

weaker, equivalent, or stronger editorial judgment than those who learn it unassisted, and whether any difference persists. The field would benefit from cohort comparisons that measure the diversity of students' final selects, their ability to justify choices, and the accuracy and ethical quality of their metadata. Until such studies exist, the most defensible position is procedural. Students should cull before they consult the machine, log every disagreement, author their own vocabularies and queries, and test their edits against real audiences. Exhibition and print offer one such test, because physical display makes the consequences of each selection concrete (see Q302). Under these conditions, AI becomes a sorting assistant whose suggestions sharpen editorial judgment rather than replace it.

Q301 How should photography and digital imaging teachers structure an "Artist Statement & Workflow Disclosure Log" so students articulate every optical, parametric, and generative decision in a final portfolio?

15 citations · 15 sources · 6 cross-references

Claim 1 emerging

Teachers should build the Artist Statement and Workflow Disclosure Log as a layered, contemporaneous record. It has three registers: optical decisions made at capture, parametric decisions made in development and editing, and generative decisions involving AI synthesis or

AI-assisted alteration. Each register is calibrated to a declared level of permitted AI use for the assignment, and the log culminates in an artist statement that must reason from the evidence it contains rather than merely accompany it. The design rests on two commitments. First, disclosure is a pedagogical instrument before it is a policing instrument; its purpose is to make visible the chain of judgments that turns light into a finished image. Second, disclosure should be proportional, so that trivial interventions are not documented with the same weight as decisions that change what a picture claims or how it was made. Perkins, Furze, Roe and colleagues (2024) offer the clearest scaffold for the first commitment. Their AI Assessment Scale lets educators select an appropriate level of generative AI use according to the learning outcomes an assessment addresses, which implies that the log's expectations should follow from what a given project is meant to teach. Aldawsari (2026) supplies the logic for the second. Writing about academic publishing, he observes that binary disclosure statements fail to distinguish minor language assistance from uses with significant effects on structure and interpretation, and he proposes a risk-proportional approach that separates disclosure by risk. Transposed to photography, that critique applies with some force. A checkbox reading "AI used: yes/no" cannot distinguish noise reduction from a synthesized sky, nor either of these from a fabricated subject. The remainder of this essay sets out how each layer of the log should work, what the evidence supports about its components, and where that evidence runs out.

The log should open with a project header. In it the teacher states the permitted level of AI involvement and the student acknowledges it before shooting begins. The revised version of the AI Assessment Scale (Perkins, Roe and Furze, 2024) describes the framework as having two purposes: to facilitate open dialogue between educators and students about appropriate generative AI use, and to support educators in redesigning assessment as AI capabilities expand. The authors ground it in social constructivist principles and design it with assessment validity in mind. Both purposes matter for a portfolio log. The header is a dialogic document. The student is not simply told what is forbidden but is asked to restate, in their own words, why a documentary series might sit at a restrictive level while a speculative compositing project sits at a more permissive one. The validity argument matters because a portfolio assessed on technical control of exposure means little if that control was outsourced, and a portfolio assessed on conceptual direction of generative tools means little if those tools were hidden. Furze, Perkins, Roe and colleagues (2024) report a pilot implementation of the scale at British University Vietnam, and the preprint situates that work against two observations: banning or blocking generative tools has proven ineffective, and punitive approaches ignore potential

benefits. The pilot shows that such a framework can be put into institutional practice. It does not establish that disclosure logs in visual arts improve learning or integrity, and photography teachers should treat it as a design precedent rather than proof of effect. Wu's (2026) analysis of 35 syllabi from a large U.S. public research university adds a governance point. Course-level statements are the formal texts through which institutional principles become student-facing rules, and Wu compared those statements against the institutional framework. For the photography teacher, the log header is therefore a governance artifact in miniature. It should be written with the precision of a syllabus clause, should reference the department's broader policy, and should be specific to the assignment rather than borrowed generically from a writing course. Where ethical rules differ between documentary and conceptual work, the header should name the relevant regime explicitly (see Q295).

The optical layer records what happened in front of and inside the camera. It covers subject and site, the light source and its modification, focal length and lens choice, aperture, shutter speed and ISO, focus strategy, and the reasons for each. Much of this can be recovered automatically from camera metadata, but metadata records settings, not intentions. A shutter speed tells the assessor nothing about whether the student chose it to freeze a gesture or simply accepted what the meter suggested. The log should therefore pair each exported metadata block with a brief statement of intent written at or near the time of capture, and those entries should be checked against RAW files and contact sheets as the authenticity evidence base (see Q294). The case for making these field notes partly handwritten, and partly diagrammatic, is suggestive but indirect. Mueller and Oppenheimer (2014), across three studies, found that students who took lecture notes on laptops performed worse on conceptual questions than students who took notes longhand. They attributed the difference to shallower processing even when laptops were used solely for note taking. Wammes, Meade and Fernandes (2016), in seven free-recall experiments, found that drawing to-be-remembered words produced better recall than writing them. Within their paradigm, the advantage could not be explained by elaborative encoding, visual imagery or picture superiority alone. These findings invite a design in which students sketch lighting diagrams and camera positions in a physical notebook and write short longhand rationales before transcribing them into the digital log. The inference requires caution. Neither study examined photographers, field logs or portfolio assessment. Both concern memory and conceptual performance under laboratory or lecture conditions, and it remains unclear whether the encoding advantages they report would translate into better articulation of photographic decisions weeks later. The optical layer also carries a sequencing argument developed

elsewhere in this volume: students who have not yet internalized manual exposure and lighting cannot meaningfully explain later automated choices (see Q291). The log makes that dependency visible, because a student unable to justify an aperture will struggle to justify an algorithmic depth-of-field simulation.

The parametric layer documents development and editing. It covers white balance, tone curves, local adjustments, masking, sharpening, noise reduction, cropping, retouching, and any AI-assisted but non-generative function such as automated subject selection or denoising. Most raster and RAW editors already generate a granular history of operations, and teachers may be tempted to treat an exported edit history as sufficient disclosure. Research on process logging in writing argues against that shortcut. Leijten and Van Waes (2013) describe keystroke logging as instrumental in identifying writing strategies and understanding cognitive processes, and they credit it with allowing ecological data collection. They also acknowledge that connecting the fine grain of logging data to underlying cognitive processes is often difficult, and they explore how a logging program can be complemented by think-aloud protocols and eye-tracking. The analogy to an editing history is close. The software can record that a student pulled highlights down by a certain amount and applied a radial mask. It cannot record whether the student did so to recover tonal separation in a white dress, to direct the eye toward a face, or by trial and error without a guiding idea. The parametric layer should therefore combine three elements. The first is the machine-generated history, exported unaltered. The second is a curated set of milestone versions with short annotations explaining what problem each stage addressed. The third, for at least one image per portfolio, is a recorded or transcribed think-aloud in which the student talks through an edit in real time. The think-aloud component mirrors the multimethod complementarity Leijten and Van Waes recommend. It also gives assessors a way to distinguish students who understand their adjustments from students who reproduce presets. Teachers should resist demanding narrative justification for every slider movement, since that converts reflection into clerical labor. The proportionality principle discussed earlier applies here as well: the student annotates decisions that alter the image's meaning, emphasis or factual content, and lets the raw history carry the rest. Where AI culling or tagging tools shaped which frames reached the edit at all, that selection stage belongs in this layer too, documented under the editorial-judgment principles treated in the chapter's discussion of asset management (see Q300).

The generative layer carries the highest disclosure burden because it concerns interventions that can create pictorial content that was never optically captured. For every generative operation the log should record the tool and version where known, the prompt or reference inputs, the number of iterations and the basis for selection among outputs, the region or proportion of the frame affected, and an explicit statement of what the generated material depicts that the camera did not. Aldawsari's (2026) risk-proportional logic is most consequential here. Generative fill that removes a sensor dust spot and generative synthesis of a figure in a documentary scene differ not in degree but in kind, and the log should require escalating levels of explanation as the epistemic risk to the viewer rises. Sun and Yuan (2026) give the clearest disciplinary rationale for asking students to articulate generative decisions rather than merely flag them. Their case study compared a graphic design student's illustration process with AI-generated works on the same themes. They examine the roles, limitations and ethical implications of AI in design education, and they identify unresolved challenges around preserving personal style, originality and meaningful human expression. A single-case study in illustration cannot settle how photography students should be assessed. It does suggest that the comparative exercise has value: setting a student's own process beside machine outputs on the same brief can sharpen what the student contributes. A generative log entry might therefore require the student to show at least one rejected output and explain why it failed the concept, which turns disclosure into evidence of authorship. Wu's (2026) interviews with twenty-one doctoral students frame a related shift as moving from production to verification. In that study, generative AI is not only an integrity or adoption problem but also bears on formative practices through which students become scholars. Although the population and discipline differ, the parallel for photography is direct. When synthesis is cheap, the formative act becomes judging, constraining and verifying what a tool produces. The generative layer should be designed to evidence that judgment, and its relationship to foundational compositing skills should follow the sequencing argued elsewhere in this chapter (see Q293).

The artist statement should be written last and assessed against the log, not separately from it. A conventional statement describes intention and influence. In this design the statement must also cite specific log entries: the optical choice that established the series' visual grammar, the parametric decisions that carried its mood, and the generative interventions, if any, together with the reasons they were consistent with the declared assessment level. Rubrics should reward coherence between statement and evidence, candor about failed attempts, and the student's ability to name where the tools, rather than the student, made a decision. That last

criterion is the most demanding. It is also the most aligned with the dialogic purpose the revised assessment scale sets out (Perkins, Roe and Furze, 2024). Whether teachers can run such a system well is a separate and less settled question. Survey and qualitative studies of teacher readiness describe a gap between aspiration and capability, but they come from other subjects and contexts. Gómez-Rey, Angosto, Alamäki and colleagues (2026) found that 198 future primary mathematics teachers in Spain assigned higher importance to AI-related and digital competencies than the performance levels they reported. Their dimensions included AI evaluation and AI ethics. Cabero-Almenara, Palacios-Rodríguez, Loaiza-Aguirre and colleagues (2025) evaluated a structural model of teaching digital competence in relation to AI with 368 university professors, and Özüdoğru and Yildiz Durak (2025) examined how pre-service teachers' AI readiness relates to AI literacy, digital citizenship, AI-enhanced innovation and perceived threats. These relationships are correlational and say nothing directly about photography educators. Day's (2026) thematic analysis of forum contributions from 76 preservice teachers in China, examining perspectives on AI as a non-human instructor and on whether AI could replace human teachers, reinforces the point that teachers' framing of AI shapes how they deploy it. Zeng, Cheah and Abdullah (2025), in a systematic thematic review of fourteen empirical papers, examined how principals' digital leadership affects teachers' capacity to integrate AI, which points toward departmental rather than individual responsibility for sustaining practices like the disclosure log (see Q085). Several things remain unclear. Few studies have tested whether structured disclosure logs improve photographic learning, reduce undisclosed generative use, or change how students conceive authorship. The supporting evidence is borrowed from writing research, memory experiments, assessment-framework pilots and single-case design studies. The disclosure literature also disagrees, at least implicitly, about granularity: binary declarations are administratively simple, while risk-proportional schemes are more informative but demand more judgment from students and assessors. Until classroom studies in photography compare log designs directly, teachers should adopt the layered structure as a reasoned hypothesis, collect their own evidence about what students learn from completing it, and revise the template as both tools and findings change.

Q302 How do student-curated physical exhibitions and printed zines alter the way learners value photographic resolution, paper surface, color calibration, and human authorship in an era of ephemeral screen images?

11 citations · 11 sources · 4 cross-references

Claim 1 disputed

Student-curated physical exhibitions and printed zines appear to change how learners value photographic resolution, paper surface, color calibration and human authorship. They turn properties that screens hide or standardize into decisions that carry visible, tactile and public consequences. On a phone, resolution is whatever the platform compresses to, surface is uniform glass, color is whatever an uncalibrated display renders, and authorship is a username beside an endlessly scrolling feed. On a gallery wall or a stapled signature of newsprint, each of these becomes a choice a student must make, defend and live with in front of peers. A file that looked crisp on a laptop prints soft at forty centimetres. A skin tone that seemed accurate on screen shifts toward magenta on uncoated stock. A wall label or colophon forces the question of who, or what, made the image.

The evidence for this claim is uneven, and the answer has to be precise about that. Few studies have directly measured how curating a show or producing a zine changes students' technical or ethical valuations. The case therefore rests on three adjacent bodies of work. The first is research comparing paper and digital media. The second is research on how photographing alters attention and memory. The third is the rapidly growing literature on generative AI and creative production. Epstein, Hertzmann and colleagues (2023) argue that understanding shifts in creative work is necessary to guide AI's impact on the media ecosystem. Hertzmann (2018) traces how photography itself was once an automating technology greeted with fear and denial before new creative opportunities blossomed. Both framings suggest that the meaning of a material practice is not fixed but renegotiated whenever a new technology arrives. Printing photographs is now being renegotiated in exactly this way, as print shifts from default endpoint to deliberate counter-practice.

The strongest empirical anchor for a material advantage of paper comes from reading research, not photography. Delgado, Vargas, Ackerman and colleagues (2018) meta-analysed studies from 2000 to 2017 that compared comprehension of comparable texts read on paper and on digital devices. Their pool comprised 38 between-participants and 16 within-participants studies, involving 171,055 participants. Both designs yielded the same advantage of paper over digital reading, with a Hedges' g of −0.21. This is a modest effect, but it is consistent across designs and drawn from a very large evidence base. On the narrow question of text comprehension, it is reasonable to say the meta-analysis demonstrates a small but reliable paper advantage. The authors themselves note that earlier findings had been mixed, which is why aggregation was necessary.

What this evidence does not show matters as much as what it does. It concerns reading comprehension of texts, not perception, appreciation or critical evaluation of photographs. It cannot tell us whether viewing a print rather than a screen image changes how a student judges tonal range, notices grain, or values the labour behind an image. Nor does it isolate which features of paper produce the advantage, whether tactility, fixity, spatial layout or the reader's own expectations about the medium. Zines complicate the extrapolation further, because they are hybrid objects of text, image, sequence and layout. Students experience them as readers and as viewers at once.

It is therefore defensible to treat the paper advantage as a plausible mechanism for photography and design education, but not as an established finding there. A cautious inference runs as

follows. If paper modestly supports deeper processing of text, the image-and-caption structure of a zine might also invite slower, more sequential engagement than a feed. Testing that inference with photographic materials, and with outcome measures relevant to visual literacy rather than comprehension quizzes, is an obvious gap in the field.

Research on photography and memory offers a second, more contested line of evidence, and the disagreement is instructive for curation pedagogy. Henkel (2013) led participants on a guided tour of an art museum, directing them to observe some objects and to photograph others. She reported a photo-taking-impairment effect. When participants photographed each object as a whole, they remembered fewer objects, fewer details about them, and less about their locations in the museum than when they simply observed. Barasch, Diehl, Silverman and colleagues (2017) reached a different conclusion across one field study and three laboratory studies. Participants who could freely take photographs during an experience recognized more of what they saw and less of what they heard than those who could not take photographs, even without revisiting the images. Merely taking mental photos had similar effects. The authors interpret this as an attentional shift toward visual aspects of experience and away from auditory ones.

The two findings are not simply contradictory, because the conditions differ. Henkel's participants photographed on instruction, capturing whole objects. Barasch and colleagues studied volitional photo taking. Read together, they suggest that the cognitive effect of a camera depends on whether photographing is an act of offloading or an act of directed looking. That distinction maps closely onto the difference between indiscriminate screen capture and curatorial practice. A student building an exhibition must revisit, cull, sequence and justify a small number of images from a much larger shoot. That work is closer to volitional, attention-directing engagement than to reflexive capture. Whether curation actually reverses or mitigates impairment of the kind Henkel observed remains unclear, because neither study examined post-capture selection, printing or display.

Attention restoration theory has occasionally been invoked in arguments for slow, physical viewing. Berman, Jonides and Kaplan (2008) contrast natural environments, which modestly grab attention bottom-up and let directed attention replenish, with urban environments, which capture attention dramatically and demand vigilance. The analogy to a calm gallery versus an attention-seizing feed is tempting. However, the theory was developed for natural and urban

settings, not for exhibitions or printed media, and applying it here is speculation rather than evidence.

The pedagogical logic becomes concrete when one follows the specific properties named in the question through an exhibition or zine project. Resolution stops being an abstract pixel count and becomes a relation between file, print size and viewing distance. Students learn that a phone image adequate for a story post may fall apart on an exhibition print. They also learn that a coarse halftone in a risograph zine can be an expressive choice rather than a defect. Paper surface becomes semantic. Matte cotton rag, glossy resin-coated stock and cheap photocopy paper each carry connotations of permanence, commerce or urgency, and a curator must decide which serves the work. Color calibration becomes a problem of fidelity across devices. Students who have never questioned their screen discover that soft-proofing, printer profiles and ambient light determine whether the image on the wall resembles the image they edited.

None of these lessons requires print to be superior to screen. Their value lies in the friction that physical output introduces, because errors are costly, visible and shared. A misprinted run of zines or a color-shifted exhibition print is a public consequence, not a private undo. This aligns with arguments elsewhere in this volume that historical and alternative processes teach the materiality of light and indexicality (see Q299). It also aligns with the case for field assignments that anchor students in direct perception rather than screen-bound habits (see Q297). Exhibitions and zines extend that materiality from capture to output and distribution.

Hertzmann's (2018) historical account offers a useful corrective to nostalgia. Photography was itself once the automating technology that unsettled painting, and the craft knowledge now taught as printing literacy was once dismissed as merely mechanical. Valuing paper surface or calibration is not a return to an authentic pre-digital state. It is the cultivation of judgment about how an image becomes an object. Educators should be wary of claims that print automatically confers seriousness. What is better supported is the narrower claim that physical output makes students' technical decisions legible to them. Even that rests mostly on practitioner reasoning rather than controlled study.

Human authorship is where the stakes of physical curation are highest and the evidence most divided. Generative systems now produce images that can be printed and hung indistinguishably from camera-originated work. The large-scale evidence on their effects points in two directions at once. Zhou and Lee (2024) analysed a dataset of over 4 million artworks

from more than 50,000 unique users. They report that, over time, text-to-image AI enhanced human creative productivity by 25% and increased value by 50%, measured as the likelihood of receiving a favorite per view. Doshi and Hauser (2024) ran an online experiment in which some writers obtained story ideas from a large language model. Access to these ideas caused stories to be evaluated as more creative, better written and more enjoyable, especially among less creative writers. Yet the AI-enabled stories were more similar to each other than stories by humans alone.

These studies concern platform-based visual art and short fiction, not student photography exhibitions. Their outcome measures, favorites per view and evaluator ratings, are not measures of authorship or learning. Still, the tension they reveal is directly relevant to curation. An individual student may produce more polished work with generative assistance, while a class exhibition risks converging on a narrower range of looks. A curated show makes that convergence visible in a way a scrolling feed does not. When twenty prints hang side by side, sameness becomes an aesthetic and ethical fact the group must discuss.

The physical object also creates a natural site for authorship claims. A wall label, a zine colophon or an artist statement must say who made the image and how. This complements the disclosure practices discussed elsewhere in this chapter (see Q301), and the broader shift toward process-centred assessment (see Q285). Hertzmann (2018) speculates about whether AI systems could ever be credited with authorship of artwork. Epstein and colleagues (2023) frame generative AI as reshaping rather than simply replacing creative work. Neither settles the normative question. Whether physical exhibition actually increases students' valuation of human authorship, or merely makes authorship more contested, has not been established empirically.

Finally, the case for exhibitions and zines must be weighed against questions of equity, wellbeing and learner variation, where the evidence is thin but the concerns are real. Printing on archival stock, buying calibration hardware and mounting a show cost money, and these costs fall unevenly across institutions and students. Hadar Shoval (2025) argues that the differential effects of AI-based tools on diverse student populations, particularly first-generation and minority students, are poorly understood. She addresses this gap through a mixed-methods case study in an introductory psychology course at a peripheral college. The same caution applies to material counter-practices. A pedagogy that valorizes expensive prints could reward students with resources rather than judgment. Zines, with their tradition of cheap

reproduction and self-publication, offer a partial corrective. Photocopied or risograph formats can teach surface, sequence and authorship at low cost.

Learner attitudes also vary. Cui (2026) studied music learners' attitudes toward AI-generated music, technology comfort, technical expertise, frequency of AI use and intention to adopt AI tools, noting that learners differ considerably in their acceptance of these tools. Analogous variation should be expected in visual arts classrooms. Some students will experience printing as liberation from the feed, while others will experience it as an arbitrary hurdle. Jukiewicz (2025) reviews concerns that generative AI may affect educational quality, student mental health and fundamental academic values. That review does not examine physical curation, but it frames why educators are seeking practices that slow production and foreground human judgment.

The defensible conclusion is narrower than enthusiasts often claim. A small, reliable paper advantage is demonstrated for reading comprehension. Photography's effects on memory depend on how and why one photographs. Generative tools appear to raise individual output while narrowing collective diversity. From these strands, it is reasonable to infer that physical curation can make resolution, surface, calibration and authorship visible as choices. Whether it durably changes what students value, and for whom, remains unclear. The field needs studies that follow students through actual exhibition and zine projects. Such studies should measure visual-literacy outcomes, track the diversity of curated work, and compare low-cost and high-cost formats, rather than extrapolating from text comprehension and museum memory.

Chapter 23: Authentic Assessment Architecture and the Post-Detection Era

10 questions · 133 citations · 84 unique sources · 44 cross-references

Q303 Why has the traditional unsupervised take-home essay or problem set collapsed as a reliable proxy for individual cognitive mastery, and what replaces it?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

The unsupervised take-home essay or problem set has collapsed as a proxy for individual mastery because generative AI has severed the inferential link between a submitted product and the cognition that was once presumed to produce it. What replaces it is not a better detector or a stricter rule. It is a structural redesign of assessment around validity: a portfolio of evidence in which secured, observed or interactive moments verify individual capability, and in which the remaining tasks are reconceived as learning activities rather than certification events. The collapse is often described as a cheating problem. That framing is understandable but analytically too narrow, and much of the institutional energy spent since 2023 has been misdirected because of it.

Take-home work functioned for generations because producing a coherent essay or a correct derivation was costly in time, knowledge and effort. An examiner could therefore treat the artefact as a reasonable trace of the student's reasoning. Montebello (2026) states the shift most directly. He argues that assessment historically worked not only as a measure of learning but as a structural mechanism that implicitly enforced cognitive engagement. With generative AI, learners can increasingly produce assessment outputs without engaging in the cognitive processes those outputs were meant to evidence. He calls this a move from cognitive necessity to cognitive choice. Corbin, Dawson and Liu (2025) make a parallel claim in the vocabulary of measurement. Generative AI challenges assessment validity by enabling students to complete tasks without demonstrating genuine capability. The two arguments converge on one point: the

artefact no longer guarantees the process. Once that guarantee is gone, the take-home task can still support learning, but it cannot by itself license a claim about what an individual knows or can do.

The most productive way to understand the collapse is through validity rather than integrity. Dawson, Bearman, Dollinger and colleagues (2024) argue that cheating attracts outsized attention in assessment debates. They propose reframing cheating as subsumed within the broader concept of assessment validity. Their reasoning begins with a plain observation: if students cheat, we cannot be sure they have met the learning outcomes. On this view the worry about undisclosed AI use is one instance of a more general question. Does the evidence an assessment generates actually support the inference we want to draw from it? The reframing addresses misconduct without moralising and places it inside the positive mission of assurance of learning.

This reframing changes the diagnosis of the take-home task. Under an integrity lens, the essay fails because some students misuse tools. Under a validity lens, it fails because the task design cannot distinguish a student who reasoned through the problem from one who delegated it, regardless of whether delegation was permitted. That holds even in courses where AI use is sanctioned. If a student legitimately uses a model to draft an argument, the grade still cannot tell us which parts of the performance belong to the student. The validity problem therefore persists after the moral problem has been defined away. This explains why permissive and prohibitive AI policies alike leave the core difficulty untouched.

The reframing also guards against a rhetorical trap. Bearman, Ryan and Ajjawi (2022), in a critical review of how artificial intelligence appears in leading higher education journals, found few and confusing definitions and little treatment of AI as a research object. They identified a Discourse of imperative change in which AI is cast as an inevitable force to which everyone must respond. That discourse can push institutions toward reactive, technology-led fixes. A validity framing slows the reaction down. It asks what claim about a learner each assessment is supposed to support, and whether the task, as now situated, can bear that claim.

The first institutional response to the crisis was to try to restore the old proxy by policing it, chiefly through AI-text detectors. The evidence that this cannot work at the level of reliability that high-stakes judgements require is now substantial. It deserves to be stated plainly, because it explains why the field speaks of a post-detection era.

Weber-Wulff and colleagues (2023) examined the general functionality of detection tools for AI-generated text, evaluating them through accuracy and error-type analysis. That framing matters because the error types carry different consequences for students. Sadasivan and colleagues (2023) stress-tested detectors against an attacker. They acknowledged that detectors can be effective under their specific settings while questioning whether that effectiveness survives adversarial conditions. Perkins, Roe, Vu and colleagues (2024) provided a direct educational test. Across 805 samples of machine-generated content modified to evade detection, they found that six major detectors showed significant reductions in accuracy, a drop of 17.4%, when confronted with simple manipulation techniques. They drew out the implications for inclusive education explicitly.

The fairness dimension is the decisive one. Liang, Yuksekgonul, Mao and colleagues (2023) found that GPT detectors frequently misclassify non-native English writing as AI-generated. They warned that such bias risks marginalising non-native speakers in evaluative and educational settings. Taken together, these studies show a pattern that undermines detection as a foundation. Detectors are evaded most easily by those who intend to evade them, and they misfire most readily against students whose writing deviates from a presumed native norm. A proxy restored by such instruments would be both porous and inequitable. This is why suspicion of undisclosed AI use now calls for a due-process approach that does not rest on detector scores (see Q312). It is also why detection cannot be the replacement this question asks about.

The second institutional response was discursive. Universities issued guidance telling students which uses of AI were allowed on which tasks. Corbin, Dawson and Liu (2025) take this approach on directly. They acknowledge that institutions have developed various ways to communicate permissible AI use, with the 'traffic light' approach now common in institutional policy. Their criticism is that these approaches share a common limitation: they focus primarily on communicating rules rather than redesigning assessment mechanics. Hence their title's claim that talk is cheap.

The argument does not dismiss AI-use scales, which retain value for setting expectations and supporting learning conversations (see Q307). It identifies what such scales cannot do. A declaration that a take-home essay is 'no AI' does not change the conditions under which the essay is produced, so it does nothing to restore the inference from product to cognition. The essay remains as vulnerable as before. The only change is that a rule now exists whose breach

is hard to verify, and verification falls back on the detectors already shown to be unreliable. Communicated rules and detection therefore form a weak pair. Each depends on the other, and neither supplies what the validity argument demands.

The structural alternative implied by this critique is that assurance must be engineered into how evidence is generated. In practice this means changing when, where and how students perform, what they must explain, and how individual performances are connected across a programme. Instructions and reminders cannot substitute for that work.

What replaces the take-home proxy is better described as an architecture than a single instrument. Its core principle is that some assessment moments are designed to verify individual capability under conditions the institution can stand behind, while others are freed to serve learning, including learning with AI.

Interactive and dialogic assessment is the most developed component. Well before generative AI, Sotiriadou, Logan, Daly and colleagues (2019) studied a suite of scaffolded authentic assessments culminating in interactive oral examinations. They argued that authentic assessment and academic integrity together build skills that advance employability. Their design anticipates the current settlement. Written and applied work is not abandoned. It is scaffolded toward a live encounter in which students must explain, defend and extend what they produced, so the oral component tests whether the student owns the reasoning in the artefact. That model transfers directly to the AI era, though it brings its own fairness obligations toward anxious, neurodivergent and multilingual students that this answer does not address.

A second component is evidence of process. When the product no longer guarantees the process, the process itself becomes something to observe and reflect upon. Revision histories, drafts and reflective accounts of how AI was used serve here as formative evidence rather than forensic proof (see Q308). A third component is programmatic. Verification is spread across many low-stakes observations and a smaller number of secured, high-stakes judgements over time, rather than concentrated in any one task (see Q311). Within such a programme a take-home essay can survive, but its role changes. It becomes practice, a stimulus for later oral defence, or one data point among many, not a stand-alone certificate of mastery.

The architecture also has to absorb tasks that deliberately integrate AI. Omeh (2026) compared an AI-assisted assessment model with a traditional model in a web design and development course, examining effects on outcomes and on students' cognitive load. The study reflects a

broader move to treat AI collaboration as part of the construct being assessed. Zhang and Liu (2025) note an increasing number of studies indicating that generative AI can help cultivate critical thinking. They also observe that evidence on its effects in open learning environments remains scarce, and their own investigation addresses that gap. Such work suggests that AI-integrated tasks can be pedagogically legitimate. It does not suggest that they solve the verification problem. A task that assesses skilful collaboration with AI measures a different construct from one that assesses unaided individual mastery, and an assessment programme has to be explicit about which claim each task supports. The same caution applies to automating the marking side. Mughal and colleagues (2026) explore GPT and Gemini for automated essay scoring, motivated by the fatigue, bias and subjectivity of manual grading. Faster scoring of artefacts, however, does nothing to restore the link between artefact and author.

Several limits on current knowledge should temper confidence in the replacement architecture. The diagnosis is well supported: the take-home product is no longer a valid stand-alone proxy, and detection cannot rescue it. The evidence that particular redesigns work better than others is much thinner. Much of the strongest writing on structural change, including the validity reframing of Dawson and colleagues (2024) and the structural critique of Corbin, Dawson and Liu (2025), is conceptual. It sets out what valid assessment requires without yet showing comparative outcomes across institutions and disciplines. Montebello's (2026) account of cognitive choice is likewise an argument about a pedagogical shift, not a measurement of how many students exercise that choice or with what consequences for learning.

Comparative empirical work on AI-era learning exists but is uneven. Bhardwaj, Sharma, Thakur and colleagues (2026) used a convergent mixed-methods design with 350 students and faculty across Indian institutions to compare AI and LLM-based learning systems with traditional education on comprehension, retention, personalisation and critical thinking. Studies of this kind help map the terrain. They are not designed to establish which assessment architectures yield valid inferences about individual mastery, and their findings should not be read as answering that question. It remains unclear how oral and interactive formats scale to very large cohorts without loss of reliability. It is also unclear how programmatic evidence should be weighed when components conflict, and whether students' cognitive engagement recovers once assessment again makes engagement necessary.

The field is also divided on emphasis. One position holds that secured, AI-free verification must anchor any credible credential. Another holds that the more authentic construct now

includes competent work with AI, so assessment should measure that collaboration rather than wall it off. These positions are not strictly incompatible. A programme can verify unaided foundations at some points and AI-augmented performance at others. Even so, the balance between them is a matter of judgement and disciplinary values that current evidence cannot settle. The warning from Bearman, Ryan and Ajjawi (2022) about the Discourse of imperative change applies here as well. The case for redesign should rest on the validity argument, not on a sense that change is inevitable.

The defensible position for the field is therefore this. The unsupervised take-home task has lost its standing as evidence of individual mastery for structural reasons, not merely behavioural ones. Detection and rule-communication cannot restore that standing, and the burden has shifted to assessment design. The emerging architecture combines interactive verification, process evidence, programmatic aggregation and explicit construct definition. It is the most coherent response now available, but its relative effectiveness still has to be demonstrated rather than assumed.

Q304 How does the "Two-Lane Assessment Architecture" (Assessment Education Working Group, Sydney / TEQSA) operationalize secure assurance of learning alongside open human-AI collaboration?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

The Two-Lane Assessment Architecture operationalizes assurance of learning by splitting assessment into two deliberately different functions. A small number of secure, supervised and verifiable tasks carry the burden of certifying that students have met program learning outcomes. Alongside them, an open lane of tasks treats human-AI collaboration as legitimate, expected and teachable rather than as a threat to be policed. The design does not ask every task to be both cheat-resistant and AI-inclusive, a demand that has paralysed much institutional policy since generative AI arrived. Instead it assigns each task one job. Secure tasks are built around conditions that allow an assessor to be confident whose capability is on display: in-person examination, live interactive oral assessment, observed practical performance, or supervised in-class work. Open tasks are built around learning: drafting, iteration, critique, feedback and the development of judgement about when and how to use AI. In these tasks the institution makes no pretence that it can control or reliably detect tool use.

The model, as it has circulated in Australian higher education and in sector-level conversations about regulatory expectations, is best understood as an architecture rather than a rule. Its unit of analysis is the program or course of study, not the individual assignment. Its central question is not "did this student cheat?" but "where in this degree do we have trustworthy evidence that the outcomes were achieved?" That reorientation is what distinguishes it from earlier responses to generative AI, and it is the reason the model sits naturally within a post-detection account of assessment.

The intellectual foundation of the two-lane approach is the argument that validity, not cheating, should organise assessment design. Dawson, Bearman, Dollinger and colleagues (2024) question how much attention cheating receives as a concept. They propose that cheating be

subsumed under the broader concept of assessment validity, so that it is addressed without moralising, as part of the positive mission of assurance of learning. This framing does real work in the two-lane model. If the purpose of a high-stakes judgement is to warrant that a graduate can do something, the relevant question about AI is whether its availability undermines the inference drawn from the task. Whether AI use breaches a rule matters less. The secure lane exists because some inferences, such as unaided disciplinary reasoning, clinical judgement or the capacity to explain one's own work, cannot be drawn from products made under uncontrolled conditions.

Corbin, Dawson and Liu (2025) sharpen the case by distinguishing communicative from structural responses. They observe that generative AI challenges validity by enabling students to complete tasks without demonstrating genuine capability. Many institutional responses, including the widely adopted traffic-light approaches, focus primarily on communicating rules about permissible AI use rather than redesigning assessment mechanics. Their argument implies that telling students a task is "no AI" does not make it so. Validity is secured only by changing the conditions under which evidence is produced. The two-lane model takes this structural principle to its conclusion. Where an inference must be secure, conditions must make it secure. Where conditions cannot be controlled, the task should be repurposed for learning rather than certification.

Montebello (2026) adds a pedagogical dimension that strengthens the case for the open lane rather than only the secure one. He argues that assessment historically functioned not only as a measure of learning but as a structural mechanism that implicitly enforced cognitive engagement. Generative AI decouples assessment performance from that engagement, so learners can produce outputs without undergoing the processes those outputs once indexed. On this reading, the problem with unsupervised take-home tasks is not only that their grades become less trustworthy. They can also no longer be relied upon to make students think. The open lane therefore has to be redesigned to elicit engagement deliberately, rather than assuming that producing an artefact guarantees it.

Operationally, the secure lane depends on a modest repertoire of supervised formats, and its credibility rests on how well those formats are designed and distributed across a program. Interactive oral assessment is the most prominent. Sotiriadou, Logan, Daly and colleagues (2019) used a suite of scaffolded authentic assessments that culminated in interactive oral examinations. They framed authenticity and academic integrity together as foundations for high

academic standards and as sources of employability-relevant skills. Their design is instructive for two-lane thinking because the oral was not an isolated interrogation. It was the endpoint of a scaffolded sequence. The secure moment drew its validity partly from its connection to earlier, more open work that students then had to explain and defend. The practical challenges of extending such formats across large cohorts and diverse sectors are treated elsewhere in this chapter (see Q305).

The secure lane also inherits the lessons of remote and online assessment. Stanoyevitch (2024) describes how the pandemic shift to digital learning intensified concerns about the integrity of online assessments. He notes the rise of online exam and homework assistance platforms and the subsequent arrival of sophisticated tools such as ChatGPT, which together placed traditional assessment methods under unprecedented strain. The implication for the two-lane model is that "secure" cannot be equated with "online and timed". Unsupervised online examinations sit closer to the open lane than many institutions would like to admit, whatever their nominal rules.

A program-level view is essential here. A secure lane that attempted to supervise every unit would be prohibitively expensive and would recreate the high-stakes distortions that authentic assessment sought to escape. The architecture instead implies that secure tasks be placed strategically, at points where program outcomes can be verified cumulatively. This is why the two-lane model fits naturally with programmatic and longitudinal portfolio approaches, whose role in verifying competence over time is discussed separately (see Q311). How many secure points a program needs, and at what stages, remains unclear. The model supplies a logic for that decision but not a formula.

The open lane is where human-AI collaboration is operationalized, and it is also where the two-lane model meets its closest competitor, the AI Assessment Scale. Perkins, Furze, Roe and colleagues (2024) presented the AIAS as a practical, simple and sufficiently comprehensive tool that lets educators select an appropriate level of generative AI use in assessments according to the learning outcomes they seek to address. A pilot at British University Vietnam, reported by Furze, Perkins, Roe and colleagues (2024), explored implementing the scale. The authors argued that banning or blocking generative AI tools had proven ineffective and that punitive approaches ignore the potential benefits of these technologies. The revised version (Perkins, Roe and Furze, 2024) recasts the scale around two purposes: facilitating open dialogue between educators and students about appropriate use, and supporting educators in

redesigning assessments as AI capabilities expand. It is grounded in social constructivist principles and designed with assessment validity in mind. The mapping of assignments to its levels is addressed in its own entry (see Q307).

The relationship between the two frameworks is a point of genuine disagreement. Read through Corbin, Dawson and Liu's (2025) critique, multi-level permission scales risk remaining communicative instruments. A task labelled as permitting limited AI use offers no structural guarantee that use was limited, so intermediate levels may describe intentions rather than secure evidence. The two-lane model resolves this by collapsing the distinction that matters for assurance into a binary: either conditions verify the inference, or they do not. Defenders of the AIAS can reasonably reply that the revised scale explicitly foregrounds validity and redesign rather than rule-setting. They can also note that graded levels remain pedagogically useful within the open lane, signalling to students what kind of collaboration a task is meant to develop. The two frameworks may therefore be complementary rather than rival. The binary governs what a task can certify, while a scale shapes what an open task is meant to teach. That synthesis is plausible, but it has not been tested empirically.

Operationalizing the open lane also requires more than permission. Elkhodr and Gide (2026) observe that higher education policy on generative AI has been stronger on governance, permission, disclosure and assurance than on pedagogy. Universities increasingly distinguish restricted from permitted contexts, require acknowledgement of tool use and introduce verification mechanisms. They find, however, that publicly visible institutional approaches appear less developed in providing structured, student-facing workflows for responsible AI engagement during assessment completion. This is precisely the gap the open lane must fill if it is to be more than a zone of non-enforcement. Lye and Lim (2024) add that redesign must contend with the outputs themselves, not only with integrity. Models trained on internet data may produce biased and discriminatory outputs, and hallucination can yield fabricated content. Open-lane tasks that ask students to evaluate, verify and critique AI outputs turn these limitations into learning objectives. Process evidence such as revision histories and prompt portfolios can make that engagement visible for feedback, a topic treated in depth elsewhere (see Q308). Comparative studies of AI-assisted and traditional assessment models, such as Omeh's (2026) examination of web design competence and students' cognitive load, indicate growing interest in what open designs do to learning itself. A single course-level comparison cannot settle that question.

Several tensions remain unresolved, and a senior reader should treat the two-lane model as a promising design logic rather than a validated system. The first concerns grading. If open-lane tasks contribute substantially to final marks, the grades they generate carry uncertain meaning about individual capability, and the architecture's assurance claim weakens. If they carry little or no weight, students may rationally disengage from them, reproducing the very decoupling of performance from engagement that Montebello (2026) describes. How institutions weight the lanes is therefore not an administrative detail but the point on which the model succeeds or fails, and current evidence does not show which weightings sustain engagement.

The second tension concerns the secure lane's costs and fairness. Supervised and oral formats demand staff time and examination infrastructure. They can also disadvantage students for whom live, timed or spoken performance is a barrier unrelated to the outcome being assessed. A model that concentrates high stakes in fewer secure moments could intensify those effects unless accommodations are designed in from the start. Dawson and colleagues' (2024) insistence on validity cuts both ways here. A secure task that measures anxiety or spoken fluency rather than the intended capability is no more valid than an unsupervised essay written by a chatbot.

The third tension is discursive. Bearman, Ryan and Ajjawi (2022) identified, in higher education scholarship, a Discourse of imperative change in which AI is presented as an inevitable transformation to which all must respond. They found few and confusing definitions of AI and little overt treatment of AI as a research object. Two-lane advocacy can slip into that discourse, presenting wholesale restructuring as the only rational response. A more cautious position treats the model as one defensible configuration among several, whose merits must be shown rather than assumed.

Finally, stakeholder alignment is uncertain. Kennedy, Benini, O'Sullivan and colleagues (2026) surveyed 158 students and 109 staff at an Irish university about generative AI in teaching, learning, assessment and academic integrity, analysing responses descriptively. Studies of this kind document perceptions at a single institution. They cannot show whether students and staff would accept, understand or trust a two-lane architecture, nor whether such acceptance predicts better outcomes.

Taken together, the evidence supports the reasoning behind the two-lane architecture more firmly than its effects. The validity argument advanced by Dawson and colleagues (2024) and

the structural critique by Corbin, Dawson and Liu (2025) give a coherent justification for separating secure assurance from open collaboration. Earlier work on scaffolded authentic assessment culminating in interactive orals (Sotiriadou et al., 2019) shows that secure and authentic designs need not be opposites. The AIAS literature (Perkins et al., 2024; Furze et al., 2024; Perkins, Roe and Furze, 2024) and policy analyses such as Elkhodr and Gide's (2026) clarify what a well-structured open lane would require. None of this demonstrates that two-lane programs produce graduates whose capabilities are more reliably verified, or students who learn more, than programs organised differently.

What the field most needs is program-level evaluation. Such studies would trace where secure evidence is gathered across a degree and test whether secure-lane judgements predict later performance. They would also examine whether open-lane designs sustain cognitive engagement rather than merely tolerating AI use. Until such evidence exists, the two-lane architecture is best read as a disciplined answer to a question the post-detection era forces on every institution: which of our judgements must be trustworthy, and what conditions make them so? On that question, the model offers clarity that permission scales and detection tools have not. Whether that clarity translates into better assurance of learning is still an open empirical matter.

Q305 How can interactive oral assessments (viva voce, Socratic defense, and two-stage collaborative exams) be scaled fairly across secondary and higher education?

11 citations · 11 sources · 4 cross-references

Claim 1 disputed

Interactive oral assessments can be scaled fairly only if they are treated as a structural component of assessment design rather than a bolt-on integrity check. In practice that means three commitments. Oral and collaborative formats should be used selectively, at the points where a programme most needs assurance that learning is genuinely the student's own. Every conversation should be governed by structured, calibrated protocols that make examiner judgement consistent and reviewable. And formats such as the two-stage collaborative exam, which spread the interactive load across peers, should be used to extend reach without multiplying staff hours. The justification for this architecture lies in validity, not detection.

Dawson and colleagues (2024) argue that the attention given to cheating as a moral category is misplaced. They propose that cheating be subsumed within the broader concept of assessment validity, so that integrity becomes part of the positive mission of assuring learning rather than an exercise in moralising. This reframing matters for oral assessment because it changes what scaling is for. The aim is not to interrogate every student as a suspect. It is to collect enough trustworthy evidence, from enough of the programme, to support defensible claims about capability. Corbin, Dawson and Liu (2025) sharpen the point. Institutional responses to generative AI that focus on communicating permissible use, such as traffic-light schemes, share a common limitation: they address rules rather than the mechanics of assessment. Oral and interactive formats are one of the few mechanical changes that alter what a student must do in the moment to succeed.

Scholars should nonetheless resist the discourse that Bearman, Ryan and Ajjawi (2022) call imperative change, in which AI is presented as an inevitable force to which all must respond. The renewed interest in orals should rest on what they assess well, not simply on what written tasks have lost.

The empirical base for oral assessment is suggestive but modest, and it supports cautious rather than sweeping claims. The most direct comparative evidence comes from Huxham, Campbell and Westwood (2012). They randomly divided a cohort of 99 biology students into oral and written groups answering the same questions. In a second cohort of 29, every student answered both written and oral questions on scientific and personal-development topics. Both cohorts showed highly significant differences in mean marks, with better performance in the oral assessment. The design is valuable because randomisation in the first cohort reduces the risk that stronger students simply selected the oral route.

The finding is open to more than one interpretation, however. Higher oral marks might reflect deeper engagement, the chance to clarify a misunderstood question, or more lenient marking in face-to-face settings. A single study in one discipline cannot separate these explanations. Anyone scaling oral assessment should therefore monitor whether oral and written marks diverge systematically, and should ask whether any divergence reflects construct-relevant capability or examiner effects.

Sotiriadou and colleagues (2019) offer a design-oriented complement. They built a suite of scaffolded authentic assessments that culminated in interactive oral examinations, framing the sequence as a way to preserve academic integrity while developing skills linked to employability. The significance for scaling is architectural. The oral was not an isolated event but the endpoint of a scaffolded sequence, so students arrived having rehearsed the reasoning they would be asked to defend. Fenton (2025) reviews the background, types, benefits and challenges of oral exams and assessments and offers practical recommendations. She situates their resurgence in the arrival of generative AI and the aftermath of the pandemic. Taken together, these works suggest that orals can yield valid evidence and can be embedded in authentic task sequences. They do not establish that the gains survive when orals are delivered at volume by many examiners of varying experience. That is precisely the condition scaling creates.

The two-stage collaborative exam is the most promising mechanism for extending interactive assessment to large cohorts, because it relocates much of the dialogic work from examiner to peers. Zipp (2007) describes the format, also known as the cooperative, group or pyramid exam. Students first sit an exam individually and then sit the same exam with their learning group. The final grade is a weighted combination of individual and group scores. Zipp positions the format within a long tradition of research on cooperative learning, associated with increased learning, retention through graduation, improved critical thinking and intrinsic motivation. He also notes that this particular technique has received relatively little attention. Its distinctive feature is that the exam serves as a learning tool as well as an evaluation.

For scaling, the two-stage format has an attractive property. The individual stage provides a secure, attributable measure, while the group stage generates argument, justification and correction among students without requiring an examiner in every conversation. A single invigilated session can thus combine individual accountability with the kind of explanatory talk that a viva elicits.

The format's fairness depends on decisions that institutions often leave implicit. How the individual and group scores are weighted determines whether a weaker student can be carried by a strong group, or a strong student penalised by a disengaged one. Group composition affects whose voice dominates. And because the group stage rewards articulate negotiation, it may advantage confident speakers in ways unrelated to the learning outcome. Zipp's account supports the pedagogical rationale, but the comparative evidence on how weighting and grouping interact with equity remains unclear. Fenton's (2025) treatment of practical considerations reinforces that format choice is only the first decision. Logistics, preparation and explicit criteria determine whether interactive assessment is fair in practice. A defensible approach keeps the individual component substantial, publishes the weighting in advance, and treats the group stage partly as a formative opportunity rather than the main source of grades.

Fairness at scale rests on standardisation of the conversation itself. An unstructured viva, conducted by many examiners, invites inconsistency: different questions, different follow-up depth and different tolerance for hesitation. Scaling such a format multiplies those risks. The remedy lies in four practices: structured question frameworks tied to explicit learning outcomes, common opening prompts with sanctioned probing routes, calibration sessions in which examiners mark sample recordings together, and moderation of a proportion of conversations by a second marker. Because Huxham and colleagues (2012) found oral marks

systematically higher than written ones, institutions should treat score distributions across examiners and formats as routine monitoring data rather than assume equivalence. Dawson and colleagues' (2024) validity framing gives this monitoring its rationale. An oral that produces inconsistent judgements is not merely unfair. It fails to support the inference it was designed to secure.

Sampling is the second lever. Not every unit, nor every student in every unit, needs a full viva for a programme to assure learning. A short, structured authentication conversation attached to a substantial piece of work can verify ownership at modest cost. Fuller Socratic defences can be reserved for capstone or high-consequence points. Sampling must be transparent and rule-governed, however, so that being selected never functions as an accusation. Where a conversation raises concerns about authorship, the matter belongs in a separate procedural track with its own safeguards (see Q312), not in the marking of the oral itself.

Third, scaling must not sacrifice students for whom spoken, synchronous performance is itself a barrier. Anxiety, neurodivergence and language background can depress oral performance for reasons unrelated to the construct. The accommodations this requires are treated in detail elsewhere (see Q306). Here the structural point is that fairness provisions such as advance notice of themes, choice of modality and time allowances must be designed in from the outset rather than negotiated case by case. Faculty interviewed by Khlaif and colleagues (2025), 61 participants in a qualitative study of assessment redesign for the generative AI era, illustrate that redesign proceeds through educators' own motivations and judgements. That makes shared institutional frameworks and calibration all the more necessary if practice is to remain consistent across a programme.

The secondary and higher education sectors face different scaling constraints, and the evidence base is notably thinner for schools. Most of the studies discussed here are set in universities: biology undergraduates, sociology courses and business programmes culminating in interactive orals. Fenton (2025) addresses oral exams and assessments as an educational approach more broadly. Even so, transferring higher education models to secondary classrooms involves assumptions that remain largely untested. Secondary teachers often carry heavier contact loads and larger aggregate student numbers across classes. Recording conversations with minors raises safeguarding and consent questions. And younger learners may need more explicit rehearsal of the discourse conventions of explaining and defending reasoning.

These differences point to sector-specific designs. In secondary settings, brief, frequent and low-stakes oral checks embedded in ordinary lessons may be more feasible and more equitable than infrequent high-stakes vivas. Two-stage collaborative tasks, as Zipp (2007) describes them, align well with the group-work routines already common in schools, though their weighting should favour individual accountability where results feed into consequential records. In higher education, the programme is the natural unit of design. Rather than every course adopting orals independently, a programme can locate secure interactive assessment at defined progression points. This logic connects to longitudinal portfolio models (see Q311) and to architectures that separate secure assurance from open collaboration with AI (see Q304).

The reason structure matters more than exhortation is that the vulnerability of conventional formats is under active investigation. Künzle and Paris (2024), for instance, analysed the performance of several large language model applications on 151 restorative dentistry and endodontics assessment questions, many in multiple-choice form. Studies of this kind document why institutions are reconsidering formats whose outputs can be produced without the student's own reasoning. Corbin, Dawson and Liu (2025) argue that communicating rules cannot substitute for redesigning assessment mechanics. Interactive formats are one such redesign, but their workload must be budgeted at programme or school level rather than absorbed invisibly by individual teachers. Otherwise scaling becomes a source of inequity among staff as well as students.

The most contested route to scale is the use of AI itself to conduct or mark oral and Socratic assessment. The appeal is obvious: a system that can question every student, at any hour, would remove the staffing bottleneck that limits human vivas. Sánchez (2026), writing about medical education, argues that delivering Socratic dialogue at scale through large language models is plausible but unproven. He identifies a mimicry trap, in which a system fluently generates Socratic-sounding questions and appears to cultivate reasoning while functioning as interactive content delivery. He frames this as an educational instance of the ELIZA effect and of the proxy-outcome problem. Although his argument concerns learning dialogue rather than summative examination, the warning transfers directly. An automated questioner that produces convincing exchanges may not be eliciting or judging the reasoning it claims to assess.

Kaldaras, Akaeze and Reckase (2024) add a measurement concern. Generative AI can consider context and could be trained to deliver quick evaluation of learning outcomes, but current tools carry considerable limitations, including social biases inherent in training data. In oral

assessment, where accent, dialect and discourse style already influence human judgement, automated scoring could encode such biases at a scale no individual examiner could reach. Bearman, Ryan and Ajjawi's (2022) observation that AI is often invoked vaguely, through a discourse of inevitability, counsels scepticism toward claims that automation will make orals scalable by default.

A defensible position for now is that AI may support the logistics of oral assessment: scheduling, generating candidate question variants for human review, or producing transcripts for moderation. Evaluative judgement in consequential decisions should remain with calibrated human examiners until validity evidence exists.

Several things the evidence does not yet show should temper confident recommendations. It remains unclear whether the oral advantage that Huxham and colleagues (2012) observed persists across disciplines, examiners and educational levels. Few studies have compared alternative weightings in two-stage exams for their equity effects. Secondary-school evidence is sparse. And no validity case yet supports automated Socratic examiners. Scaling fairly, then, is less a matter of choosing a format than of building the institutional infrastructure that makes any interactive format trustworthy: structured protocols, calibration, transparent sampling, designed-in accommodations and continuous monitoring of outcomes. That infrastructure, more than the conversation itself, is what converts a renewed enthusiasm for talk into valid assurance of learning.

Q306 How do educators protect neurodivergent, anxious, and multilingual learners from unfair penalties during oral and in-person synchronous assessments?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Educators protect neurodivergent, anxious, and multilingual learners in oral and synchronous assessment mainly through design rather than exception. They decide in advance which capability is actually being judged. They then strip out the performance channels that are incidental to it, such as speed of response, spoken fluency, accent, composure under observation, and conventional social signalling. Only after that do they layer individual adjustments, procedural safeguards, and a route to review on top. This ordering matters because the post-detection turn toward vivas, Socratic defences, and live problem-solving is often justified as a way to restore confidence in authorship. A modality chosen for its resistance to generative AI is not thereby a fair one. If the redesign simply moves the gatekeeping from the written script to the examination room, it risks relocating rather than removing disadvantage.

The conceptual case for this ordering is now well articulated. Nieminen (2022) observes that higher education's most common answer to student diversity is the individual assessment accommodation. He notes that inclusive design has also been promoted to make assessment accessible for all. He argues, however, that both approaches rest on a procedural understanding of inclusion as enhanced academic outcomes. In their place he proposes a critical, socio-political reading that situates assessment within a wider context of academic ableism. Tai and colleagues (2022) arrive at a compatible position from a design perspective. They note that underperformance is frequently positioned as a problem of the student, attributed to diversity or

background characteristics, when the assessment itself may be inequitable and exclude students inappropriately. Their recommendation is that educators look beyond simplistic categories of disability or social equity groups and account for diversity on many spectra. Applied to oral formats, these two arguments imply that the anxious, the neurodivergent, and the multilingual are not three separate populations awaiting three separate fixes. Rather, they mark overlapping dimensions along which a single live assessment can misread competence. The operational questions of running such assessments at volume are treated elsewhere (see Q305). The concern here is the narrower matter of who is unfairly penalised when they are run.

Anxiety is the most thoroughly evidenced risk, and it is also where the evidence pulls in two directions. Hembree's (1988) meta-analysis integrated 562 studies and concluded that test anxiety causes poor performance. It found that anxiety relates inversely to self-esteem and directly to fear of negative evaluation, defensiveness, and other forms of anxiety. It also found that differential anxiety levels are associated with ability, gender, and school grade level. That synthesis predates the current wave of oral assessment and concerns academic testing broadly. Even so, its emphasis on fear of negative evaluation is pointed for formats in which evaluation is embodied in an examiner sitting opposite the student. In an oral assessment, the evaluating gaze is continuous and visible rather than deferred to a marker who never meets the candidate.

Against this, Huxham, Campbell and Westwood (2012) found that oral assessment can advantage students. In a cohort of 99 students randomly divided into oral and written groups and answering the same biology questions, and in a second cohort of 29 students examined in both modes on scientific and personal development topics, both cohorts showed highly significant differences in mean marks, with better performance in the oral assessment. The two findings are not strictly contradictory. Hembree establishes that anxiety depresses performance in general. Huxham and colleagues show that, on average and in their setting, oral examination did not depress marks relative to writing. What neither demonstrates is how the most anxious students fare under oral conditions relative to written ones. Cohort means can conceal a minority for whom the live format is markedly worse, and the evidence on that distribution remains unclear.

The practical implication is to treat anxiety as something the design can lower rather than something the student must overcome. Hembree's account of fear of negative evaluation points toward several measures. These include low-stakes rehearsal orals in the same format before any graded one, published question types and assessment criteria, and permission to bring notes

or a prepared opening statement. Examiners can also be trained to normalise pauses and requests for repetition. Structurally, Zipp (2007) describes the two-stage cooperative examination. Students first sit an exam individually and then retake it with their learning group, and the grade is a weighted combination of individual and group scores. This turns the examination into a learning tool as well as an evaluation. A synchronous assessment built on that logic distributes the evaluative spotlight and gives students a second, collaborative opportunity to demonstrate understanding. Zipp's account concerns cooperative learning gains rather than anxiety reduction specifically, however, and its protective effect for highly anxious students has not been established.

For neurodivergent learners, the central hazard is that oral assessments silently import criteria of normative social performance. Marks drift toward students who maintain eye contact, answer without latency, tolerate interruption, follow conversational turn-taking conventions, and process spoken questions as quickly as written ones. Nieminen's (2022) framing of academic ableism names this precisely. The disadvantage lies in an assessment culture that equates a particular communicative style with intellectual competence, not in the student. Tai and colleagues' (2022) caution against simplistic categories is equally important here. Neurodivergence is heterogeneous, and the student who needs extended processing time may not be the student who needs a quiet room. Neither may share needs with the student who finds a group stage overwhelming rather than supportive.

Several design commitments follow, although direct empirical studies of neurodivergent candidates in contemporary oral examinations are few. Questions can be provided in written as well as spoken form, and silent processing time can be granted before a response is expected. Rubrics should explicitly exclude delivery features unrelated to the learning outcome, such as gaze, gesture, and fluency of speech, unless spoken communication is itself the outcome being assessed. Students can be offered a choice of modality, so that a live conversation, a recorded response, or an in-person written problem-solving session can each evidence the same construct. Agreed breaks and predictable session structures reduce load further. The two-stage format Zipp (2007) describes offers a useful contrast. A collaborative second stage that steadies one student may impose sensory and social demands that destabilise another. This reinforces the case for choice over any single 'inclusive' format applied uniformly. Where AI-based supports for neurodivergent learners are introduced into these settings, their documented benefits and harms deserve separate scrutiny. Educators should also guard against a deeper risk:

that the move away from writing, adopted as an integrity measure, removes an asynchronous mode in which many neurodivergent students had been able to demonstrate competence on their own terms.

For multilingual learners, the governing distinction is between language as the construct and language as the vehicle. In a language course, spoken accuracy may legitimately be assessed. In a biology viva or a history defence, it usually should not be. Yet examiners listening in real time are prone to conflating hesitation, accent, and lexical searching with conceptual weakness. Several protections address this conflation. Rubrics can separate disciplinary reasoning from linguistic polish and say so explicitly. Students can be allowed to request rephrasing without penalty and to use a brief bilingual glossary of key terms. Where institutional capacity permits, candidates might reason in their first language before producing a summary in the language of instruction. Because these practices sit close to the question of what counts as legitimate linguistic scaffolding, they should be aligned with policy on assistive translation and grammar support (see Q310).

The evidence base here is indirect. Lee (2019) studied EFL students who wrote in their first language, translated into English without machine translation, and then compared their versions with a machine translation to revise. That design treats the learner's first language as a legitimate resource for second-language production rather than a contaminant. The study concerns writing, not speaking, and cannot be read as evidence about oral examinations. It nonetheless supports the general principle that thought formulated in one language and expressed in another is still the learner's own thought. Akinwumi and Qian (2026) offer a methodological rather than substantive lesson. In developing an equity-aware AI tutoring framework using learner spelling data annotated by first language and proficiency, they examined feedback quality, accessibility, personalisation, and potential subgroup disparities. Their object is automated feedback, not human examiners. The practice of disaggregating outcomes by first language and proficiency level, however, is exactly what institutions adopting oral assessment rarely do and ought to. Without such disaggregation, a format that raises average marks, as Huxham and colleagues (2012) found, could still systematically underrate multilingual candidates, and nobody would see it.

A further risk is specific to the post-detection moment. Oral follow-ups are increasingly used to probe suspected undisclosed AI use. Multilingual students whose written work is more fluent than their spontaneous speech are then vulnerable to having that gap read as evidence of

outsourcing. A discrepancy between written and spoken register is ordinary in second-language development. It should never by itself trigger or support a misconduct finding, and any such inquiry belongs within a formal due-process protocol rather than an informal oral 'check' (see Q312).

Artificial intelligence enters synchronous assessment from another direction as well, through automated question generation, live transcription, captioning, and draft scoring. Each could protect or penalise the groups considered here. Real-time captioning and transcripts can support students with auditory processing differences and give multilingual candidates a visual anchor. Transcripts also create a record that enables moderation and appeal. Shaw (2024), writing for music educators, argues that AI will change traditional assessment and grading practices while also potentially facilitating new directions for assessment and differentiation. That argument generalises cautiously to other performance-based disciplines.

The ethical terrain is unsettled. Chinoracky and Stalmasekova (2025) conducted a thematic review of 42 peer-reviewed articles published between 2022 and 2025. They classified educators' activities into teaching, research, and other duties, and examined the ethical problems that arise when educators use AI in each. Güler's (2026) survey of 123 Swiss adult educators, a non-probability sample, found widespread AI use. Usage frequency was associated primarily with self-reported AI knowledge rather than demographic characteristics, and respondents reported substantial constraints, most notably privacy and security concerns and limited perceived institutional support. These are associations in a single national sample, but they signal that recording and transcribing students' voices, including the voices of disabled and minority-language students, will often happen without robust institutional governance. Zou, Xie and Kohnke (2025) propose a framework for educators' pedagogic AI competence on the grounds that existing frameworks lack systematic guidance for AI-specific skill development. Fair use of automated tools in oral assessment is plausibly one such competence, though their framework does not address it specifically.

Smith's (2026) analysis adds a philosophical caution. He argues that formative epistemic injustice is done to students when instructors encourage them to farm out literacy learning tasks to generative AI. His argument concerns learning rather than assessment. Still, the concept of epistemic injustice he employs invites a parallel reflection. If automated transcription or scoring represents some speakers less accurately than others, the resulting record could discount those students' knowledge before any human examiner exercises judgement. No

automated component should therefore be deployed in graded oral assessment without accuracy audits disaggregated by accent, first language, and speech pattern, along the lines Akinwumi and Qian (2026) model for feedback. Human examiners should retain final responsibility for judgement.

Procedural safeguards complete the architecture. These include recording sessions with consent, so that judgements can be moderated, and second marking or calibration across examiners, since live judgement is vulnerable to impression effects. Students should have a clear and non-punitive right to request review. Most importantly, a single oral occasion should not carry decisive weight. Embedding orals within programmatic or portfolio assessment, where competence is triangulated across tasks and time, reduces the stakes of any one anxious or misread performance (see Q311). This applies Nieminen's (2022) and Tai and colleagues' (2022) shared insight at the level of the programme. The fairest protection is a system in which no single format becomes the sole gate.

What the evidence does not yet show should be stated plainly. Hembree's (1988) synthesis firmly establishes that test anxiety harms performance. Huxham and colleagues (2012) show that oral formats can raise average marks. Between these lies an unanswered question about the distribution of benefit and harm across anxious, neurodivergent, and multilingual students specifically. Few studies have disaggregated oral-assessment outcomes along these lines. The protective value of two-stage formats, choice of modality, and automated captioning for these groups is plausible but largely untested. Until such evidence accumulates, the defensible stance is precautionary. Institutions should design for variation and monitor outcomes by subgroup. They should also treat any widening gap as a design failure rather than evidence of student deficit.

Q307 What is the "Assessment AI Traffic-Light / 5-Level AI Assessment Scale (AIAS)" (Perkins, Furze, Roe, & MacVaugh, 2024), and how should instructors map specific assignments to each level?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

The AI Assessment Scale (AIAS) is a five-level framework, first published by Perkins, Furze, Roe and colleagues (2024), that lets instructors specify for each assessment how much, and what kind of, generative AI (GenAI) use is legitimate. The choice is made from the learning outcomes the task is meant to evidence, not from a blanket institutional rule. Instructors map an assignment to a level by asking a sequence of questions. Which capability must this task certify? Could GenAI perform that capability on the student's behalf? Can the conditions of the task actually secure the level being claimed? The authors present the scale as a practical, simple and sufficiently comprehensive tool for bringing GenAI into assessment while acknowledging both its pedagogical promise and its ethical and academic risks (Perkins et al., 2024). The levels run from a No AI condition, through intermediate levels where GenAI may support planning or work alongside the student, to a Full AI condition. The adaptation for English for Academic Purposes keeps the same five-level span from "No AI" to "Full AI" (Roe, Perkins, & Tregubova, 2026).

The framework is often called a "traffic-light" scale, but that label should be used with care. Corbin, Dawson and Liu (2025) identify the traffic-light approach as a familiar feature of institutional policy. They group it with other schemes whose main function is to tell students which AI uses are permitted, and they distinguish such schemes from the redesign of assessment mechanics. The AIAS overlaps with this family because it too is a communicative device. Its authors, however, increasingly frame it as a design instrument as well. The revised version states two purposes: to open dialogue between educators and students about appropriate GenAI use, and to support educators in redesigning assessment as AI capabilities expand (Perkins, Roe, & Furze, 2024). Readers should also keep this AIAS separate from the four-item AI Attitude Scale (AIAS-4), a psychometric attitude measure validated with Turkish undergraduates (Köse, Şimşek, & Demir, 2025) and with 2,329 Norwegian university students (Møgelvang & Grassini, 2025). The shared acronym has no conceptual link to the assessment scale discussed here.

The intellectual core of the AIAS is a shift away from policing and toward validity. The original framework is explicitly outcome-led: the appropriate level follows from the learning outcomes an educator seeks to address (Perkins et al., 2024). The revised framework goes further. It describes itself as grounded in social constructivist principles and designed with assessment validity in mind (Perkins, Roe, & Furze, 2024). This places the scale within a broader argument in the assessment literature. Dawson, Bearman, Dollinger and colleagues (2024) contend that cheating is best treated as a sub-problem of validity. If students cheat, we cannot be confident they have met the learning outcomes. Addressing cheating without moralising therefore becomes part of the positive project of assuring learning. The AIAS can be read as an operational form of this stance. A level designation is in effect a claim about which inferences the task's evidence can support.

This framing changes the question instructors ask when mapping assignments. "How do I stop students using AI?" gives way to "what must this task let me infer about this student, and what AI use would corrupt or leave intact that inference?" An essay meant to certify independent argument construction supports a different inference from one meant to certify the ability to commission, critique and refine machine-generated analysis. Both can be valid, but not under the same level. The framing also guards against a failure mode that Bearman, Ryan and Ajjawi (2022) identified in higher education's broader talk about AI. Their critical review found few and confusing definitions of AI, and it delineated a Discourse of imperative change in which AI

appears as an inevitable force to which everyone must respond. The original AIAS paper opens by predicting that GenAI use is likely to become a defining feature of education (Perkins et al., 2024). Instructors who use the scale well need not accept that premise wholesale. Anchoring each level decision in a specific outcome keeps the decision pedagogical rather than reactive. It also leaves room to choose the most restrictive level whenever the outcome demands it.

At the restrictive end of the scale, the decisive mapping criterion is security, not intention. A No AI designation is appropriate when the outcome concerns capabilities that must be shown unaided. Examples include recall and fluent application of foundational knowledge, spontaneous oral reasoning, clinical or laboratory judgement under time pressure, and unassisted language production. The designation is only credible, however, when the task conditions can actually exclude GenAI. Stanoyevitch (2024) documents how online assessment was already strained by exam- and homework-assistance platforms before sophisticated tools such as ChatGPT arrived. His account suggests that an unsupervised take-home task labelled "No AI" rests on student compliance alone. Corbin, Dawson and Liu (2025) make the same point structurally: communicating a rule does not change the mechanics that determine whether the rule can hold. A defensible mapping practice therefore attaches the most restrictive level only to supervised, synchronous or otherwise observable formats. These include invigilated examinations, practical demonstrations and interactive orals.

Interactive orals are especially useful here. Sotiriadou and colleagues (2019) describe a suite of scaffolded authentic assessments culminating in interactive oral examinations. They present this design as serving academic integrity, skill development and employability together. For an instructor applying the AIAS, this suggests that a No AI checkpoint need not be a decontextualised exam. It can be the culminating moment of an authentic sequence in which earlier stages permitted more AI use. The scaling and equity challenges of such orals are treated elsewhere in this chapter (see Q305). The next level up, where GenAI may assist with early-stage thinking such as brainstorming, outlining or locating starting points, suits tasks whose outcome lies in the student's own execution: drafting the argument, writing the code, producing the analysis. The design implication is to make the boundary visible. Instructors should ask students to submit planning artefacts alongside final work, so that the permitted AI contribution and the student's subsequent development can be seen and assessed (see Q308). Without such evidence, the gap between "AI helped me plan" and "AI drafted this" cannot be verified.

The middle and upper levels are where mapping requires the most pedagogical imagination, because the outcome being certified changes. At an intermediate collaborative level, students may use GenAI during drafting, revision or problem-solving. The assessable capability then moves toward critical engagement with machine output: judging accuracy, detecting weaknesses, integrating sources and taking ownership of the final product. Lye and Lim (2024) give a concrete reason why this capability deserves assessment. Models trained on internet data can produce biased and discriminatory outputs, and hallucination yields fabricated content. A task that requires students to audit, correct and justify their acceptance or rejection of AI suggestions turns these known weaknesses into the object of assessment. Suitable assignments include a literature synthesis in which students verify every AI-suggested claim against primary sources, a policy brief annotated to show where the student overrode the model, and a code review in which an AI-generated solution must be tested and defended.

At the Full AI level, students may use GenAI throughout the task as they see fit. The outcome then concerns orchestration, meaning the ability to direct AI toward a goal, to evaluate what it produces, and to take responsibility for a product that exceeds what either party could produce alone. Fitting cases include professional simulations in which AI use mirrors workplace practice, design projects where rapid prototyping is the point, and capstone tasks where the student's judgement about which machine contributions to keep is itself the evidence. The revised framework positions the scale as a support for redesigning assessment as AI capabilities expand (Perkins, Roe, & Furze, 2024), and the most permissive levels are where that redesign is most visible. Discipline-specific comparisons are beginning to appear. Omeh (2026), for instance, contrasts an AI-assisted assessment model with a traditional model in a web design course, attending to student cognitive load. Such studies do not map directly onto AIAS levels, however, and how student learning differs across levels remains unclear. Instructors should also expect rubric weightings to change at these levels. Fluent prose and polished syntax cease to discriminate, so criteria must reward judgement, verification and synthesis instead (see Q309).

The evidence for the AIAS in practice is still early and comes largely from its originators, and readers should weigh it accordingly. Furze, Perkins, Roe and colleagues (2024) report a pilot implementation at British University Vietnam. They frame it against the view that banning or blocking GenAI tools has proven ineffective and that punitive approaches ignore the potential benefits of these technologies. The pilot shows that the scale can be put into operation across real courses. As a single-institution study by the framework's designers, however, it cannot

establish that AIAS adoption improves learning, reduces misconduct, or holds up across institutional cultures. Independent replication, comparative designs and outcome measures beyond stakeholder perception are what the field now needs.

The framework's adaptability is better documented than its effects. Roe, Perkins and Furze (2025) apply the AIAS to writing and translation in English as a Foreign Language. They note that although much research has examined GenAI as a learning aid, and its potential harms, for language learners, few formalised frameworks exist to support integration and the development of AI literacy in that context. Roe, Perkins and Tregubova (2026) go further and propose the EAP-AIAS, which keeps the five-level structure while defining appropriate GenAI use for English for Academic Purposes tasks. These adaptations are instructive for mapping because language education exposes the hardest boundary cases. When a student uses AI to translate, paraphrase or correct grammar, the same act may be legitimate scaffolding under one outcome and substantive offloading under another. In a course certifying disciplinary reasoning, grammar support may sit comfortably at a permissive level. In a course certifying independent written production in the target language, the same support may undermine the very outcome being assessed. Policies that distinguish these cases for multilingual learners are treated in their own right elsewhere (see Q310). For mapping, the point is that a level is never a property of a tool or an activity in the abstract. It is always relative to the outcome, which is precisely the logic on which the AIAS was built.

The most serious critique of the AIAS concerns what it can and cannot do as a rule-communicating device. Corbin, Dawson and Liu (2025) argue that traffic-light and similar approaches, though well intentioned, share a limitation: they focus mainly on communicating rules rather than redesigning assessment mechanics. As a result, they cannot by themselves secure validity when GenAI lets students complete tasks without demonstrating genuine capability. Taken at face value, this critique applies to any use of the AIAS in which a level is assigned to an unchanged task, published in a course outline, and enforced through trust. The revised framework's emphasis on dialogue and redesign (Perkins, Roe, & Furze, 2024) can be read as partly answering this objection. Whether it does so sufficiently is disputed. The scale still asks students to observe boundaries that, outside supervised conditions, no instructor can verify. Combined with the unreliability of automated detection, this means that a breached level designation cannot be settled by software. It must be handled by due process.

The most defensible synthesis treats the AIAS as necessary but not sufficient. It provides a shared vocabulary that makes expectations explicit and invites honest conversation, and its outcome-led logic is consistent with the validity-first view that Dawson and colleagues (2024) advance. Its levels carry real assurance only when backed by task structures capable of securing them. In practice, instructors should reserve the most restrictive levels for observable formats. They should use the intermediate and permissive levels where the outcome itself involves working with AI, and require process evidence wherever a boundary matters. Above all, they should plan at the programme level rather than assignment by assignment. Programme-level planning would pair a limited number of secure checkpoints with open, AI-integrated tasks. That arrangement converges with the two-lane architecture discussed elsewhere in this chapter (see Q304). In this reading, the five levels collapse functionally into two categories: tasks that can secure the absence of AI and tasks that cannot. Whether this convergence will make the intermediate levels redundant, or keep them valuable as pedagogical scaffolding, remains unclear. What the current evidence does not yet show is equally important. It does not show that students reliably understand or honour level boundaries, that level choices predict learning gains, or that the scale performs equivalently across disciplines, educational stages and national contexts. Until such evidence accumulates, the AIAS is best treated as a well-reasoned design heuristic with modest empirical support, not as a validated instrument.

Q308 How do version-history telemetry, keystroke/revision replay, and reflective "Process & Prompt Portfolios" function as formative evidence of authentic student cognition?

15 citations · 15 sources · 4 cross-references

Claim 1 disputed

Version-history telemetry, keystroke and revision replay, and reflective Process & Prompt Portfolios work as formative evidence of authentic cognition only when they are read as partial traces of a learning process that student and teacher interpret together. Treated as forensic proof that a student did or did not use generative AI, they fail. The distinction matters because the post-detection era has made clear that the most useful question is not whether a student cheated but whether an assessment supports a valid inference about what the student can do. Dawson, Bearman, Dollinger and colleagues (2024) argue that cheating is better understood as subsumed by assessment validity. They also question how justifiable the approaches used to address cheating are, and propose that integrity be pursued without moralising, as part of the broader mission of assurance of learning. Read through that lens, process evidence earns its place by widening the base of observations from which a teacher infers capability: drafts, deletions, restructurings, false starts, prompts issued to an AI system, and the student's own account of why choices were made. It should not become a surveillance layer added in the hope of catching misconduct.

This reframing also explains why process evidence belongs in assessment design rather than in policy statements. Corbin, Dawson and Liu (2025) observe that many institutional responses to generative AI, including the familiar traffic-light approach, focus on communicating rules about permissible use rather than redesigning assessment mechanics. They argue that GenAI threatens validity because students can complete tasks without demonstrating genuine capability. A process portfolio, a revision replay discussed in tutorial, or a staged submission

whose history is visible is a structural change of exactly this kind. It alters what the task requires students to produce and what teachers can see. The formative value lies in the alteration, not in the data stream itself.

The strongest evidential foundation for process telemetry comes from writing research, where keystroke logging has a substantial methodological history. Leijten and Van Waes (2013) describe keystroke logging as instrumental in identifying writing strategies and understanding cognitive processes. They note that technological advances have refined logging efficiency and analytical outputs, and that logging permits ecological data collection: writers compose in conditions close to their ordinary practice rather than in a laboratory. Pauses, bursts of production, revisions at the point of inscription, and movement through the developing text can all be captured, and researchers have used such patterns to characterise how writers plan, formulate and revise.

The same authors identify the central limitation that any educational use of telemetry must confront. It is often difficult to connect the fine grain of logging data to the underlying cognitive processes. A long pause may indicate planning, reading back, distraction, consulting a source, or reading an AI output in another window. A burst of fluent text may reflect a well-rehearsed idea or a passage transcribed from elsewhere. Leijten and Van Waes (2013) respond by arguing for methodological complementarity, combining logging with think-aloud protocols and eyetracking so that each technique offsets the blind spots of the others. The lesson for assessment is direct. The logging tradition demonstrates that process data can illuminate cognition, but it equally demonstrates that the data do not interpret themselves. Inference requires triangulation with other evidence, ideally including the writer's own verbal account.

Two cautions follow when this research is carried into classrooms. First, the version-history features built into common document platforms usually capture far coarser snapshots than research-grade keystroke loggers, so the gap between trace and cognition is wider still. Second, the research tradition developed process measures to describe writing, not to adjudicate authorship. How far revision patterns can distinguish independent composition from assisted composition remains unclear, and teachers should resist treating a smooth or a jagged revision history as diagnostic in itself. This is one reason why process telemetry should never substitute for the procedural safeguards required when misconduct is suspected (see Q312).

Process & Prompt Portfolios extend the logic of process evidence from the keyboard to the student's interaction with generative AI and to reflective commentary on that interaction. Their conceptual rationale is that prompting can make thinking visible. Dourvas, Kokkonis and Kontogiannis (2026), writing about teacher development rather than student assessment, propose reconceptualising prompt engineering from a technical competency into a reflective professional practice. They argue that prompting can externalise pedagogical thinking, so that AI interaction becomes a process of knowledge externalisation. Their analysis is conceptual, and its transfer from teachers to students is an extrapolation. Even so, it offers a plausible account of why a curated record of prompts, outputs, and the user's subsequent decisions might reveal reasoning that a polished final product conceals.

Early empirical work points the same way, though it falls short of validating portfolios as assessment instruments. Rebouças de Lira, Burneo, Costa and colleagues (2026) start from the tension between the operational efficiency GenAI offers in qualitative analysis and the latent risk of eroding higher-order cognitive competencies. Noting that the monitoring of these competencies remains underexplored, they used reflective portfolios to examine cognitive competences within a human-AI qualitative analysis workflow. The design treats the portfolio as a window onto whether the human retains intellectual agency, which is precisely the formative function proposed here. Gabrovšek and Rihtaršič (2025) analysed 208 student-tutoring tool interactions with a configurable generative AI tutor in an undergraduate electrical engineering laboratory, using a mixed-methods approach that combined evaluation by the research team with learner feedback. Their study shows that student-AI interaction logs can be systematically analysed as evidence about learning episodes. Lee (2025) worked in a related direction, comparing three levels of prompts, from very basic to progressively more detailed and contextualised, for getting ChatGPT to design formative questions on TED Talks. That work concerns teacher prompting, but it reinforces the point that the specificity and context of a prompt are themselves meaningful, analysable features of a person's engagement with a task.

Bach and Le (2026) offer a classroom-scale illustration of how reflection can be orchestrated around AI use. In a non-equivalent groups quasi-experiment with 120 undergraduate Information Technology students in a Programming Techniques course, they examined lecturer-guided AI-supported flipped learning in which AI tools were deployed across pre-class preparation, in-class practice and post-class reflection, while maintaining lecturer guidance, student reasoning and responsible AI use. The study treats reflective learning as an outcome of

interest alongside programming performance and autonomy. As a quasi-experiment without random assignment, however, it cannot isolate the contribution of the reflective component. Taken together, this work suggests that prompt logs and structured reflection can be made legible and can be studied systematically. Whether they reliably index authentic cognition at the level of the individual student, under assessment conditions, remains unclear.

The most serious complication for reflective portfolios is that reflection itself is a genre that generative AI can produce. Brondani, Alves, Ribeiro and colleagues (2024) set out to assess whether university instructors in dental education could differentiate reflections generated by ChatGPT from those written by students. They also compared a ChatGPT-generated thematic analysis with one produced by qualitative researchers on the same reflections. The very framing of that study signals a vulnerability: a reflective statement offered as evidence of the student's thinking may not be the student's at all. Knight, Parthasarathy and Huang (2025), writing on periodontal reflective portfolios, describe these portfolios as a key pedagogical tool for bridging theory and clinical application through critical thinking, self-awareness and evidence-based reasoning. They acknowledge that AI can help with idea generation and organisation but warn that it may undermine deep reflection and independent analysis, and they insist that it should not replace the reflective process necessary for professional growth.

The field is divided here. One position, implicit in the work on prompting as externalisation, holds that documenting AI use within a portfolio turns a threat into evidence. The other, reflected in the dental education literature, worries that the portfolio's reflective layer is exactly where unacknowledged AI substitution is easiest and hardest to see. Both positions are defensible, and neither is yet settled by evidence. A practical resolution is to stop treating any single artefact, whether reflection, prompt log or revision history, as self-authenticating, and to design for convergence among them. Sotiriadou, Logan, Daly and colleagues (2019) offer a model for this. They used a suite of scaffolded authentic assessments that culminated in interactive oral examinations, framing authenticity and academic integrity as mutually reinforcing and as contributors to skill development and employability. In such an architecture, a revision replay or prompt portfolio becomes material for a conversation in which the student explains decisions and responds to probing. The oral component tests whether the documented process is one the student actually inhabits, a function examined in detail under scalable interactive orals (see Q305).

Where process evidence sits within an institution's assessment architecture determines what it can legitimately do. The AI Assessment Scale developed by Perkins, Furze, Roe and colleagues (2024) lets educators select an appropriate level of GenAI use for an assessment according to the learning outcomes it addresses (see Q307 for the levels themselves). Process & Prompt Portfolios fit most naturally at levels where AI use is permitted, because there the question shifts from whether AI was used to how judiciously and reflectively it was used. Furze, Perkins, Roe and colleagues (2024) report a pilot implementation of the scale at British University Vietnam. They note that banning or blocking GenAI tools has proven ineffective and that punitive approaches ignore the potential benefits of these technologies. In their revision of the framework, Perkins, Roe and Furze (2024) describe its purposes as facilitating open dialogue between educators and students about appropriate GenAI use and supporting assessment redesign. They ground it in social constructivist principles and design it with assessment validity in mind. A prompt portfolio is one concrete vehicle for that dialogue: it turns the agreed level of AI use into something students document and teachers can discuss.

Corbin, Dawson and Liu (2025) supply the necessary counterweight. Scales and traffic lights communicate expectations, but communication alone does not secure validity. Without structural mechanisms, a declared level of AI use is an honour-system label. Process evidence partly answers that critique because it changes what is submitted, yet it does not by itself provide secure assurance. A determined student can stage a plausible revision history or curate a flattering prompt log. Process evidence therefore belongs chiefly in the developmental, formative strand of assessment, where its purpose is feedback, metacognitive development and dialogue. It does not belong in the secured strand, where high-stakes judgements require controlled conditions. Accumulated across a programme, such evidence also becomes more informative than any single instance, which links it to longitudinal portfolio designs that verify cumulative competency (see Q311).

Several limits deserve plain statement. Bearman, Ryan and Ajjawi (2022) identify in higher education writing a Discourse of imperative change, in which AI is presented as an inevitable change to which everyone must respond. They also find few and confusing definitions of AI in that literature. Process telemetry is vulnerable to the same pull: institutions may adopt fine-grained monitoring because it seems like a necessary response to an inevitable technology, not because its validity for the inferences they wish to draw has been shown. Dawson and colleagues' (2024) question about the justifiability of anti-cheating measures applies with

particular force to keystroke capture, which records far more of a student's working life than an assessment strictly requires. If students experience process evidence as surveillance, it is likely to distort the very process it aims to reveal, encouraging performed drafting rather than genuine exploration. That effect is plausible on general grounds but has not been established in the work reviewed here.

The evidence also leaves important questions open. Few studies have tested whether reviewing revision replays or prompt portfolios improves learning outcomes compared with feedback on final products alone. The available portfolio studies are largely domain-specific, drawn from dental education, qualitative research training and engineering or computing courses, and their generalisability is uncertain. How reliably teachers can interpret process traces, how often their readings agree, and how those readings vary across writing styles, disabilities and language backgrounds all remain unclear. That last point matters for multilingual learners, whose drafting and translation practices may produce process signatures easily misread as offloading. The keystroke logging tradition offers the most defensible guiding principle: process data illuminate cognition only when combined with other evidence, above all the learner's own explanation (Leijten and Van Waes, 2013). Version histories, revision replays and Process & Prompt Portfolios are best understood as prompts for that explanation, structured invitations to make thinking visible and discuss it. They are not windows that reveal thinking unaided. Used that way, they serve the validity-centred, structurally redesigned assessment the post-detection era requires. Used as covert detectors, they repeat the failures of the detection tools they were meant to replace.

Q309 How must analytical rubrics shift their weighting when routine prose fluency and syntactic polish can be generated at zero marginal cost?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Analytical rubrics must move weight away from criteria that describe surface prose (fluency, syntactic polish, mechanical correctness, generic organisation) and toward criteria that describe judgements a student can be shown to own. These include the warrant behind a claim, the selection and appraisal of evidence, discipline-specific decisions among real alternatives, the handling of counter-positions, and the capacity to explain and revise those choices. Reweighting rows on a grid is not enough on its own, however. It works only when the criteria are tied to assessment conditions that make the newly weighted qualities observable and attributable. The starting point is what a rubric is for. Brookhart (2018), reviewing higher-education rubric studies from 2005 to 2017, argues that true rubrics combine criteria appropriate to an assessment's purpose with descriptions of performance along a continuum. She found that most rubrics studied were analytic and descriptive, typically with four or five performance levels. By that standard, a criterion earns its place only if it samples the learning outcome the task is meant to certify. Once polished prose can be produced at negligible cost by a tool the assessor cannot see, a high score on a 'style and expression' row no longer tells us what the student can do. The criterion has not become wrong in principle. It has stopped being informative under unsupervised conditions.

This is a validity problem before it is an integrity problem. Dawson and colleagues (2024) argue that cheating is better understood as one threat to assessment validity, to be addressed without moralising as part of the broader work of assuring learning. Applied to rubric design, that reframing shifts the question. The question is no longer whether a student has used a tool improperly to achieve fluency. It is whether the fluency row still supports a defensible inference about capability. Montebello (2026) sharpens the point by describing a decoupling of assessment performance from cognitive engagement. Assessment once enforced engagement structurally, because producing the output required the thinking. Generative tools now allow outputs without the associated cognitive processes. Rubric rows that reward the output's surface are the rows most exposed to that decoupling.

Downweighting polish does not mean deleting it, and the distinction matters. Fluency can be construct-relevant or construct-irrelevant. In a composition course, a professional-writing module, or a language programme, controlled and fluent expression is the learning outcome. Removing it from the rubric would misrepresent the curriculum. The right move there is to keep the criterion but relocate the evidence. Fluency should be judged where it can be attributed, such as in supervised writing, in drafting sequences, or in spoken explanation. It should not be inferred from a take-home artefact whose production history is invisible. In most disciplinary assignments, by contrast, prose quality has functioned as a carrier for the real construct: historical argument, clinical reasoning, policy analysis, experimental interpretation. Polish was rewarded partly because it correlated loosely with careful thought, and partly because it was easy to see. Where that correlation can no longer be assumed, the defensible response is to shrink the weight sharply. One practical option is to convert the row from a graded continuum into a threshold judgement, for example 'communicates clearly enough for a disciplinary reader to follow'.

That conversion is a deliberate design choice with consequences. Brookhart's (2018) distinction between rubrics and checklists or rating scales rests on the presence of performance-level descriptions. Turning a communication criterion into a gate therefore removes it from the rubric proper and leaves the graded continuum to the criteria that carry the construct. The benefit is that a fluent but thin submission can no longer bank marks on presentation. The cost is that genuinely excellent writing in a disciplinary task earns less explicit credit. Programmes should decide that trade-off openly rather than by drift.

The equity implications cut in a direction often missed. Rubrics that weighted mechanical correctness heavily have long penalised multilingual writers for features unrelated to disciplinary understanding. Lowering that weight can remove a source of construct-irrelevant variance, provided policies on grammar and translation support are coherent (see Q310). Bikanga Ada's (2026) Master's Dissertation Marking Framework is relevant here. It was developed through design-based research spanning a pre-generative-AI literature review, survey and interviews in 2022 and follow-up phases from 2023 to 2025, with the explicit aim of fairer and more transparent marking. It shows that marking frameworks can be revised longitudinally as conditions change. Whether its particular weightings transfer beyond master's dissertations remains unclear.

The weight released from surface criteria has to land somewhere. The most promising destinations are criteria describing judgement under constraint. A rubric row on 'use of evidence' can be rewritten so that its higher levels describe a student choosing between competing sources and justifying the choice, or recognising the limits of a dataset, rather than simply citing appropriately. A row on 'argument' can describe the anticipation and handling of the strongest objection, rather than logical flow. New rows can make the student's relationship to tools assessable. Examples are the critique of a generated draft, the identification of where a machine-produced explanation is wrong or shallow, and a rationale for which parts of the work were delegated and why.

Balzan and colleagues (2026) offer a useful conceptual frame for that last category. They describe the introduction of generative tools as a matter of budgeting human and machine autonomy, so that environments remain safe and autonomy-supporting. A rubric that rewards well-reasoned delegation is one concrete way of operationalising such a budget. Abedin, Hayajneh and Raahemi (2026), in a systematic review of 30 peer-reviewed articles, identify the deliberate fostering of critical thinking among the opportunities generative tools present. That finding is a synthesis of opportunity claims rather than evidence that reweighted rubrics produce better thinkers.

There is an uncomfortable complication. The same tools that produce fluent prose also produce fluent-looking reasoning. A plausible counterargument, a tidy evaluation of sources, or a reflective paragraph about one's own learning can all be generated. Rewriting rubric rows to name higher-order qualities therefore does not, by itself, protect them. Montebello's (2026) account of a shift from cognitive necessity to cognitive choice implies that any criterion judged

solely from a finished artefact can be satisfied without the cognition it names. The criteria that hold up best are anchored in what is specific and situated. These include local data the student collected, decisions taken in a particular studio or laboratory, and responses to feedback received in the course. Above all, they include the student's ability to explain and extend the work when questioned. Criteria of this kind shift the burden from describing a quality to specifying the evidence that will count as displaying it.

This is why rubric reweighting, taken alone, risks repeating a mistake already visible in institutional responses to generative AI. Corbin, Dawson and Liu (2025) distinguish approaches that communicate rules about permissible AI use, such as the familiar traffic-light schemes, from changes to assessment mechanics. They argue that the former, however well intentioned, share a common limitation: they focus on telling students what is allowed rather than redesigning how evidence of capability is gathered. A rubric is partly a communicative device. Moving fifteen percent of the marks from 'expression' to 'critical evaluation' tells students what the assessor values, but it does not change what the assessor can actually observe. If the submitted artefact remains the only evidence, the reweighted rubric is still talk rather than structure.

The structural complement is to attach each heavily weighted criterion to an evidence source capable of bearing it. Sotiriadou and colleagues (2019) used a suite of scaffolded authentic assessments that culminated in interactive oral examinations, and framed the design as both preserving academic integrity and developing skills relevant to employability. Their design illustrates the principle. The written components carry developmental value, and the culminating oral supplies attributable evidence of the reasoning the rubric rewards (see Q305 on scaling such orals fairly). Process records such as revision histories and reflective accounts of drafting can supply evidence for criteria about judgement and delegation (see Q308). Over a programme, weighting can be distributed so that no single artefact carries the full inference (see Q311).

The validity framing of Dawson and colleagues (2024) gives the coherent test. For each row, assessors should ask what inference the score licenses and whether the conditions of the task support it. Where they do not, the options are to change the evidence, to change the weight, or to move the criterion to a different task. A well-designed rubric in this period is therefore less a free-standing grid than a map connecting criteria to the occasions on which they are observed.

Several risks deserve plain statement. The first is that, in reaching for criteria generative tools cannot easily satisfy, designers introduce rows for 'authentic voice', 'personal style' or 'originality of expression' that function as covert detection instruments. Such criteria invite assessors to mark down prose that seems too fluent or too generic. That penalises some students, including multilingual and neurodivergent writers, on impressionistic grounds, and it imports suspicion into the marking scheme rather than handling it through due process (see Q312). A rubric should describe the qualities of good work, not the signature of a suspected tool.

The second risk is rhetorical. Bearman, Ryan and Ajjawi (2022) found that references to artificial intelligence in leading higher-education journals offered few and confusing definitions. They identified a Discourse of imperative change in which AI appears as an inevitable force to which everyone must respond. Calls to overhaul rubrics can borrow that urgency without specifying which tool capabilities, in which tasks, actually undermine which criteria. Reweighting should follow an explicit analysis of construct and conditions for each assessment, not a general sense that writing no longer matters.

The third risk concerns automated scoring. Muñoz-Collazos and González-Serrano (2025) review how machine-learning techniques contribute to evaluating STEM education projects through frameworks and rubrics, motivated by goals of fairness, consistency and transparency. If rubrics are increasingly applied by automated systems, there is a structural pull toward criteria that are computationally tractable. Surface features of text are among the most tractable. Institutions adopting machine-assisted marking should check that the scoring model has not quietly re-weighted the very criteria that human designers deliberately demoted.

On the empirical side, the evidence base is thin. Ateeq and colleagues (2024) surveyed 218 university students and faculty in Bahrain about AI's implications for academic integrity and the adoption of more comprehensive, holistic assessment. Their cross-sectional design captures perceptions and associations, not the effects of any particular rubric change. Creely's (2026) narrative review frames the wider ethics of generative AI in education through consequentialism. That framing usefully directs attention to what reweighting decisions actually do to students, but it offers no evidence about specific weightings. Few studies have compared the reliability, validity or equity of reweighted rubrics against their predecessors.

The defensible position, given this state of knowledge, combines a firm principle with a cautious practice. The principle follows directly from Brookhart's (2018) account of appropriate criteria and from the validity reframing advanced by Dawson and colleagues (2024). Rubric weight should track the inferential value of a criterion under the actual conditions of the task. When prose fluency and syntactic polish can be produced without the student, their inferential value in unsupervised artefacts collapses, and their weight should fall accordingly. In practice that often means falling to a threshold, except where fluency is itself the outcome and can be observed directly.

The practice has several parts. Weight should migrate toward situated judgement, evidential reasoning, disciplinary decision-making and reasoned delegation. Each heavily weighted criterion should be paired with an evidence source, whether oral, procedural or longitudinal, that can carry it, because changes that merely communicate expectations remain, in the phrase of Corbin, Dawson and Liu (2025), cheap talk. Revised frameworks such as Bikanga Ada's (2026) should be read as evidence that marking can be redesigned transparently over time, not as validated templates.

What the evidence does not yet show is equally important to state. It remains unclear how much weight a demoted communication criterion should retain in different disciplines. It also remains unclear whether threshold judgements of clarity are applied consistently across markers, and whether reweighted rubrics narrow or widen gaps between student groups. Nor is there yet good evidence that rewarding critique of machine output develops the autonomous judgement that Balzan and colleagues (2026) hope to protect, rather than a new genre of performable reflection. Until such studies exist, rubric redesign should be treated as a hypothesis about validity, and documented, monitored and revised as such.

Q310 How can assessment policies distinguish legitimate assistive translation and grammar scaffolding for multilingual/EAL learners from substantive cognitive offloading?

16 citations · 16 sources · 6 cross-references

Claim 1 disputed

Assessment policies can separate legitimate translation and grammar scaffolding from substantive cognitive offloading only by anchoring the distinction in two things: the construct a task claims to measure, and the direction of authorship. Assistance is legitimate when the learner originates the ideas, reasoning, evidence and organisation, and the tool renders, checks or clarifies their surface form. It becomes offloading when the tool supplies the content, the argument, or the very language competence the grade is meant to certify.

This principle has an awkward consequence that policies must state openly. Identical keystrokes can fall on either side of the line. Passing a paragraph drafted in Arabic or Mandarin through a translation engine is a reasonable accommodation in a first-year history seminar, where the outcome is historical argument. It is plain substitution in an English composition course whose outcome is the learner's own control of English syntax. It is something else again in a translation programme, where judging and correcting machine output may itself be the competence under assessment.

A policy that lists permitted and forbidden tools without naming the construct will therefore misclassify in both directions. It will penalise multilingual students for using aids that are irrelevant to what is being assessed, and it will permit offloading wherever the tool happens to be on an approved list. Roe, Perkins and Furze (2025) make this point in adapting the AI Assessment Scale to writing and translation in English as a Foreign Language. They note that formalised frameworks for integrating generative AI and AI literacy into EFL learning remain scarce. Their adaptation treats the permissible level of assistance as a property of the assignment's purpose rather than of the technology. The general logic of mapping assignments to scale levels is treated elsewhere (see Q307). Here the more specific task is to work out what the assessed construct implies when the learner's first language sits between their thinking and the submitted text.

The case for construct-based design over detection-based enforcement is strongest for multilingual learners, because the evidence against automated detection weighs most heavily on them. Liang and colleagues (2023) report that GPT detectors frequently misclassify non-native English writing as AI-generated. They warn that this bias risks marginalising non-native speakers in evaluative and educational settings. The mechanism is easy to grasp even without the technical details. The plainer, more formulaic and less lexically varied prose that many writers produce in an additional language resembles the statistical signature that detectors associate with machine text. The students most likely to rely on grammar scaffolding are therefore also the most likely to be falsely accused of using generative AI, whether or not they used it.

The broader reliability literature compounds the problem. Weber-Wulff and colleagues (2023) assessed detection tools for accuracy and error type and raised doubts about their general functionality. Elkhatat, Elsaid and Almeer (2023) ran tools from OpenAI, Writer, Copyleaks, GPTZero and CrossPlag on fifteen paragraphs each from ChatGPT 3.5 and 4 and on five human-written controls. This was a small, single-topic design that should not be over-generalised. Sadasivan and colleagues (2023) stress-tested detectors against an attacker and questioned whether reliable detection is achievable at all under adversarial conditions. Perkins and colleagues (2024) found a 17.4 per cent reduction in detector accuracy across 805 samples when simple manipulation techniques were applied, and drew out the implications for inclusive education explicitly.

Taken together, these studies show a striking asymmetry. Determined offloaders can evade detectors with modest effort, while learners whose natural prose looks machine-like stay exposed. A policy that leans on detection to police the line between scaffolding and offloading would invert its own purpose. It would catch the honest multilingual writer and miss the strategic one. The due-process consequences of acting on suspicion without reliable instruments are addressed separately (see Q312). The design consequence is that the distinction must be built into the task and its evidence trail rather than inferred from the finished text.

Once detection is set aside, the first operational test is construct relevance. Every assessment policy should ask whether linguistic accuracy in the language of instruction is a stated learning outcome of this task. Where it is not, as in most disciplinary coursework in science, business, engineering or the humanities, translation of the learner's own drafting and grammar correction of their own sentences are construct-irrelevant supports. They belong in the same family as spell-checkers and screen readers. Denying them introduces construct-irrelevant variance, because the grade then partly reflects English proficiency rather than disciplinary understanding. Rubric weightings should move accordingly, away from surface fluency that can now be produced at negligible cost (see Q309).

Where language competence is the outcome, the policy problem changes rather than disappears. The useful question is no longer whether a tool was used but in what sequence and for what cognitive purpose. Lee's (2019) study of EFL writing is instructive here. Instead of having students post-edit machine output, the dominant design in earlier work, Lee had students translate their own first-language writing into English without machine translation. Only then did they correct their English drafts using the machine translation as a point of comparison. In this arrangement the learner produces first and consults second, so the tool works as a mirror against which their own interlanguage is checked, not as a generator that replaces it. The study's own conclusions are best read as support for machine translation as a pedagogical tool under this structured design. They do not license unrestricted use.

The sequencing principle carries over into policy. Assistance that comes after a learner-generated attempt and prompts noticing and revision preserves the cognitive work that language assessment targets. Assistance that comes before any attempt removes it.

Translation education adds a third case, where using AI may itself be the competence. Yang and colleagues (2025) collected open-ended responses from 45 translation students. They found

perceptions organised around AI integration, preparedness and limitations, and students expected their training to incorporate these tools. In such programmes, judging, post-editing and critiquing machine output is a professional skill. A blanket prohibition would misdescribe the field, and the line falls between critical engagement with the output and uncritical acceptance of it.

The second operational test concerns where meaning originates, and here the classroom evidence is encouraging but thin. Burner and colleagues (2026) studied a real-time AI translation tool built into an interactive presentation platform in five Norwegian lower secondary schools. They combined survey data and system logs from 148 students with four focus groups involving 19 students. They report that the tool was beneficial for students overall and particularly for multilingual students. The finding matters for policy because the tool mediated access to curriculum content rather than producing assessed work. That is the clearest instance of legitimate scaffolding: it lowers the linguistic barrier to the thinking without doing the thinking.

Magwa's (2026) qualitative case study at Zimbabwe Open University frames AI as scaffolding for self-directed learning in open and distance settings. It suggests that learners and lecturers judge legitimacy partly by whether the tool supports or supplants the learner's own direction of study. These are perception data from a single institution. They do not show learning gains.

Cognitive load theory offers a vocabulary that policies could borrow, with caution. Scaffolding that reduces load from decoding an unfamiliar language can free capacity for the task's intrinsic demands, and offloading removes those intrinsic demands altogether. Sun and colleagues (2026) designed an explainable AI scaffolding system to address the high cognitive load bel canto students face when learning vocal works in several languages. Omeh (2026) compared students' cognitive load under AI-assisted and traditional assessment models in web design. Both studies show researchers treating load reduction as a design goal. Neither settles how to separate productive from counterproductive reductions in load in written assessment, and their domains are distant from academic writing.

The analogy with disability accommodation is more directly useful. Dang's (2026) scoping review maps AI-powered assistive technologies for disabled students in higher education, covering the tools in use, the benefits and barriers reported, and the gaps in research. Its framing treats assistive AI as a support for access rather than a threat to integrity. Policies for

multilingual learners could adopt the same logic: a support is legitimate when it removes a barrier unrelated to the outcome being certified.

In practice, verifying where meaning originates relies on process evidence rather than inspection of the product. Draft histories, first-language planning notes, annotated comparisons between the learner's version and the tool's suggestion, and brief reflective statements on which suggestions were accepted or rejected and why can all show that ideas preceded rendering. The broader evidential value of such telemetry and portfolios is examined elsewhere (see Q308). For multilingual learners specifically, policies should explicitly accept first-language drafts as valid process evidence instead of treating them as suspicious.

Turning these tests into institutional policy requires an architecture that is declared, tiered and equitable. Declaration means each assessment brief states its construct and the corresponding status of translation and grammar tools: unrestricted, restricted to the learner's own drafts, permitted only after an unaided attempt, or excluded because language production is the outcome. Students then disclose their use against that declared standard rather than against a vague general prohibition.

Tiering means institutions accept that one programme will contain assessments at different points on this range. Secure, supervised tasks verify unaided language competence where it truly matters. Open tasks permit scaffolding where it does not. This is the logic of a two-lane design applied to linguistic support (see Q304). Equity means supervised tasks must not quietly reintroduce the penalties that open tasks were designed to remove. That concern is especially acute in oral formats, where accent and fluency can be mistaken for understanding.

The policy landscape is not yet organised along these lines. Penev, Slavov and Deliyski (2026) map ethical guidelines that universities are beginning to formulate in response to generative AI. The concerns those guidelines address include academic integrity, bias, transparency, data protection, and the possible erosion of critical thinking and creativity. They also note the opportunities AI offers for accessibility. Bias and accessibility clearly sit alongside integrity on the agenda. How often guidelines address multilingual learners specifically, as distinct from listing bias in general terms, is a question their abstract does not settle.

Liu, Fang and Lan (2025) show through policy documents and 33 faculty interviews at Chinese research universities that national governance is interpreted and contested on campus rather than applied uniformly. Any institutional rule on translation tools will likewise be reinterpreted

by individual instructors. Clear construct statements at the level of each assessment are therefore more dependable than abstract institutional principles.

Zhao's (2024) argument that AI should prompt an end to the inherited grammar of schooling, in favour of student-driven personalised learning and problem-oriented pedagogy, poses a deeper challenge. If assessment centred on authentic problems that learners pursue in whatever languages serve them, much of the policing anxiety around translation would fall away. Zhao's essay is a reasoned argument rather than empirical evidence, however, and it does not tell institutions how to certify language proficiency where certification is required.

Several things remain unclear, and policies should be written with that uncertainty in view. First, the field lacks robust evidence on the boundary itself. Few studies have directly compared learning outcomes when multilingual students use translation for comprehension, for drafting from their first language, or for wholesale generation. The strongest supporting studies involve perceptions, structured classroom designs, or single contexts. Lee's sequenced design and the Norwegian findings suggest that tools which mediate access, or prompt comparison after an attempt, are beneficial. They do not demonstrate that unrestricted use is harmless, nor that restricted use preserves long-term language acquisition.

Second, the boundary is moving as the tools converge. General-purpose language models translate, polish, restructure and elaborate within a single interaction. A request to fix the grammar can return a reorganised argument the learner did not write, which blurs the distinction between surface rendering and substantive contribution in practice. Policies that rely on a tidy separation between grammar checking and content generation should expect more grey cases. They are better served by requiring students to keep their pre-assistance draft so the extent of change can be inspected.

Third, there is genuine disagreement about whether using AI in language courses erodes or reshapes competence. The translation students in Yang and colleagues' study expected AI to be part of their training, which reflects how practitioners in the field already see these tools. Whether the same holds for general EFL learners, whose goal is independent communicative control, has not been established.

What is established is narrower but decisive. Automated detection cannot reliably draw this line and is biased against the very learners at issue. A defensible policy must therefore define legitimacy by construct and authorship, verify it through process evidence and appropriately

supervised tasks, and accept first-language thinking as a resource rather than a red flag. The practical safeguards for multilingual students in synchronous oral settings are addressed separately (see Q306). The principle common to both settings is that a grade should certify the competence it names, and nothing that merely correlates with being a native speaker.

Q311 How do programmatic and longitudinal portfolio assessments prevent single-exam high-stakes distortion while verifying cumulative competency?

16 citations · 16 sources · 4 cross-references

Claim 1 disputed

Programmatic and longitudinal portfolio assessment prevents single-exam distortion by changing where a decision draws its evidence from. Instead of resting a high-stakes judgement

on one sitting, it aggregates many deliberately varied, individually low-stakes observations over time. Cumulative competency is then verified from the converging pattern of that evidence rather than from any single performance. The theoretical foundation is the argument of Van Der Vleuten and Schuwirth (2005) that assessment is not primarily a measurement problem but an instructional design problem, with educational, implementation and resource dimensions. Their utility model holds that reliability, validity and educational impact are not inherent qualities of any instrument. Choosing a method always involves context-dependent compromises, and the weight given to each characteristic shifts with purpose and setting. Their most consequential claim for this chapter is that reliability depends not on structuring or standardisation but on sampling.

That claim reverses the logic of the traditional terminal examination. A tightly standardised final test buys apparent rigour by controlling conditions. Yet it samples a narrow slice of tasks, contexts and moments, and so concentrates all decision risk in one event. If reliability is a function of sampling breadth, an assessment programme that gathers evidence across many tasks, assessors and occasions can reach defensible judgements even when each component is modest or unstandardised. Distortion falls for a structural reason. No single data point carries enough weight to reward gaming, cramming or outsourcing, and no single bad day can decide a learner's trajectory. Montebello (2026) explains why this matters more now than it did in 2005. Assessment has historically worked both as a measure and as a mechanism that implicitly enforced cognitive engagement. Generative AI decouples the two, because learners can now produce assessment outputs without engaging in the cognitive processes those outputs once signalled. An architecture that depends on one product at one moment is therefore exposed to exactly this decoupling.

Recent work on high-stakes examinations shows how fragile the single-event model has become. Koçak, Oğuz and Akçalı (2025) presented 240 questions from the Basic and Clinical Medical Sciences papers of the 2021 Turkish Medical Specialty Training Entrance Exam, in Turkish, to four large language models. They scored the responses against the official answers and also examined how interpretable the answers were for users. Motaghi Niko and colleagues (2026) tested GPT-3.5 on 195 multiple-choice questions from Iran's March 2022 national pre-internship examination, covering 23 specialties. They excluded items with visual content, posed each question in a fresh chat, and had 55 experts rate the responses on a five-point scale against the official key. Such studies document that national, multi-disciplinary selection examinations

are now routinely used as benchmarks for machine performance. Precise accuracy levels vary by model, language and item type and should be read in the original reports. The implication is that a closed-format, single-sitting test increasingly measures something a machine can also produce, at least where conditions are not invigilated.

A second form of distortion predates AI: construct under-representation. Mirsanjari (2025) notes that Iran's Konkur university entrance examination assesses English proficiency solely through multiple-choice items and neglects writing and speaking despite their academic importance. That study compared AI-assisted language assessment through DeepSeek with traditional instructor-led assessment over 12 weeks. It involved 120 intermediate learners at CEFR B1–B2 levels, divided equally into experimental and control groups who completed identical essay and oral tasks. Its focus on motivation and anxiety alongside proficiency reflects a recognised concern that high-stakes formats shape affect as well as scores. When a single gatekeeping instrument omits whole domains of competence, teaching and learning narrow towards what it measures. Kaldaras, Akaeze and Reckase (2024) place the generative AI moment within a wider movement away from memorisation-based systems and towards assessing learners' ability to apply knowledge to real-world problems and explain phenomena. Programmatic assessment answers both problems together. It widens the construct by sampling performance types a single test cannot hold, and it lowers the stakes of any one occasion so that narrowing no longer pays.

The verification of cumulative competency depends on how a portfolio is constructed, not merely on its length. A defensible longitudinal portfolio has three properties. It samples across task types, contexts and assessors, so that judgements generalise. It records performance over time, so that growth, plateaus and regressions become visible. And it separates the low-stakes function of individual data points, which is to generate feedback, from the high-stakes function of the aggregate, which is to support a progression decision. This last separation follows from Van Der Vleuten and Schuwirth's (2005) insistence that educational impact is a design property. Feedback-rich components help learning when learners can engage with them honestly, and that honesty is easier when no single component determines their future.

Longitudinal research on AI use supports the temporal logic, although indirectly. Polyportis (2024) argues that measuring students' ChatGPT usage at one moment, though useful, misses the temporal dynamics of adoption, and that behaviour change must be tracked over time. Melanou, Beege and Kimmig (2026) followed students through an entire semester. They

examined how generative AI related to knowledge gain, motivation, cognitive load, critical thinking and reflective use, and whether prior knowledge and AI experience moderated these effects. They framed the moderation question explicitly around possible Matthew effects, in which advantaged learners benefit disproportionately. Neither study evaluates portfolio assessment as such. Both show, however, that learning and tool use unfold dynamically across a term, which a cross-sectional snapshot cannot capture. A portfolio that samples repeatedly can detect divergence between learners whose understanding deepens alongside AI use and those whose outputs improve while their underlying engagement does not. This is the divergence Montebello (2026) identifies as the defining risk of the post-detection era.

Process evidence is what makes such divergence legible. Version histories, revision replays and reflective prompt logs supply the within-task trail (see Q308). Periodic oral defences supply direct, hard-to-delegate checks on whether submitted work reflects the learner's own reasoning (see Q305). Within a programme, these serve as calibration points rather than as stand-alone gates.

Translating these principles into institutional practice requires curricular, not merely course-level, design. Cole and colleagues (2026) observe that AI education in undergraduate medical education remains fragmented, largely confined to electives or isolated workshops. They argue this leaves future military medical officers underprepared, and they respond by proposing a longitudinal framework that embeds AI competencies across the curriculum. The structural point extends beyond their domain. Competencies developed episodically are hard to verify cumulatively, because there is no continuous thread of evidence to aggregate. A programmatic portfolio presupposes a programmatic curriculum, in which outcomes recur, deepen and are reassessed in progressively more authentic settings.

High-stakes professional fields also face external constraints that shape what a programme can look like. Alturkistani and Almalki (2026) note that healthcare e-learning must at once be evidence-based, acceptable to regulators, clinically credible and delivered on time. They argue that established instructional design models such as ADDIE, the Successive Approximation Model, Dick and Carey, and Kemp were not built for these combined demands, and that these models predate routine AI use in content production. Their proposed methodology concerns instructional design rather than assessment. Still, the tension they describe applies directly to programmatic assessment, where regulators often expect a visible, standardised gate. Van Der Vleuten and Schuwirth's (2005) utility model offers a principled reply. Standardisation is one

way to pursue reliability, not the only way, and broad sampling with transparent aggregation rules can meet accountability demands while sparing learners the distortions of the single gate. Many institutions are moving towards secured assurance points used alongside open, AI-permissive learning activities (see Q304). A longitudinal portfolio is the natural container that links those secured points into a cumulative judgement.

Implementation depends heavily on staff capability. Ren and Wu (2025) conducted a systematic review of AI integration competencies from an intelligent TPACK perspective. They found that instructors lack guidelines, policies and resources for integrating AI efficiently and ethically. Programmatic assessment asks more of educators than setting a final paper does. They must write narrative feedback, sit on progress committees, and make holistic judgements across heterogeneous evidence. Without investment in these competencies, portfolios risk becoming archives that are filed but never interpreted.

The main practical objection to programmatic assessment has always been workload. Many observations mean many judgements, and constructed responses are expensive to score. AI-assisted scoring is increasingly proposed as the answer, and the evidence here is genuinely mixed in scope. Terrazas-Arellanes and colleagues (2025) frame the problem precisely. Multidimensional, phenomenon-based science instruction needs constructed-response assessments that probe explanation and problem-solving, and these are time-consuming and labour-intensive for teachers to score. Their response was a machine-learning system for scoring performance-based science assessments in upper elementary classrooms, designed to promote agency among teachers and students. Twabu and Nakene-Mginqi (2024) used an iterative design-thinking approach to prototype an AI-driven auto-marking system for practical assessments at an online distance-learning institution in South Africa, with the explicit aim of reducing lecturer workload and providing accurate feedback. Cvengros and Kortemeyer (2026) compared AI-assigned and human scores on a handwritten general chemistry examination. Their material included reaction equations, open-ended answers, symbolic derivations and pencil sketches, and was uploaded as images with the grading rubrics. On the design side, Lee (2025) tested whether ChatGPT could produce valid formative quiz questions from TED Talk transcripts for preparatory students, using prompts that ranged from very basic to progressively more detailed and contextualised.

Together these studies suggest that AI may lower the marginal cost of generating and scoring the frequent, low-stakes items that give a programme its sampling density. They do not show

that machine scoring is suitable for aggregate progression decisions. Kaldaras, Akaeze and Reckase (2024) warn that generative AI tools carry social biases inherited from their training data, and that validity must be established rather than assumed. A sensible division of labour follows. Automated scoring and item generation can support the many formative data points, while human panels interpret the aggregate. This keeps the high-stakes judgement with accountable people and lets the machine handle volume. Whether such hybrid systems keep their reliability across diverse learner populations remains unclear.

Several limits deserve plain acknowledgement. First, the core claim that aggregating many observations reduces distortion rests on a strong theoretical case about sampling and reliability (Van Der Vleuten and Schuwirth, 2005). Few studies, however, have directly compared programmatic and single-exam regimes on gaming, outsourcing or strategic narrowing under generative AI conditions. The longitudinal AI studies cited above examine learning dynamics and adoption, not assessment architecture, so their bearing on portfolio validity is inferential.

Second, distributing stakes can slide into continuous surveillance. If every artefact is scrutinised for authenticity, the low-stakes promise collapses and the programme reproduces high-stakes pressure across a whole term. Maheux and Maes (2026) emphasise that adolescence is a sensitive period in which autonomy, emotion regulation, social belonging and identity formation carry lifelong consequences, and that generative AI is changing the context of that development. For secondary-school learners especially, an assessment regime that treats every interaction as evidence may encroach on the space in which autonomy develops. Institutions also need clear, fair procedures for cases where portfolio patterns raise concerns about undisclosed AI use, rather than informal suspicion (see Q312).

Third, longitudinal designs may widen inequalities they were meant to correct. The Matthew-effect question that Melanou, Beege and Kimmig (2026) posed about generative AI applies equally to portfolios. Learners with more prior knowledge, more time or more fluent AI use may build richer evidence trails. Portfolio expectations should therefore be scaffolded and explicit, not left as tacit cultural capital.

The defensible position is therefore qualified. Programmatic, longitudinal portfolios are the most coherent available answer to single-exam distortion, because they align evidence collection with how competence actually develops and with how reliability is actually achieved. As Montebello (2026) argues, they matter in this era because they can restore a

visible link between performance and cognitive engagement. Their effectiveness, however, depends on curricular integration, assessor capability, proportionate use of automation, and deliberate protection of learner autonomy. The empirical case that they outperform terminal examinations under generative AI conditions is still being built.

Q312 What due-process protocol should institutions follow when an instructor suspects undisclosed AI use in the absence of reliable automated detectors?

11 citations · 11 sources · 4 cross-references

Claim 1 disputed

Institutions should treat a suspicion of undisclosed AI use as the start of an inquiry, not its conclusion. A sound protocol has five elements. First, it requires a documented, articulable

basis for concern that does not rest on a detector score. Second, it gives the student written notice and a genuine opportunity to demonstrate authorship through process evidence and conversation. Third, it separates the person who raises the concern from the person who decides it. Fourth, it applies an explicit standard of proof with proportionate outcomes. Fifth, it guarantees appeal and an institutional audit of how cases are distributed.

The case for excluding automated detectors as a decisive element is well grounded. Weber-Wulff and colleagues (2023) evaluated detection tools on both accuracy and error type. That framing matters for anyone imposing sanctions, because the question is not only whether tools find AI text but what kinds of mistakes they make. Elkhatat, Elsaid and Almeer (2023) tested tools from OpenAI, Writer, Copyleaks, GPTZero and CrossPlag. Their sample was fifteen paragraphs each from ChatGPT 3.5 and 4 on cooling towers, with five human-written controls, which shows how narrow the evidentiary base for such tools has been. A test set of that size cannot establish how a tool behaves across disciplines, genres, proficiency levels or the revised and blended texts students actually submit.

Adversarial work sharpens the concern. Sadasivan and colleagues (2023) stress-tested detectors against an attacker. Perkins and colleagues (2024) examined six major detectors across 805 samples and reported a 17.4% reduction in accuracy when machine-generated content was altered by simple techniques. The resulting asymmetry is troubling for due process. Students who deliberately evade detection are the least likely to be flagged, while flags may fall on honest writers whose style happens to resemble model output. Liang and colleagues (2023) found that detectors frequently misclassify non-native English writing as AI generated, which turns a technical error into a fairness problem borne by an identifiable group.

Taken together, this evidence demonstrates that detector output cannot carry the weight of an accusation. It does not establish that every tool fails in every setting, and performance may change. A due-process protocol, however, must be built for the error rates and biases already documented, not for those vendors hope to achieve. Procedures should also be reviewed whenever new independent evaluations appear.

The first procedural stage is defining reasonable grounds. Instructor intuition is a legitimate trigger for inquiry. Typical prompts include a sudden shift in voice, unusual fluency, generic argument or citations that cannot be located. Intuition is not evidence, however, and the protocol should require the instructor to write down what prompted concern before contacting

the student. This discipline forces a distinction between observable features and impressionistic ones. A nonexistent reference or a response that ignores the assigned material is observable; prose that "sounds like ChatGPT" is impressionistic. The written note also creates a record against which later judgements can be checked.

Cotton, Cotton and Shipway (2023) stress how difficult it is to detect and prevent dishonesty with these tools. The procedural implication is that stylistic resemblance alone should rarely suffice. Polished, formulaic prose is also what many students are taught to produce, and what grammar and translation aids legitimately help multilingual writers achieve (see Q310). Given the findings of Liang and colleagues (2023), stylistic markers associated with non-native writing should be explicitly excluded as grounds.

Stronger evidence bears on process and comprehension rather than surface features. Examples include fabricated or misattributed sources, content inconsistent with what was taught, discrepancies with the student's supervised work, and the presence or absence of drafts, notes and version histories. Even these are probabilistic. A missing draft history may reflect working habits rather than misconduct. A mismatch with in-class writing may reflect time pressure or anxiety. For this reason no single indicator should be treated as sufficient, and the written note should record innocent explanations the instructor has considered alongside the suspicious features.

The underlying problem of verifying authorship is not new. Bretag and colleagues (2018) surveyed 14,086 students across eight Australian universities about outsourcing assessments to third parties and the contextual factors that may influence it. Contract cheating long ago confronted institutions with work whose text revealed nothing about its origin. Generative AI generalises that problem rather than inventing it. Procedures centred on a student's ability to explain and extend their own work are therefore a better inheritance than plagiarism procedures built on text matching. Institutions should specify in advance which evidence types may initiate a case, which may support a finding, and which are prohibited.

The second stage is notice followed by a structured authorship conversation. Before any meeting, the student should receive written notice stating the specific concern, the evidence relied upon, the possible outcomes and their right to a support person, with reasonable time to prepare. The meeting should be framed as an opportunity to demonstrate understanding rather

than as an interrogation designed to elicit confession. The student might explain choices, walk through sources, extend an argument orally, or produce notes and drafts.

Students' own accounts show why framing matters. Gorichanaz (2023) analysed 49 Reddit posts and discussions from December 2022 to June 2023 in which students described being accused of using ChatGPT, often asserting that the accusations were false. Five themes emerged: a legalistic stance built on argumentation and evidence; higher education's role as a societal gatekeeper; shifting trust in students versus technology; uncertainty about what constitutes cheating; and the need to rethink assessment.

The legalistic stance is telling. When students experience accusation as arbitrary, they litigate, assembling timestamps and contesting procedure, and a pedagogical relationship becomes adversarial. A transparent protocol can partly pre-empt this by granting the guarantees students would otherwise have to demand. These data are self-selected online testimony and cannot indicate how often false accusations occur, but they capture the experience institutions must design against.

Authorship conversations carry their own risks. Oral performance is affected by language proficiency, anxiety, disability and cultural norms about challenging authority, so a halting explanation is not proof of non-authorship. Reasonable adjustments should be available, and questions should probe substance rather than fluency. Questions should be prepared in advance and recorded, and the student should be able to respond in writing afterwards. The record protects both parties: it lets the student show what was actually asked, and it lets a later decision-maker judge whether the conversation tested understanding fairly.

Trust runs both ways in this encounter. Baldus (2026) surveyed 340 students and seven instructors across ten sections of a marketing course. The study treated instructor AI use as a service encounter in which students judge trust, effort and role performance. It concerns instructors' rather than students' AI use, but it suggests students attend to how AI norms are applied. A regime that demands disclosure from students while staff use AI opaquely may struggle for legitimacy.

The third stage is adjudication by someone other than the accusing instructor. Separating these roles is the core protection against confirmation bias, because the person who formed the suspicion is poorly placed to weigh the student's explanation neutrally. Where capacity for a panel is lacking, a trained integrity officer or a colleague from another course can review the

written grounds, the student's response and the conversation record. The decision-maker should apply a standard of proof stated in advance and give written reasons identifying which evidence was decisive. Any detector score in the file should be recorded as having been given no weight.

Many cases turn less on what happened than on what the rules were. Gorichanaz (2023) found uncertainty about what constitutes cheating among students' recurring themes. Cotton, Cotton and Shipway (2023) set ChatGPT's benefits for engagement and accessibility against its risks for honesty, a duality that blurs boundaries. If an assignment's AI policy was absent, ambiguous or inconsistent with neighbouring courses, the appropriate finding may be a policy failure rather than misconduct. The response should then be educational, such as clarification and resubmission. The decision-maker should therefore establish what the student was told about permitted AI use before considering whether a breach occurred.

Proportionality follows from this. Undisclosed use for language polishing may fall within accepted assistive practice for multilingual learners and usually warrants guidance. Substituting generated text for the intellectual work being assessed may warrant academic penalty. Where evidence is inconclusive, the default should favour the student. That default is not leniency for its own sake; it reflects the fact that a wrongful finding can damage a transcript, a visa or a professional registration in ways that are difficult to reverse.

Practice is genuinely divided on one point. Some institutions treat a supervised reassessment as a neutral way to resolve doubt. Others regard it as a de facto penalty imposed without a finding. Few studies have examined how students experience such outcomes, and their fairness remains unclear.

Equity monitoring should accompany every decision. Detectors are documented to be biased against non-native writers (Liang et al., 2023), and the same stylistic cues that mislead software may mislead human judges.

The fourth stage is appeal and institutional oversight. Students should be able to appeal on procedural grounds, new evidence or disproportionate outcome to a body independent of the original decision. Beyond individual cases, institutions should keep anonymised records of every allegation, including those ending without a finding. These records allow audit of whether concerns cluster among international students, particular disciplines or particular instructors, and whether outcomes differ by group. Without such records an institution cannot know whether its protocol is fair, only that it exists.

There is a deeper institutional reason for this investment. Frimpong (2025) proposes that institutions founded on assumptions of procedural oversight and human cognitive authority may become epistemically misaligned with AI-driven environments. On this view the risk is not mere disruption but invalidation. The theory is conceptual rather than empirically tested. It nonetheless names what is at stake when universities sanction students on grounds neither party can verify: the credibility of judgement itself. Gorichanaz's (2023) gatekeeping theme points the same way, since gatekeeping is more readily accepted when its operation is legible.

Feasibility also matters. Lakhno (2026) conducted a PRISMA-guided review covering 2022 to 2024, framed by diffusion-of-innovations theory. The review argues that debates on AI in higher education are dominated by high-income contexts that assume institutional capacity and robust infrastructure. A model presuming integrity officers, digital version histories and recorded meetings may be unrealistic elsewhere. Where staff are few and connectivity is unreliable, procedural guarantees that depend on platforms or specialist roles may simply not be delivered, leaving students with less protection than a simpler model would provide.

The minimum standard requires people and time rather than technology. It consists of written grounds, notice, an opportunity to respond, a separate decision-maker and a route of appeal. Protocols should be specified at that minimum, with richer elements treated as enhancements rather than preconditions.

The final element sits outside the disciplinary process: reducing how many cases depend on retrospective judgement at all. Every safeguard described here is costly. Post-hoc adjudication becomes harder to sustain as generative tools improve and, as Perkins and colleagues (2024) show, as simple manipulation techniques degrade detector accuracy.

Assessment architecture can build authorship evidence into the task itself. Staged submissions, process documentation, in-class components and oral defences can be planned for all students rather than imposed on the suspected few. Done this way, the authorship conversation becomes routine practice rather than accusation. It also spreads the burden of demonstrating authorship evenly, so that no student is singled out because of how their prose happens to read. Rubrics that reward reasoning, judgement and engagement with specific materials over fluent prose (see Q309) narrow the gap between what AI produces and what earns credit. Longitudinal portfolios (see Q311) supply a baseline against which anomalies can be interpreted fairly. Cotton, Cotton and Shipway (2023) urge universities to pursue strategies for ethical and responsible use.

Students in Gorichanaz's (2023) data themselves called for rethinking assessment. Bretag and colleagues' (2018) attention to contextual factors in outsourcing is a reminder that integrity is partly a property of the learning environment.

What the evidence does not yet show is considerable. Few studies have evaluated due-process protocols for suspected AI use directly. We do not know how often authorship conversations reach correct conclusions, whether separating roles changes outcomes, or how procedural design shapes students' sense of fairness. How students actually use these tools when unsupervised also differs from what they report (see Q052), which complicates any estimate of how many suspicions are warranted.

The protocol recommended here therefore rests on two foundations: the established unreliability and bias of detection, and general principles of fair process. Its specific components should be treated as emerging practice to be evaluated, not settled doctrine.

Q051 What does current peer-reviewed evidence show about the effects of AI tutoring systems on learning outcomes, and how strong is that evidence?

20 citations · 20 sources · 5 cross-references

Claim 1 disputed

Current peer-reviewed evidence shows that AI tutoring systems can improve learning outcomes, sometimes substantially. The strength of that evidence depends heavily on which generation of technology is being evaluated. For rule-based intelligent tutoring systems, the evidence is comparatively well established. For tutors built on large language models, it is promising but thin, recent and methodologically uneven. As of mid-2026, the most defensible summary is that the evidence is encouraging yet still maturing. Two forces cut across both strands. The first is the way outcomes are measured. The second is the way the tutor is designed to help.

This is one of the most consequential questions in contemporary education research. Answering it requires keeping two literatures apart. The older literature evaluates systems that model a domain and a learner explicitly and deliver scripted hints and feedback. These systems have accumulated decades of controlled evaluation and several meta-analyses. The newer literature concerns generative AI. Here a handful of rigorous trials sit alongside a far larger volume of descriptive, small-sample and satisfaction-based studies, and public claims have often run ahead of the data. Treating the two as a single body of evidence would overstate what is known about the systems most schools and universities are now adopting. It would also understate what is known about their predecessors.

The older, pre-generative strand of evidence is the firmest ground in the field. Kulik and Fletcher's (2016) meta-analysis of 50 controlled evaluations of intelligent tutoring systems found a median effect size of 0.66 standard deviations over conventional instruction. That is

roughly equivalent to moving a typical student from the 50th to the 75th percentile. Positive effects appeared at every level of education and in nearly all subject domains evaluated. The pattern held after the authors accounted for potential publication bias. By the standards of educational research, where effects above about 0.4 are generally regarded as substantive, these are meaningful numbers. An earlier meta-analysis by Ma, Adesope and colleagues (2014) reached broadly consistent conclusions about the positive association between intelligent tutoring and learning outcomes. Taken together, these syntheses demonstrate that well-engineered adaptive tutoring can outperform conventional instruction under controlled conditions.

The same body of work also contains its most important qualification. In Kulik and Fletcher's synthesis, the size of the improvement depended heavily on whether outcomes were measured with locally developed tests or standardized ones. This suggests that close alignment between test content and the tutor's instructional objectives is a critical driver of reported gains. Effects measured on instruments written by the system's developers are likely to be larger than effects on independent, broad-based assessments. Any headline figure should therefore be read alongside the type of test that produced it.

The research base has also grown rapidly. A bibliometric analysis by Kuncoro and colleagues (2026) identified 237 peer-reviewed articles and conference papers on AI and intelligent tutoring in mathematics education indexed in Scopus between 2001 and 2025. Output grew slowly in the early 2000s and increased markedly after 2019, in step with interest in machine learning and large language models. Growth in output, however, is not growth in evidence. Much of the recent surge concerns systems whose effects have not yet been tested with the rigour applied to earlier tutors.

The newer wave of research concerns tutors built on large language models rather than rule-based logic. Here the evidence base is thinner but expanding quickly. A Brookings review of the field cautions that many claims about the educational benefits of generative AI have outpaced high-quality evidence. The same review notes that a number of recent rigorous studies suggest such tutors can deliver learning gains and may offer a path to individualized education at scale.

The most cited of these is a 2025 randomized controlled trial by researchers at Harvard, published in Scientific Reports. It compared college students' learning when content was

delivered through a research-designed AI tutor with learning in an in-class active-learning session. Active learning is itself a demanding comparison condition. Students learned significantly more in less time with the AI tutor, and they also reported feeling more engaged and motivated.

A separate exploratory randomized trial in UK secondary mathematics classrooms is registered in the American Economic Association's registry. In that trial, an AI tutor was integrated into a mathematics platform and supervised by human tutors. It produced a 5.5 percentage-point increase in students' likelihood of correctly answering novel questions. The human supervision matters here, because the result describes a hybrid arrangement rather than an autonomous machine.

Supporting evidence comes from adjacent syntheses. Zhang and colleagues (2025) conducted a meta-analysis of emotional AI in education. It drew on 172 articles published between 2000 and 2025, of which 54 studies reported in 49 articles quantified effects on cognitive and emotional outcomes. Systems integrating cognitive and emotional support showed a large effect on knowledge acquisition ($g = 0.88$). The authors are candid about the limits of their analysis. They did not run formal asymmetry tests for outcomes with fewer than 20 studies. For affective outcomes ($k = 31$), Egger's test indicated asymmetry, which signals possible publication bias. These findings suggest that tutors attending to both understanding and emotion may be especially effective, but they fall short of demonstrating it (see Q059).

These results are encouraging, but they rest on a small number of trials, often short in duration and conducted in single institutions or single subjects. Whether the gains persist, transfer across domains and survive deployment without researcher involvement remains unclear.

The picture is not uniformly positive, and the most important caveat comes from a large-scale field experiment by Bastani and colleagues (2025), published in PNAS. The study examined GPT-4's effect on high school mathematics learning. AI-based tutoring improved performance during practice sessions. Students who had relied on the technology, however, tended to underperform once AI access was removed, which indicates reduced independent skill acquisition. The remedy the researchers identified was deliberate design. Carefully designed safeguards mitigated the negative effects, especially instructing the AI tutor to offer teacher-designed hints rather than give away answers. The headline lesson is that the same underlying

model can help or harm depending on how it is constrained. It is a mistake to read the study simply as "AI harms learning."

This finding is echoed elsewhere, though the wider evidence is more mixed in quality. A 2025 literature review in the National High School Journal of Science notes studies indicating that over-reliance on AI hints can worsen outcomes. It also cites a systematic review by Zhai and colleagues (2024) that associated regular use of AI dialogue and tutoring systems with a decline in students' cognitive abilities and a greater tendency toward cognitive offloading. That evidence is associational. It shows that heavy use and weaker cognitive performance co-occur, not that one causes the other.

Fan and colleagues (2024) add experimental texture from writing. They conducted a randomized study with 117 university students who completed a writing task under one of four conditions: support from ChatGPT, chat with a human expert, writing analytics tools, or no additional tool. The researchers collected multi-channel data on motivation, self-regulated learning processes and performance. Their warning against "metacognitive laziness" names a plausible mechanism for the PNAS pattern: learners may hand over the monitoring and regulation of their own work to the tool.

The theoretical scaffolding for studying such effects is still underdeveloped. Banihashem and colleagues (2025) mapped 84 studies at the intersection of AI and self-regulated learning. They found that the research concentrated on metacognitive and cognitive aspects of self-regulation, with motivation underexplored. Over one-third of the studies did not specify a self-regulated learning theory. The mechanisms by which AI assistance supports or erodes durable learning are therefore not yet well characterised (see Q053).

The positive trials and the offloading evidence do not contradict each other so much as describe different designs and different outcome windows. Still, credible sources currently disagree about how large and how common the risk of dependence is.

Beyond individual trials, the reviews paint a consistent picture of a literature with significant methodological gaps. A 2025 systematic review of AI-driven intelligent tutoring in K-12 education, published in npj Science of Learning, offers a useful summary for younger learners. Effects on learning and performance are generally positive, but they shrink when the comparison is a non-intelligent tutoring system rather than conventional instruction. Longer interventions and more diverse samples are needed. The point about comparison conditions is

significant. Some of the apparent advantage of AI tutors may reflect the benefits of structured digital practice in general rather than anything specifically intelligent.

The same weakness recurs across the wider literature. Empirical evidence remains scarce. Many published evaluations rely on user satisfaction or short laboratory tasks rather than field experiments with validated learning measures.

Professional education shows the problem starkly. Dicheva and colleagues (2026) conducted a scoping review of intelligent tutoring systems in nursing education. Of 881 records retrieved, only 9 studies met inclusion criteria. Most of those described incomplete system architectures, and there was limited evidence of user-needs evaluation, theoretical framing, empirical validation or curricular integration. The authors concluded that the evidence is limited and inconsistent. Shaw, Henning and Webster (2025) reviewed 42 peer-reviewed articles on AI in medical education published between 2010 and 2022. They found promising early applications in surgical simulation and interactive learning, but evidence on educational and clinical outcomes remained limited, and they called for validated outcomes in larger trials. Gordon and colleagues' (2024) BEME scoping review synthesised 278 medical-education publications, including perspective pieces as well as original studies. About 68 percent of those publications came from North America and Europe, which illustrates both the volume of commentary and its geographic concentration.

Reviews of reviews reach similar verdicts. Mustafa and colleagues (2024) synthesised 143 literature reviews on AI in education. They found the research dominated by work from China and the United States and concentrated on higher education, with special education receiving little attention. Bond and colleagues (2024) analysed 66 secondary reviews of AI in higher education and explicitly called for greater ethics, collaboration and rigour. The volume of syntheses now far exceeds the number of well-powered experiments they can draw upon. This is one reason several confident generalisations about AI tutoring deserve scepticism (see Q060).

Three conclusions emerge from this body of work.

First, well-designed AI tutoring systems can produce real academic gains. This holds particularly for systems that adapt to the learner, provide formative feedback and resist simply handing over answers, and especially in structured domains such as mathematics and science. For rule-based tutors this conclusion is established. For generative tutors it is suggested by a

few strong trials rather than demonstrated across settings. Awang, Yusop and Danaee's (2025) systematic review of AI in mathematics education distinguishes two kinds of tool. Some narrowly solve problems, such as solving equations or visualising geometry. Others offer broader pedagogical support through adaptive systems and generative platforms. The tutoring evidence reviewed here mostly concerns the second kind. Results for the first kind should not be extrapolated from it.

Second, design choices matter enormously. Safeguards that constrain how the AI assists are not merely a safety feature but a pedagogical necessity. They are needed to ensure that human learning is preserved rather than displaced. The gap between a well-designed AI tutor and an unconstrained language model is not cosmetic. It may determine whether the technology helps students learn or merely helps them complete tasks.

Third, implementation and equity shape outcomes as much as the software does. Sevilla and colleagues (2025) argue that the impact of computer-assisted learning and AI-guided tutors depends less on access to devices than on integration into teaching: curriculum alignment, teacher training and interactive design that promotes active learning. Their new evidence from Italy shows persistent digital divides in AI adoption across schools and regions, reflecting broader social and economic disparities. Without careful implementation, these tools risk widening the very gaps they are promoted to close.

The priorities for the next generation of research follow from these conclusions. Studies should run longer, test retention after AI access is withdrawn, use comparison conditions that isolate the contribution of the AI itself, and rely on independent standardized assessments. Until such studies accumulate, institutions should treat the strongest generative-AI results as proof that benefits are possible. They should not treat them as guarantees of what any particular product will deliver.

Q171 How is AI being used in multilingual and newcomer classrooms, and with what measured results?

14 citations · 14 sources · 5 cross-references

Claim 1 emerging

AI is being used in multilingual and newcomer classrooms in three main ways: real-time translation and interpretation, automated translation of instructional and family-facing materials, and AI-mediated language practice and feedback. The measured results are mixed. The evidence suggests clear gains in access, inclusion and teacher workload, alongside documented risks of overdependence, reduced productive language output, and algorithmic bias against writers who are not native speakers.

The weight of these findings is uneven. Studies of student attitudes and of structured training are reasonably consistent. Studies of learning outcomes over time are few, short and often reliant on self-report. The most rigorous work on harm concerns assessment rather than instruction. Any account of results therefore has to distinguish what has been measured from what schools and vendors have merely reported.

The scale of the need explains why adoption has outpaced evidence. EdSurge's November 2025 reporting on district practice notes that more than 5.3 million students in the United States are classified as English language learners. The same report states that roughly 71% of them do not reach reading proficiency by fourth grade, compared with 31% of their non-ELL peers. These figures come from journalistic coverage rather than a peer-reviewed study, but they are consistent with the pressure practitioners describe.

Multilingual classrooms in many OECD countries face comparable demands. Newcomer students are expected to access grade-level content while still acquiring the language of instruction, often in schools with few bilingual staff and little budget for professional interpreters. This is the context in which schools have turned to AI tools, frequently with limited evidence and under pressure to respond quickly.

It is also why the question of results cannot be separated from the alternatives actually available to a given school. Where the realistic counterfactual is no translation at all, even imperfect machine output may represent a gain in access. Where the counterfactual is a trained bilingual aide, the same tool may represent a loss.

The most visible use is real-time translation. EdSurge's June and November 2025 accounts of schools working with emergent bilingual students describe handheld AI interpretation devices, such as those sold by Pocketalk and Timekettle. Schools deploy these alongside browser extensions and translation built into learning platforms, so that newcomers can follow lessons, take part in group work and communicate with teachers and classmates as events unfold. The June report emphasises student voice: learners who had been silent for weeks could ask questions and contribute ideas.

The most systematic recent study of this kind of use comes from Norway. Burner, Lindvig, Steimler and colleagues (2026) examined lower secondary students' use of a real-time translation tool embedded in an interactive presentation platform developed by Learnlab, which combines a version of ChatGPT fine-tuned to the Norwegian curriculum with the Learnlab AI Translator. Drawing on survey data and system logs from 148 students and on four focus-group interviews with 19 students across five schools, the authors found the tool beneficial for students overall and particularly for multilingual students. The design is significant. Translation was not delivered through a separate device but built into the shared lesson display, so a newcomer could read the same content as classmates, in a stronger language, at the moment it was presented.

The study's mixed-methods design, which pairs usage logs with self-report, gives it more weight than journalistic accounts. It nonetheless measures use and perceived benefit rather than attainment or language acquisition, and it cannot say whether students who leaned most heavily on translation developed Norwegian more slowly or more quickly than those who did not.

The practitioner accounts point in the same direction while adding texture that survey data cannot. The EdSurge reporting presents real-time interpretation as a bridge into participation rather than a substitute for language instruction, and it describes teachers who treat the devices as one support among several. Neither the journalism nor the Norwegian study quantifies how often translation errors occur in live classroom speech, how they vary across languages, or

what they cost in comprehension. Those gaps matter most for newcomers who speak lower-resourced languages, for whom commercial systems are typically least accurate.

Beyond live interpretation, schools use machine translation to convert worksheets, reading passages, assessments and family communications, and students use it independently for homework and writing. Here the research base is older and larger, though it comes mostly from foreign language and higher education settings rather than newcomer programmes in schools.

A systematic review of student and teacher perspectives on machine translation in education finds a consistent split. Students generally view the tools favourably, valuing faster comprehension, help with vocabulary and reduced anxiety when facing unfamiliar texts. Teachers are more ambivalent. They acknowledge the access benefits but worry about overreliance, about students submitting translated work as their own, and about learners skipping the effortful processing through which language is acquired. The review also notes that most included studies rely on questionnaires and interviews, so the consensus it reports concerns attitudes rather than measured learning.

Work on machine translation and foreign language education frames the issue pedagogically rather than as a question of permission. Its central argument is that translation tools change what language learning tasks demand. A task that once required students to produce a sentence may now require them to evaluate, correct or compare machine output instead. That can support metalinguistic awareness when teachers design for it, but it can also reduce the volume of productive output, especially writing and unscripted speech, if the tool simply replaces the student's attempt. This is the mechanism behind the concern, noted at the outset, that AI may reduce productive language output among learners who most need practice.

Teachers' responses to these tensions are now being studied directly. Ayesha (2026) examined how Saudi TESOL teachers in English for Academic Purposes classrooms reconcile generative AI with academic integrity and critical thinking. The setting is university writing rather than school newcomer programmes, but the strategies described, including redesigning tasks so that reasoning and drafting are visible and setting explicit expectations about acceptable AI use, mirror the dilemmas school teachers report with translation tools. The study documents strategies and teacher perceptions; it does not test whether those strategies change student outcomes.

The third strand involves AI used not to bypass the language barrier but to help students cross it, through conversational practice, automated writing feedback and adaptive tutoring. Empirical work on AI feedback in English language learning reports generally positive effects on writing accuracy and on learner engagement, particularly for surface features such as grammar, vocabulary and mechanics. The same body of evidence is weaker on higher-order features such as argument and organisation, and many studies are short interventions with small samples, often in university English-as-a-foreign-language courses. Few track whether gains persist once the feedback is withdrawn, which is the result that matters most for newcomer students expected to write independently in content classes.

Adjacent classroom research offers clues about design rather than direct evidence about multilingual learners. Billings and Chang (2024) used natural language processing to identify the ideas in grade 7 students' science explanations, then formed discussion groups that maximised the variety of ideas among participants and supported their chat with prompts grounded in Knowledge Integration pedagogy. Comparing these groups with randomly formed ones across two classrooms, the work illustrates how AI can structure peer talk around students' own reasoning. For multilingual classrooms the implication is plausible but untested: tools that organise discussion around content ideas might give language learners more meaningful opportunities to speak than tools that simply translate what others say.

Omar and Daher (2025) examined academic emotions among 92 eighth-grade algebra students in Nablus, comparing an experimental group using the AI-powered CK-12 Flexi application with a control group taught by traditional methods. Emotional responses to learning, such as anxiety, enjoyment and frustration, are especially relevant for newcomers, who often experience high stress when working in an unfamiliar language. The study did not focus on multilingual learners and used convenience sampling, so it cannot be generalised to newcomer settings, but it points to a dimension of outcomes that translation-focused research rarely measures.

Taken together, this strand suggests that AI feedback and tutoring can produce short-term gains in accuracy and engagement, while the evidence that these gains translate into durable language proficiency among school-age newcomers remains thin.

The clearest evidence of harm concerns assessment. Research on scoring bias in AI evaluation of English learner writing examines how automated and large-language-model scoring systems

treat essays by students who are not native speakers. It finds that such systems can systematically misjudge these essays, penalising features typical of developing English, such as non-standard syntax or limited lexical range, in ways that do not track the quality of the ideas expressed. The work is more rigorous than most classroom studies because it compares machine scores with human ratings on the same texts, which allows bias to be measured rather than inferred.

The implications are practical. Schools increasingly use AI to score formative writing, flag students for intervention and, in some cases, contribute to placement decisions. If those systems disadvantage English learners, they can reinforce exactly the achievement gaps that translation tools are meant to narrow, and they can do so invisibly, because a lower score looks like an objective measurement. The bias findings also bear on AI-detection tools used to police academic integrity, a concern echoed in teacher accounts such as Ayesha's (2026), since writing that departs from native-speaker norms can be misread as either weak or machine-generated.

This is why the strongest documented risk sits in assessment rather than instruction. A translation error in a lesson is usually visible and correctable in the moment; a biased score may shape decisions about a student for months before anyone questions it.

Professional guidance has tried to translate this mixed evidence into practice. The National Education Association's tools and tips for multilingual learners recommend using AI to scaffold access, for example by translating directions, generating bilingual glossaries or adjusting text complexity, while keeping students producing language themselves and preserving the role of their home languages as assets. The NEA's broader AI guidance for schools and educators adds conditions: human review of translated family communications, caution about entering student data into commercial tools, attention to bias in assessment, and professional development so that teachers can judge when a tool is helping and when it is substituting for learning. These documents are guidance rather than evidence, but they reflect the pattern in the research, with access gains welcomed and production and assessment treated as areas of risk.

Institutional capacity shapes whether that guidance can be followed. Nyamboga's (2026) systematic review of AI in global higher education, conducted under PRISMA guidelines, argues that outcomes depend on the combination of AI integration, adaptive leadership and digital infrastructure readiness rather than on the tools alone. The review concerns universities, but the finding transfers readily to schools serving newcomers, where uneven device access,

connectivity and staff training can determine whether a translation tool reaches the students it is bought for.

Work outside education also indicates what more careful design might look like. Chen and Liu (2026) built and evaluated a multilingual health education chatbot for migrant and multicultural populations, routing queries to language-specific processing modules and grounding responses in domain-specific medical knowledge. The parallel for schools is the difference between general-purpose translation and tools tuned to curriculum vocabulary and school procedures, which is precisely the design choice that distinguished the Norwegian Learnlab tool.

The overall picture, then, is of tools adopted quickly in response to real need, with reasonably consistent evidence that they improve access and participation, encouraging but short-term evidence on feedback and practice, and well-measured risks in assessment. What remains largely unmeasured is the outcome schools most care about: whether newcomer students who learn with AI support acquire the language of instruction, and reach grade-level content, faster than they would have without it.

Q313 How does generative AI advance Universal Design for Learning (UDL 3.0) across multiple means of engagement, representation, and action/expression?

16 citations · 16 sources · 4 cross-references

Claim 1 disputed

Generative AI can advance Universal Design for Learning 3.0 chiefly by making it cheap to produce many versions of the same learning experience. It can generate alternative representations of content, varied entry points and scaffolds for engagement, and more channels

through which learners can show what they know. Whether that technical capacity becomes the learner agency UDL 3.0 aims for remains unclear, because direct evidence is thin and much of it is indirect. The revised guidelines from CAST (2024) keep the three familiar principles: multiple means of engagement (the why of learning), representation (the what) and action and expression (the how). Version 3.0 attends more explicitly to learner identity, belonging, bias and systemic barriers. It also reframes the goal as learners who are purposeful and reflective, resourceful and authentic, and strategic and action-oriented. That reframing matters for any assessment of generative AI. A tool that multiplies formats but leaves learners passive, or that reproduces bias in the content it generates, may satisfy an older checklist reading of UDL while working against its current intent.

The mechanism behind the promise is easy to state. Large language models and related generative systems, which Kalota (2024) situates within the lineage of machine learning, deep learning and artificial neural networks, produce new text, images and other outputs on demand from a prompt. For UDL, this shifts the main constraint. Before, the bottleneck was the labour of preparing alternatives. Now it is the judgement needed to choose, check and frame them. A teacher who once had to write a simplified reading, a glossary, a worked example and an audio version can now request all four in minutes. The pedagogical work moves from authoring to curating, verifying and deciding which variation serves which barrier. The rest of this essay follows that distinction between producing variability and designing for agency across the three principles, and then turns to the evidence on how educators learn to do the second.

Representation is the principle where the continuity with earlier assistive technology is clearest. Here the field has more than speculation to draw on. Converting text to speech, adjusting reading level, and producing visual or summarised versions of dense material extend tools that special education has used for decades. Wood and colleagues (2017) carried out a meta-analysis of text-to-speech and related read-aloud tools for students with reading difficulties. They started from the observation that such tools were being widely implemented even though their effect on reading comprehension was not clear. Perelmutter, McGregor and Gordon (2017) asked a parallel question for adolescents and adults with learning disabilities aged 14 and over. They synthesised 38 quantitative group-design and single-subject studies, 5 survey studies and 13 qualitative studies, and examined both effectiveness and how the interventions affect users' lived experience. These syntheses set the evaluative standard generative tools should now meet. Adoption had run ahead of evidence, and lived experience had to be studied alongside

measured outcomes. Generative systems repeat that pattern at a larger scale and with a new risk. Earlier read-aloud tools converted the text they were given. Generative tools rewrite, summarise and reinterpret it, so the alternative representation can drift from the original in accuracy or emphasis.

Arkenback, Stenberg and Wyszynska Johansson (2026) add a conceptual caution. Studying professional practice, they argue that the significance of generative AI cannot be inferred from individual prompts, outputs or nominal categories of use. What a representation supports depends on the practice it is embedded in. Translated to classrooms, a generated diagram or plain-language summary is not accessible in itself. Its value depends on whether it connects to the learner's task, prior knowledge and subsequent activity. This view fits the UDL 3.0 emphasis on reducing barriers rather than merely adding formats. It also explains why counting the representations a tool can produce says little about learning. The specific affordances of multimodal systems for dyslexia, visual impairment and D/deaf learners are treated in detail elsewhere (see Q315). The general point here is that generative AI expands the supply of representations faster than the evidence on which ones help whom.

For engagement, the evidence is more recent, mostly from higher education, and largely descriptive. Leahy, Ozer and Cummins (2025) report a multicentre programme of teacher-led, AI-focused interventions across three cohorts in different subject areas. Its stated aims were to support student engagement and to explore what generative tools contribute to learning engagement, efficiency and skill development. It also sought to build awareness of the tools' strengths and limitations. The authors note that chatbots such as ChatGPT lacked empirical grounding as teaching and learning tools, which is a fair summary of the field's starting point. Vo (2026) studied 17 students in a lighting design classroom that paired generative AI for ideation with virtual reality for revision. The sequence was intended to promote lateral and vertical thinking within Goel's design problem space, and the study examined creativity and interest. Vo explicitly criticises earlier work for relying mostly on self-reported data. The study's contribution lies less in its small sample than in its claim about sequencing. Whether generative tools help engagement depends on how and when they are integrated, not on their presence alone.

Kasie (2026) brings engagement closest to UDL 3.0's concern with identity and systemic barriers. Studying undergraduate English as a foreign language writers in Ethiopia, Kasie frames writer's block as intensified by writing anxiety, linguistic insecurity and unreliable

internet access in low-resource Global South settings. The study extends an affective process and strategic engagement framework through critical AI literacy and ethical use. It asks how learners engage with tools such as ChatGPT critically and purposefully, rather than assuming that access alone produces engagement. This matters for UDL because it treats the affective barrier and the infrastructural barrier together. A generative tool that lowers the threshold for starting to write may reduce anxiety, but only where connectivity allows its use. That condition is itself a systemic barrier the revised guidelines ask designers to see. Taken together, these studies suggest that generative AI can open new routes into a task, especially at the moment of initiation. None of them yet shows that such engagement persists, or that it produces the purposeful and reflective learner UDL 3.0 describes. The related question of task initiation and executive function for ADHD and autistic learners, and the line between accommodation and atrophy, is addressed separately (see Q314).

Action and expression is where the promise and the risk of generative AI are most tightly entangled. In principle, generative tools allow a learner who struggles with handwriting, spelling, sentence construction or a second language to express understanding through dictation and drafting support. They also permit multimodal formats that a single written assignment would foreclose. This is a direct expansion of the options UDL has always recommended. Montebello (2026) identifies the complication. Historically, assessment did more than measure learning: it worked as a structural mechanism that implicitly enforced cognitive engagement. With generative AI, learners can increasingly produce assessment outputs without engaging in the cognitive processes traditionally associated with learning. Montebello describes the result as a decoupling of performance from engagement, a shift from cognitive necessity to cognitive choice. For UDL, the implication is uncomfortable. The very flexibility that removes construct-irrelevant barriers to expression can also remove the construct-relevant effort the task was meant to elicit.

The tension is unresolved, and the literature divides along it. One reading, consistent with a strong accessibility stance, holds that offloading transcription or language production is precisely what a well-designed accommodation should do, so long as the learning goal is separated from the means of expression. The opposing reading, closer to Montebello's argument, holds that generative output can stand in for the thinking itself, not only for the mechanics, and that unbounded flexibility in expression erodes the evidence on which judgements of learning rest. Bikanga Ada (2026) offers one institutional response at the level of

judgement rather than prohibition. The Master's Dissertation Marking Framework was developed through design-based research with phases before and after generative AI emerged, and it aims at fairer and more transparent assessment. Approaches of this kind suggest that UDL-aligned expression in a generative era depends on making criteria explicit enough that learners and markers can distinguish the goal from the medium. Expression also has an equity dimension the tools themselves may undermine. Systems that handle non-standard speech, augmentative and alternative communication, or neurodivergent communication styles poorly will narrow the means of expression for the learners UDL most needs to reach (see Q317).

The most direct evidence linking generative AI to UDL concerns educators as designers, not learners as users, which is itself revealing. Padrón Alvarez and Estrada-Molina (2026) evaluated an Integrated Inclusive AI Challenge Model that combines UDL, challenge-based learning and generative AI in postgraduate teacher education. They used a concurrent mixed-methods participatory action research design with 83 students, 80 proposals and 178 learning artefacts. An independent rater blinded to the hypotheses re-evaluated a stratified subsample, with an ICC of 0.84 and weighted kappa of 0.74 to 0.78. Their premise is that teacher education has been incorporating generative AI without developed inclusive pedagogical frameworks. The study examined participation, engagement and pedagogical creativity in designing inclusive AI-mediated proposals, so its outcomes concern design capability, not student learning. McGregor (2026) offers a qualitative case of an educator collaborating with Claude 3.5 Sonnet to design a final-year mechatronics laboratory practical, treating the model as a mediating tool. In that account, the educator evaluated and constrained the model's proposals against established learning theory throughout. This is an instructive picture of where professional judgement sits.

Professional development studies point the same way while staying modest about their claims. Mlinarić and Özkaya (2026) describe a pedagogy-first workshop in which life-science educators worked with their own course materials. They state plainly that it is an exploratory feasibility report whose evaluation was not designed to test whether it changed practice. Schröder and colleagues (2026) used a repeated cross-sectional programme evaluation of physiotherapy students' generative AI use, perceptions and literacy before and after structured learning activities. Alenezi (2026), writing about Kuwait's higher education institutions, argues that AI adoption, UDL, responsible AI governance and digital transformation have been studied as separate lines of enquiry rather than as interacting institutional capabilities. Alenezi also

notes that this work has largely failed to engage critical literature questioning whether AI adoption strengthens or erodes inclusion. The pattern is longstanding. A decade ago, Al-Azawei, Serenelli and Lundqvist (2016) could identify only 12 peer-reviewed empirical studies from 2012 to 2015 that applied UDL as a framework, using four selection criteria. Even before generative AI, then, the empirical base for UDL was narrow, and generative tools are being layered onto a framework whose own outcome evidence was still developing.

Several conclusions follow, along with clear limits on what the evidence shows. Generative AI plainly lowers the cost of providing multiple means of representation, engagement and expression. That is a genuine advance for a framework that has long been constrained by teacher time. The evidence suggests that the benefit depends on sequencing, framing and educator judgement rather than on the tools themselves. The design-focused studies show that teachers can be prepared to build inclusive AI-mediated activities with measurable reliability in how those designs are rated. What the evidence does not yet show is equally important. Few studies have tested generative tools against UDL-relevant outcomes for disabled or neurodivergent learners specifically, and most available work comes from higher education, small samples or self-report. The earlier syntheses on read-aloud and assistive technology remain the closest rigorous precedent, but generative systems differ from them in a crucial way: they transform content rather than simply convert it. No study here establishes that generative AI fosters the agency UDL 3.0 defines, as distinct from convenience or task completion. The decoupling of output from cognition that Montebello describes is a reasoned argument rather than a measured effect, yet it has not been refuted.

For practice, the implication is to treat generative AI as an instrument of UDL design rather than a substitute for it. Each generated alternative should be judged against the barrier it is meant to remove, the learning goal it must preserve and the identity and bias concerns the revised guidelines foreground. Institutions should require evidence on accessibility and UDL alignment before adopting tools, not afterwards (see Q362). Researchers should prioritise designs that follow disabled learners over time and measure both learning and lived experience. They should also report how generated variations were checked for accuracy and bias. Until such work accumulates, the most defensible claim is a measured one. Generative AI greatly expands the means UDL calls for, but the ends, namely purposeful, resourceful and strategic learners, still depend on human design.

Q314 How can AI tools support executive functioning, working memory, and task initiation for students with ADHD and autism—and where is the line between empowering accommodation and skill atrophy?

16 citations · 16 sources · 6 cross-references

Claim 1 disputed

AI tools can support executive functioning, working memory, and task initiation for students with ADHD and autism by externalising the cognitive work that these profiles often find costly. That work includes breaking tasks into steps, holding instructions in mind, sequencing a plan, and getting started. The line between empowering accommodation and skill atrophy is not a property of the tool. It depends on whether the support removes a barrier that is irrelevant to the learning goal or performs the very skill the student is meant to develop. That distinction is easy

to state and hard to apply. The evidence needed to apply it well for these populations is still thin.

The starting point is a working definition. Klarin and colleagues (2024) describe executive functioning as including planning, inhibition, and cognitive flexibility, processes they call essential for academic success. Students with ADHD and many autistic students experience difficulties in precisely these areas. Generative chatbots are, in effect, general-purpose engines for planning, rephrasing, and restructuring. The overlap between what these students find hard and what the tools do well is therefore unusually direct. That overlap is the source of both the promise and the risk.

The field is not starting from nothing. Assistive technology for learning differences has a substantial research history. Perelmutter, McGregor and Gordon (2017) located 38 quantitative group-design and single-subject studies, 5 survey studies, and 13 qualitative studies of assistive technology for adolescents and adults with learning disabilities aged 14 and over. They asked not only whether such interventions work but how they shape users' lived experience. That dual framing, efficacy alongside experience, is the right template for judging AI supports for executive function. Universal Design for Learning offers a second template. Al-Azawei, Serenelli and Lundqvist (2016) analysed 12 empirical studies applying UDL between 2012 and 2015 and framed it as a way to bridge learner abilities and individual differences. Read together, these traditions suggest that support should be designed into the environment rather than rationed as a deficit-based exception (see Q313).

Current tools could plausibly support executive function through three mechanisms, each with a different evidential footing.

The first is task decomposition and initiation. For a student who freezes in front of an open-ended assignment, a chatbot can turn "write an essay on the causes of the First World War" into a sequence of concrete first actions. It can also do so repeatedly and without impatience. Hershkovitz, Tabach and Lurie (2025) coded 825 open-ended responses from students at a large multidisciplinary university and found that generative AI is used across a range of identifiable academic task types. That task-centred view matters here. Initiation support is a distinct use, and it is different from content generation.

The second mechanism is working-memory offloading. A tool can hold the rubric, the reading notes, and the half-formed outline so that the student does not have to keep all of them active at

once. The closest established analogue is read-aloud technology. Wood and colleagues (2017) meta-analysed text-to-speech and related read-aloud tools for students with reading difficulties. They addressed the question of whether listening while reading improves comprehension, an accommodation that also redistributes processing load. The perceptual channel differs from the executive one, but the logic is the same: relieve a bottleneck so that capacity is freed for the target task (see Q315 for the multimodal access dimension).

The third mechanism is responsiveness. Triberti and colleagues (2024) note that conversational pedagogical agents can provide timely feedback while learning is under way. They also observe that many such tools perform tasks human educators could perform, only faster. For students whose attention decays during waiting, or who lose momentum when help arrives late, timeliness may itself function as an executive accommodation.

Motivation is the mechanism's hinge. Hmoud and colleagues (2024) interviewed 15 students about their ChatGPT use and analysed the characteristics of their task motivation in that context. For students with ADHD, task initiation difficulties are often bound up with motivation and reward. A sample of 15 general university students cannot settle how these dynamics play out for neurodivergent learners. Even so, it signals that AI changes the motivational texture of tasks, and not only their difficulty.

The single most directly relevant study connects generative AI use to executive functioning in school-age learners. Klarin and colleagues (2024) ran two studies, one with younger adolescents (N = 385, 46% girls, mean age 14) and one with older adolescents (N = 359, 67% girls, mean age 17). They examined how often students used LLM chatbots for schoolwork, and how useful they found them, in relation to executive functioning and academic achievement.

The design is the important point for this chapter. It is correlational and cross-sectional. It can show whether students with different executive-functioning profiles use and value these tools differently. It cannot show whether AI use strengthens, weakens, or merely tracks executive skills. Any association in such data is open to at least three readings. Students with weaker executive functioning may seek out AI because it compensates. Heavy AI use may erode the practice through which executive skills develop. Or a third factor, such as academic pressure, may drive both. The atrophy debate often slides from the second reading to a conclusion that the data cannot carry.

This matters because the populations at the centre of this chapter sit at the tail of the executive-functioning distribution. If students with greater executive difficulty find these tools especially useful, that is consistent with genuine accommodation value. It is equally consistent with a dependency pathway. Distinguishing the two requires longitudinal designs that follow the same students over time, ideally with independent measures of executive function rather than self-report, and with samples that identify diagnosed ADHD and autistic students. Few studies have done this, and none of the evidence reviewed here isolates those diagnostic groups. Whether generative AI functions for them as a ramp, a crutch, or both depending on use remains unclear.

The mainstream adoption evidence widens the uncertainty rather than resolving it. Ribeirinha, Santos and Correia (2025) applied the extended UTAUT2 acceptance model to Portuguese university students' behavioural intentions and use. González and colleagues (2026) surveyed 289 students in northwestern Mexico on AI perception and its relationship with learning and academic performance. Gupta, Raj and Gupta (2026) validated a five-component perception scale with 187 Indian students, with components including Academic Utility and Learning Impact. These studies document that students perceive academic utility. Perceived utility is a measure of satisfaction, however, and it is not a measure of skill growth. For neurodivergent students in particular, tools that feel most helpful may also be those that do the most executive work on their behalf (see Q248).

The more defensible approach is to draw the line by construct relevance rather than by tool. An accommodation is legitimate when it removes demands that are not part of what is being taught or assessed. It becomes substitution when it performs the target competence.

Consider a history assignment for a student with ADHD. If the learning goal is historical argument, AI-generated task sequencing, reminders, and a scaffolded outline template are accommodations. They lift an executive burden that is incidental to the historical reasoning. If the explicit goal is learning to plan an extended piece of writing, the same outline does the student's work for them. Identical tool use can be accommodation in one lesson and atrophy-risk in the next. That is why blanket permissions and blanket bans both fail these students.

A second distinction concerns time horizon. Some supports are scaffolds meant to fade as the student internalises a routine. Others are permanent prostheses, in the way a calendar is for most adults. Neither is inferior. The decision about which applies should be explicit and individualised, and it should be revisited, a task that properly belongs to planning processes

(see Q316 on the boundaries governing AI in IEP and 504 drafting). The risk is drift. A support introduced as a fading scaffold becomes permanent because nobody reviews it, or a support that should be permanent is withdrawn in the name of independence.

The general concern about cognitive offloading is real but uneven in its evidence. Ruiz-Rojas, Salvador-Ullauri and Acosta-Vargas (2024) investigated generative AI's impact on critical thinking and collaboration. They found that 87% of their predominantly female sample knew of such tools, while 38% used them occasionally. Gasaymeh, Beirat and Abu Qbeita (2024) surveyed 95 education students in Jordan about AI writing tools. They reported moderate familiarity ($M = 3.14$, $SD = 0.81$), with engagement outpacing technical knowledge, alongside perceived concerns as well as benefits.

Neither study measures skill loss directly. Both suggest that students hold mixed views and often lack the technical understanding needed to judge when a tool is substituting for their thinking. That metacognitive gap is arguably the real atrophy risk for neurodivergent students. The danger is less that executive skills vanish than that students lose the ability to monitor which skills they are exercising.

This is where literacy frameworks become relevant. Hershkovitz, Tabach, Reich and colleagues (2025) developed a task-centred generative AI literacy framework of eight skills informed by the six cognitive domains of Bloom's Taxonomy, and surveyed 1667 students with an instrument built on it. Mapping AI use onto cognitive levels gives teachers and students a vocabulary for asking whether the tool is handling recall and organisation, which is often appropriate offloading, or evaluation and creation, where substitution is more costly.

For autistic students, executive support is often entangled with social and communicative demands. Initiating a group task, interpreting an ambiguous instruction, or emailing a teacher for an extension can be as much a barrier as planning itself. AI can rehearse, decode, or draft these interactions.

Shi (2026) proposes a human–machine collaborative framework that uses AI-assisted communication tools to make online education more inclusive for students with impairments. The argument is that traditional methods restrict participation and comprehension for learners with diverse communication needs. The framework is a design proposal rather than an outcome trial. Its emphasis on collaboration, with the human remaining in the loop, is nonetheless the right orientation.

There is a parallel caution. Li and Ritchie (2026) interviewed 16 UK university students who scored 3 or above on the De Jong Gierveld Loneliness Scale about their use of conversational AI for emotional and relational support. They explored how students positioned it alongside other coping strategies. The study does not concern autism specifically. It does show that conversational AI is already occupying relational roles for some students.

For autistic learners, a tool that lowers the cost of social initiation could be a bridge to human interaction or a substitute for it. The skill-atrophy question in this domain is not only cognitive but social. It also intersects with documented concerns that generative and speech systems may misread or penalise neurodivergent communication styles (see Q317). An executive-function aid that rewrites an autistic student's message into a normative register may help in the short term while quietly teaching that their own register is wrong. Whether that trade-off is acceptable is a values question as much as an empirical one. Students themselves should have a central voice in answering it.

Several principles follow for practice, held with appropriate tentativeness.

First, executive supports should be built into the learning environment for everyone where possible, in the UDL tradition reviewed by Al-Azawei and colleagues (2016). Supports available to all carry less stigma. They also make it easier to observe who uses them heavily, and why.

Second, AI use should be teacher-mediated rather than left to unsupervised discovery. Leahy, Ozer and Cummins (2025) examined teacher-led AI interventions across three cohorts in different subject areas. They aimed to support engagement and skill development and to promote awareness of generative AI's strengths and limitations. That model of explicit instruction in when and how to use AI matters more for students whose executive difficulties make self-regulated tool use hardest.

Third, students should be taught to name what a tool is doing for them, using task-centred and Bloom-based vocabulary of the kind Hershkovitz and colleagues (2025) propose. A student who can say "I am using this to hold my plan, not to write my argument" has retained the executive oversight that matters most.

Fourth, the assistive-technology tradition's insistence on lived experience, exemplified by Perelmutter and colleagues (2017), should be carried forward. Neurodivergent students' own

accounts of which supports feel empowering, and which feel diminishing, are evidence, not anecdote.

The evidence does not yet show whether sustained AI-based task decomposition improves or impairs independent planning in students with ADHD, or whether working-memory offloading transfers to, or competes with, internal strategy development. Nor does it show whether autistic students who use AI for social scaffolding go on to increase or decrease direct human interaction, or what effect sizes such supports produce, given that the general AI-tutoring evidence base remains contested (see Q051).

What the field can say is narrower but still useful. The capacities these tools offer map closely onto documented executive needs. Established assistive-technology research provides tested frameworks for evaluating such supports. Associations between executive functioning and AI use exist in adolescent samples but are uninterpreted as to causation. The line between accommodation and atrophy is best drawn task by task, by asking what a given lesson is actually trying to teach.

Q315 How are multimodal AI systems transforming access for learners with dyslexia, dysgraphia, visual impairments, and D/deaf or hard-of-hearing profiles?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

Multimodal AI systems are widening access for learners with dyslexia, dysgraphia, visual impairments, and D/deaf or hard-of-hearing profiles mainly by converting content between modes on demand: text to speech, speech to text, image to description, audio to caption. This lets a learner meet the same material through the channel that suits them best. The transformation is real but uneven. The strongest evidence concerns older, narrower assistive technologies that generative systems now absorb and extend, while evidence for the newer tools is still largely descriptive. What makes the present moment different is integration. Claman and Sezgin (2024) describe how large language models and multimodal foundation models combine text, images, and audio within a single system. In practice, one tool can now read a worksheet aloud, describe its diagram, transcribe a spoken answer, and reformat the result. Where a student with a disability once needed a separate device or service for each conversion, a single interface can now perform several. Istrate (2026) adds that generative tools have sharply reduced the time and expertise teachers need to produce multimodal material. He reads this through multimodal pedagogy, social semiotics, and the cognitive theory of multimedia learning, which treat teaching as the deliberate orchestration of several semiotic modes. That argument matters for special education. Accessible alternatives have historically been scarce because each one was costly to make, and that cost is what is falling. The connection to universal design is direct, and the broader case for generative AI across multiple means of representation and expression is treated elsewhere in this volume (see Q313). Scale should be kept in proportion, however. Garzón, Patiño and Marulanda (2025) reviewed 155 peer-reviewed empirical studies of AI in education published between 2015 and 2025 and found a sharp rise in research activity since 2022, driven by tools such as ChatGPT. Rapid growth in publication is not the same as accumulated evidence of benefit for specific disability

groups. The normative reference point for judging any of these tools remains the Web Content Accessibility Guidelines. Version 2.2, a W3C Recommendation published in October 2023, organises testable success criteria under the principles of perceivable, operable, understandable, and robust content (World Wide Web Consortium, 2023).

For learners with dyslexia and related reading disabilities, the most mature strand of evidence concerns read-aloud technology, now a standard capability of multimodal systems. Read-aloud software, including text-to-speech, turns written text into spoken text so that a student can listen while reading along. Wood, Moxley, Tighe and colleagues (2017) note that such tools were being widely deployed even though their effect on reading comprehension was not clear. Their meta-analysis of text-to-speech and related read-aloud tools for students with reading difficulties was designed to close that gap. The study matters for the generative era because it treats comprehension, not decoding, as the outcome of interest. That is the right test for any tool that bypasses print: the question is whether the learner understands more, not whether they read more fluently. Perelmutter, McGregor and Gordon (2017) widened the lens to adolescents and adults aged 14 and over. They gathered 38 quantitative group-design and single-subject studies, five survey studies, and 13 qualitative studies, and asked both whether assistive technology works and how it affects the lived experience of users. That dual framing is instructive. A tool can help on a comprehension measure yet feel stigmatising, cumbersome, or isolating in a classroom, and the reverse can also be true. Generative systems push beyond simple narration. They can produce paired pronunciations, illustrations, and semantic explanations for difficult words. Yu, Song and Lu (2025) proposed a framework that uses generative AI to build multimodal resources for distinguishing visually similar Chinese characters, whose complex orthography links symbol, pronunciation, and meaning. Their work was not designed for dyslexic learners. It does show, however, that generative pipelines can semi-automate exactly the kind of orthographic, phonological, and semantic scaffolding that reading interventions have long required and rarely had time to build. What remains unclear is whether AI-generated scaffolds of this kind produce the comprehension gains that dedicated read-aloud tools have been evaluated for. The same uncertainty applies to whether constant conversion to audio supports or displaces the development of independent reading in younger children. Few studies have yet compared generative and conventional read-aloud tools directly with dyslexic learners.

For dysgraphia, the access story runs in the opposite direction, from speech or rough drafts to polished text. Two capabilities dominate: automated speech recognition for dictation, and generative feedback or rewriting for spelling, grammar, and organisation. Dictation offers a learner whose handwriting or keyboarding is laborious a route around the transcription bottleneck. The ideas then reach the page without being filtered through the motor difficulty, which is precisely the accommodation that dysgraphia warrants. The reliability of that route cannot be assumed, though. Koenecke, Nam, Lake and colleagues (2020) observe that automated speech recognition has improved dramatically through deep learning and large training datasets and now powers virtual assistants, automated captioning, and dictation platforms. They also raise concern that these systems do not work equally well for all subgroups of the population, and their study examined racial disparities in recognition. For a student who relies on dictation, uneven accuracy is not a minor annoyance. It shifts the burden from handwriting to correction, and it may fall hardest on students who already speak in ways the training data underrepresent. The mechanisms of this bias and its consequences for neurodivergent speakers and AAC users are examined in detail elsewhere (see Q317). Generative writing feedback is the second strand, and its evidence base is thinner where disability is concerned. Duan and Wang (2026) studied generative AI-assisted feedback with 400 undergraduate EFL learners in a sequential explanatory mixed-methods design, followed by interviews with 30 students. They reported large pre-to-post gains, for example in grammar scores from 65.12 to 94.84. The study did not involve learners with dysgraphia, and pre-post gains alone cannot separate the effect of the tool from practice or instruction. It suggests that generative feedback can raise surface accuracy. It does not show that it develops the compositional skill or independence a dysgraphic writer needs. The lived-experience findings gathered by Perelmutter and colleagues (2017) are a reminder that perceived ownership of the text matters to users. When a model rewrites rather than transcribes, the boundary between accommodation and substitution blurs. That boundary is closely related to the debate over skill atrophy discussed for executive-function supports (see Q314).

For blind and visually impaired learners, multimodal models address a longstanding barrier: educational material is saturated with images, diagrams, and layouts that text-to-speech alone cannot convey. Scene description, recognition of printed text in photographs, and conversational questioning about an image let a student ask what a figure shows instead of waiting for a human to write alternative text. Asiri, Barayan, Almutairi and colleagues (2026) conducted a PRISMA-guided systematic review of 27 studies published between 2020 and

2025 on AI and quality of life for blind and visually impaired people. The studies clustered in four areas: mobility, education, social interaction, and safety. Education is thus one domain among several in which AI is being tested for this population. Because the review addresses quality of life broadly, it does not establish learning outcomes specifically, and its coverage of short-term studies leaves durability open. Retrieval architectures that index images alongside text point to another route. Raza, Jameel and Azmat (2025) built a system that encodes textbook text with a Sentence Transformer and images with Inception V3, stores the vector embeddings in Elasticsearch, matches learner queries by cosine similarity, and synthesises the retrieved material using large language model APIs. Their work targets semantic search for learners generally, not accessibility. Still, the design principle of treating images as searchable, describable content rather than decoration is exactly what non-visual access requires. Lampropoulos (2025) analysed 201 documents from Scopus and the Web of Science on combining AI with augmented and virtual reality in education. Immersive environments built around vision illustrate the risk that new multimodal formats create fresh exclusion unless they offer non-visual equivalents from the outset. Here the WCAG 2.2 requirement that content be perceivable, explicitly including blindness and low vision, remains the relevant standard (World Wide Web Consortium, 2023). A generated description that is fluent but wrong is arguably worse than no description, because a blind student has no independent means of checking it. Systematic evaluation of how accurately multimodal models describe instructional diagrams, charts, and mathematical notation remains limited.

For D/deaf and hard-of-hearing learners, the central multimodal capability is automated captioning and transcription of lectures, videos, and classroom talk. Its promise is immediacy and coverage: captions can be available for every recording and every live session, not only those for which human captioning was budgeted. WCAG 2.2 explicitly addresses deafness and hearing loss within its perceivable principle, and conformance at levels A, AA, and AAA provides a framework for deciding whether captioned content is actually accessible (World Wide Web Consortium, 2023). The evidence on recognition accuracy should temper enthusiasm, however. Koenecke and colleagues (2020) name automated closed captioning as one of the functions now powered by speech recognition, and their concern that these systems do not perform equally across subgroups applies directly here. A deaf student reading captions of a teacher, or of classmates whose speech the system recognises poorly, receives a degraded and potentially misleading record. Unlike a hearing student, they cannot cross-check it against the audio. Accuracy for disciplinary vocabulary, overlapping talk in group work, and accented

or atypical speech therefore becomes an equity question, not merely a technical one. Two further limits deserve plain statement. First, captioning treats English or another spoken language as the target. For many Deaf learners, a signed language is the primary language, and text is a second language. Rigorous research evidence on whether AI systems can reliably translate between signed and spoken or written languages in classroom settings remains thin. Claims that multimodal models already serve signing learners should be treated with caution. Second, the gesture-, avatar-, and spatially rich environments that Lampropoulos (2025) surveys in AI-enhanced augmented and virtual reality could in principle support visual communication. They could equally rely on spoken audio cues that exclude hard-of-hearing users if accessibility is not designed in. The balance of evidence suggests that automated captioning substantially expands availability while its quality remains contested and dependent on the speaker. Human review is still advisable wherever captions carry assessed content.

Across all four profiles, whether multimodal AI is transforming access depends less on model capability than on the conditions of use, and here the evidence is weakest. First, the effect evidence is asymmetric. Read-aloud and assistive technology for reading and learning disabilities has been meta-analysed (Wood et al., 2017; Perelmutter et al., 2017). By contrast, generative and multimodal tools are mostly supported by design frameworks, reviews of broad application areas, and pre-post or survey studies in non-disabled populations. Yeribatuah and Boateng (2026) used a cross-sectional survey and structural equation modelling to link AI use with mathematics interest, performance, and perception among Ghanaian learners. Designs of this kind show associations, not causal effects, and they did not focus on disability. The same caution applies to wider claims about AI tutoring (see Q051). Second, acceptance and benefit may vary across groups in ways that matter for disabled learners too. Wang and Ren (2025) found gender-based differences in how Hong Kong undergraduates perceived the usefulness and ease of use of ChatGPT and an AI image-generation function, and in the emotions and self-efficacy they reported. Intersections of disability with gender, race, language, and age are rarely examined. The recognition disparities documented by Koenecke and colleagues (2020) show why they should be. Third, access to the tools themselves is unequal, so the populations most likely to benefit may be least likely to have devices, bandwidth, or licences (see Q186). Fourth, the reduced cost of producing multimodal material that Istrate (2026) describes cuts both ways. It lowers the barrier for teachers to create accessible alternatives. It also floods classrooms with generated images, video, and audio that may themselves fail accessibility criteria unless captions, descriptions, and structure are checked against the WCAG 2.2 success criteria (World

Wide Web Consortium, 2023). What the evidence does not yet show is equally important. Comparative trials pitting generative tools against established assistive technology are lacking. Long-term studies of skill development under continuous modality conversion, independent accuracy audits for diagrams and disciplinary captions, and research co-designed with dyslexic, dysgraphic, blind, and Deaf learners themselves are all scarce. Until such work exists, the defensible position is that multimodal AI has made accessible alternatives cheaper and more immediate. Whether it reliably improves learning for these students, and for which students it fails, remains to be demonstrated.

Q316 What legal, privacy, and professional boundaries govern the use of generative AI by special educators when drafting Individualized Education Programs (IEPs) and 504 plans?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

Special educators who use generative AI to draft Individualized Education Programs (IEPs) and 504 plans work within three overlapping sets of boundaries. The first is legal: student privacy law governs what information may leave the school's control. The second follows from the purpose of disability law: these documents must record individualized decisions made through a team process that includes families, not text produced generically by a machine. The third is professional: the educator who signs the plan remains accountable for its accuracy, its fairness and its fidelity to the child. None of these boundaries was written with large language models in mind. Each therefore has to be interpreted rather than simply applied, and the empirical evidence available to guide that interpretation is thin.

The practical stakes are rising, although adoption is less advanced than public discussion implies. In a theory-informed survey of 314 Wisconsin special education teachers, Naatz and Ruppar (2025) found that the profession is still in an exploratory phase of generative AI use. Fewer than 15% reported weekly use and fewer than 5% reported daily use. Interest in the IEP specifically is driven by a documented need. Rakap (2023) begins from the observation that novice special educators often struggle to write high-quality IEP goals for children with autism, and that tools such as ChatGPT have shown potential to help. Low current use combined with high perceived need is the condition under which norms are set early, often informally and by individual teachers rather than by districts. The boundaries discussed below are best read as an attempt to set those norms deliberately before habits harden.

The clearest legal boundary in the United States is the Family Educational Rights and Privacy Act (FERPA). The federal statute protects the privacy of student education records and applies to all schools that receive funds under applicable U.S. Department of Education programmes (U.S. Department of Education, 1974). FERPA gives parents the right to inspect and review their children's education records and to request their correction. These rights transfer to the student at age 18 or on attendance at a postsecondary institution. IEPs and 504 plans contain some of the most sensitive information a school holds: diagnoses, evaluation results, behavioural histories, medical needs, family circumstances and descriptions of what a child cannot yet do. Entering such material into a consumer chatbot moves protected information outside the institution. Whether that information is then retained, logged or used to train the

model depends on terms of service that teachers rarely read and districts may never have negotiated.

The parental rights that FERPA establishes also bear on AI-assisted drafting in a less obvious way. If machine-generated language enters the record, parents are entitled to inspect it and to request correction of what it says. A plan containing plausible but inaccurate statements about a child's functioning creates a record that families must then contest, which shifts labour and risk onto the people the plan is meant to serve. Several questions remain unclear without formal guidance. One is whether prompts, intermediate drafts and model outputs themselves constitute part of the education record. Another is whether a given AI vendor can lawfully receive identifiable student information at all. These are questions for district counsel and contracts, not for individual teachers improvising under time pressure.

Teachers commonly answer the privacy problem by removing names. This helps, but it is weaker than it appears. Disability information is often rare enough that a combination of age, school, diagnosis and specific behaviours can identify a child even without a name, particularly in small districts or low-incidence categories. Removing identifiers reduces risk without eliminating it. A defensible boundary is to restrict drafting assistance to tools the district has vetted and contracted for, and to keep identifiable or rare details out of any prompt.

These concerns are not only regulatory. In a UTAUT-based study of academic staff in Slovenian higher education, Weis, Lapuh Bele and Erčulj (2026) built trust and the protection of personal and institutional data directly into their model of generative AI acceptance. They treat privacy as a determinant of whether and how professionals adopt these tools, not as an afterthought. Whether the same dynamics hold among special educators handling disability records has not been tested. It is plausible, however, that privacy anxiety partly explains the cautious adoption Naatz and Ruppar (2025) observed. If so, clear institutional rules could make use both safer and more confident.

The second boundary concerns individualization, and it is more fundamental than privacy. Under the Individuals with Disabilities Education Act and Section 504 of the Rehabilitation Act, the plan is meant to be the product of decisions about a particular child, reached with the participation of the family. A generative model produces statistically typical text. Its fluency can disguise the absence of individualization. It may offer goals that sound measurable but reflect no assessment data, or list accommodations that are common but not demonstrably

needed by this student. The professional boundary that follows is that AI may assist with the wording of decisions but must not originate them. Present levels of performance must come from the educator's own evaluation and observation. Goals must be traceable to those data, and services must reflect what the team decided rather than what the model proposed.

The research on drafting assistance is promising but limited. Rakap (2023) randomly assigned 22 novice special education teachers either to use ChatGPT or to serve as controls. The study examined effects on the quality and content of IEP goals and on the time spent developing them, and also considered whether prior training in IEP and goal development made a difference. This is a valuable early experiment. It is also small, confined to novices and to goal writing for children with autism, and it evaluates goal text rather than downstream outcomes. It cannot show that AI-assisted goals are implemented with greater fidelity or that students make more progress, nor that families experience the resulting plans as more responsive. Any claim that AI improves IEPs rather than IEP prose goes beyond what the evidence currently demonstrates.

A related concern is deskilling. Educators in Dutch academic medical settings interviewed by Bruijn and Vlachopoulos (2026) described a tension between "co-intelligence" and cognitive offloading. Seventeen participants worried that generative AI's capacity to accelerate work may remove the cognitive processes that underpin professional judgement. The transfer to special education is direct. Writing a measurable goal is a reasoning exercise as much as a writing task: it forces the author to specify baseline performance, conditions and criteria. Novices who outsource that exercise may produce acceptable documents while failing to develop the analytic skill the documents are supposed to reflect. Rakap's (2023) attention to prior training implicitly recognizes this. The tool's value may depend on what the teacher already knows, and it may be most useful to those least likely to need it most.

The third boundary is fairness. Language models are not neutral when they describe disability. Trewin and colleagues (2019) reported, from a workshop with participants experiencing a range of disabilities, that AI can affect fair treatment of disabled people in education both positively and negatively. Because many non-AI practices are already discriminatory, introducing AI risks perpetuating and replicating those flaws. Guo and colleagues (2020) similarly warned that widely deployed AI systems may not work properly for people with disabilities, or may actively discriminate against them, and noted that such fairness concerns had received little attention. Gadiraju and colleagues (2023) moved from roadmap to evidence.

Across 19 focus groups, 56 participants with disabilities probed a dialogue model and annotated its responses, identifying categories of harm the model perpetuated toward the disability community. Their title, "I wouldn't say offensive but...", captures the difficulty well. Many of the harms are subtle framings rather than overt slurs.

Subtle framing is exactly the risk in IEP drafting. A model asked to describe a student's present levels may default to deficit language. It may describe behaviour as something to be extinguished rather than as communication, or reproduce assumptions about what students with a given label can achieve. Such language shapes how future teachers read the child, and once it enters the record it persists. Special educators therefore need to review drafts not only for factual accuracy but for the stance the text takes toward the student. This is a professional competence distinct from proofreading. These risks are compounded for students whose communication is non-standard, including users of augmentative and alternative communication, where speech and language models show particular weaknesses (see Q317). None of these studies examined IEP documents directly. Their relevance is inferential, and research auditing AI-generated special education documentation for biased framing has yet to appear in substantial form.

Beyond law and fairness lie questions of professional practice: transparency, supervision and accountability. Here special education can learn from fields where AI is entering high-stakes, person-specific decisions. Anand and Vaderhobli (2025), examining chairside use of ChatGPT in dental school clinics, argue that generative AI can be used ethically if implemented with transparency, structured oversight and robust ethics training. They stress supervision and the safety of the person receiving care. Kotzki and colleagues (2026) surveyed health professional students in France about generative AI use during clinical placements, where responsibility for patients increases. They documented perceived benefits and risks alongside unmet needs for training and governance. The parallel is close. Like a clinical record, an IEP describes a specific person and directs services to them, and errors carry consequences for that person rather than for the author.

Translated into special education, these analogues suggest several boundaries. Districts should state whether, and with which tools, AI drafting is permitted. Educators should be able to disclose to families that drafting assistance was used, in the same spirit in which confidentiality and authorship norms govern AI in research and peer review (see Q358). The signing professional should be able to explain every goal and accommodation without reference to the

tool. Novice teachers using AI should receive structured review from experienced colleagues rather than being left alone with a model. Whether disclosure to parents should be mandatory remains genuinely contested. Some practitioners consider it essential to trust. Others argue that AI assistance with wording is no different from a template bank or a colleague's edit, provided the decisions are human. The evidence does not settle the question, and it belongs within a broader professional code for teachers' AI use (see Q217).

Research on other educators shows how such norms tend to form. Kozan and colleagues (2025), in a multiple-case study of six professional instructional designers, examined how generative AI was integrated into practice and which factors shaped that integration. Chinoracky and Stalmasekova (2025), in a thematic review of 42 peer-reviewed articles, classified ethical problems across university educators' teaching, research and management duties, anchoring responsibilities in legislation that defines educators' roles. Rajaram (2026) argues conceptually that generative AI is redefining educators' professional identities. Each comes from a different setting, and none addresses special education. Read together, however, they indicate that professional norms around AI are being negotiated role by role, and that ethical obligations are most tractable when tied to the specific duties a professional is legally assigned. For special educators those duties are unusually well specified, which is an advantage. The boundary on AI use can be drawn around obligations already owed, rather than invented anew.

The current state of the field can be stated plainly. The privacy obligations are established: student records are protected, and families hold rights of inspection and correction that apply to whatever text enters a plan (U.S. Department of Education, 1974). The concern that AI can reproduce disability bias is well grounded conceptually and supported by participatory evidence on language models (Trewin et al., 2019; Guo et al., 2020; Gadiraju et al., 2023). The proposition that AI can help teachers write better IEP goals has been tested in only a small randomized study of novices (Rakap, 2023). Adoption remains limited and exploratory (Naatz & Ruppar, 2025). The evidence does not yet show whether AI-assisted plans differ in implementation, student outcomes, family satisfaction or legal defensibility. Nor does it show how often teachers enter identifiable information into consumer tools.

On that basis, the defensible position is a bounded permission rather than a prohibition. Generative AI may help a special educator rephrase, structure, check measurability and draft family-friendly explanations of decisions already made. It may also support accessible formats

for communicating plans, in keeping with universal design principles (see Q313). It should operate only through institutionally vetted tools and with identifiable or rare details withheld. It should never be the source of assessment findings, eligibility reasoning, service decisions or descriptions of a child the educator cannot personally verify. The professional's signature on an IEP or 504 plan certifies that a human who knows the child stands behind every line, and AI assistance does not reduce that accountability.

Q317 How do speech-recognition and generative models exhibit bias against non-standard speech patterns, AAC users, and neurodivergent communication styles, and how can schools mitigate these harms?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Speech-recognition and generative models disadvantage people whose speech or communication departs from the patterns most common in their training data. These systems learn statistical regularities, so speakers with dysarthria, stuttering, atypical prosody or accented and dialectal speech are recognized less accurately. Augmentative and alternative communication (AAC) users meet prediction and generation tools tuned to other people's language. Neurodivergent writers and speakers risk having direct, literal, repetitive or unconventionally structured expression treated as error. Schools can reduce these harms, but only through sustained effort. They need to evaluate tools locally with the students who will use them, keep humans accountable for any consequential judgement, preserve non-AI alternatives, and involve disabled students and families in procurement and review. Accessibility claims made by vendors are not a substitute for this work.

The conceptual case was set out before generative models reached classrooms. Trewin and colleagues (2019) reported on a workshop with participants experiencing a range of disabilities. It identified opportunities and risks across employment, education, public safety and healthcare. Its central warning was that many existing non-AI processes are already discriminatory, and that introducing AI risks perpetuating and replicating those flaws rather than correcting them. Guo and colleagues (2020) sharpened the paradox. Improving the lives of people with disabilities motivates many state-of-the-art systems, including automated captioning for deaf and hard-of-hearing users and language prediction for people with speech or cognitive disabilities. Yet widely deployed systems may not work properly for these users, or may actively discriminate against them. The authors noted that fairness for people with disabilities had received little attention.

Cicatiello and Fusco (2026) offer a useful lens, although their review concerns gender bias rather than disability. They argue that bias in generative AI emerges at several levels: historically patterned data, technical representation, benchmark evaluation, institutional deployment and accountability. On this view, bias is neither purely an engineering defect nor purely a social one. That multi-level framing applies with particular force to speech and communication disability, where each level can compound the others.

The strongest empirical evidence that automated speech recognition (ASR) performs unequally across groups comes from studies of race, accent and language background, not disability itself.

Koenecke and colleagues (2020) note that ASR quality has improved dramatically through deep learning and large-scale datasets, and that ASR now powers virtual assistants, automated captioning and dictation. Their study documented racial disparities in these systems. It is now a reference point for the claim that headline accuracy gains can mask unequal performance across subgroups. That this pattern appears for race and dialect demonstrates the general mechanism. Systems optimized on aggregate accuracy can fail particular populations systematically while appearing excellent on average.

Educational settings show the same dynamic. Jeon, Lee and Coronel-Molina (2024) examined speech-recognition chatbots in English language teaching from a Global Englishes perspective. They observed that the chatbots' recognition was primarily attuned to native-speaker pronunciation. This works against multilingual approaches that treat varied Englishes as legitimate. Their study also examined learners' attitudes toward English after using such a chatbot, which signals a harm beyond transcription error. When a machine repeatedly fails to understand a student, it can teach that student that their speech is deficient. The multilingual and newcomer dimensions of this problem are treated more fully elsewhere (see Q171). The relevant point here is that the attitudinal harm plausibly carries over to students whose speech is shaped by disability.

Methodological work helps explain why such failures persist. Wojnar, Hryszko and Roman (2024) built an evaluation tool that draws on YouTube to test general-purpose ASR across languages, accents, dialects, speaking styles and audio quality levels, and applied it to 141 randomly selected videos. The tool's premise is that curated benchmarks underrepresent real-world variation. Haider and colleagues (2025) examined a related question for generative architectures. Their systematic study asked how diffusion models, generative adversarial networks and variational autoencoders internalize and replicate rare generative factors, the latent sources of variability that occur infrequently in data. Their work does not address speech disability directly. It does, however, frame the core technical concern: patterns that are rare in training data may be poorly captured. Speech from people with motor-speech disorders, stuttering or atypical prosody is rare in this statistical sense.

The disability-specific extension is therefore well motivated. The direct evidence base for school-age speakers with communication disabilities, however, is considerably thinner than the evidence on race and accent. How large the accuracy gaps are for these students in classroom conditions remains unclear.

For AAC users, the risks are shaped less by transcription and more by prediction and generation. Guo and colleagues (2020) identify language prediction for people with speech or cognitive disabilities as a motivating use of AI. Prediction carries a structural tension, though. A model that proposes the most probable next word or phrase favours typical phrasing, typical topics and typical registers. An AAC user who accepts suggestions gains speed but may lose idiosyncrasy, humour or precision. The resulting message can drift toward what the model expects rather than what the person meant. Large language models make this tension more acute because they can expand a few selected symbols into fluent sentences. The output reads well, but its authorship is shared in ways that are hard to see.

Disabled people's own assessments of generative models show why that fluency should not be mistaken for neutrality. Gadiraju and colleagues (2023) conducted 19 focus groups in which 56 participants with disabilities probed a dialogue model about disability, then discussed and annotated its responses. The study's purpose was to identify categories of harm that large language models perpetuate toward the disability community. It extended earlier research that had concentrated on age and race. The title phrase, "I wouldn't say offensive but...", captures something important for schools. Many harms are not overt slurs but subtler framings that are still damaging. When such a model mediates an AAC user's expression, or produces classroom materials about disability, those framings can enter a student's voice or curriculum without anyone noticing.

Optimistic accounts deserve a fair hearing. Lopez-Gazpio (2025) reviews trends suggesting that large language models could reduce barriers related to language diversity, learning disabilities, cultural differences and socioeconomic inequality, personalizing content and responding to learners' educational and emotional needs. That potential is real, and it connects to Universal Design for Learning approaches discussed elsewhere (see Q313). The disagreement in the literature is therefore one of emphasis and evidence rather than outright contradiction. Advocates point to transformative capacity. Disability-centred studies show that the same models can reproduce the stereotypes disabled students already face. Neither strand yet offers controlled classroom evidence on outcomes for AAC users specifically.

Bias against neurodivergent communication styles is the least directly evidenced of the three harms. It is also the one most likely to operate unnoticed. Autistic students, students with ADHD and students with language-processing differences may write or speak in ways that are direct, literal, highly detailed, repetitive or organized unconventionally. Generative systems

increasingly serve as feedback engines, rewriting assistants and conversational tutors in schools. They may treat these features as stylistic problems to fix rather than legitimate variation. Trewin and colleagues' (2019) caution applies directly. Schools already judge communication against neurotypical norms in many non-AI ways. A tool trained on majority writing and deployed to give feedback can automate those judgements at scale, and its apparent objectivity makes them harder to contest.

Integrity regimes create a second risk. Zdravkova (2026) describes how large language models complicate the verification of independent work. Universities increasingly require disclosure of AI use, but the scope and implementation of these requirements remain inconsistent, and disclosed interactions are of uncertain reliability as evidence of authentic authorship. These ambiguities fall unevenly. A student who composes through predictive AAC, speech-to-text or assistive rewriting may be unable to separate their own contribution from the tool's in the way disclosure policies assume. Unusual phrasing may invite suspicion where conventional phrasing would not. Schools therefore need integrity policies that recognize assistive composition explicitly. Those policies should be written with special education staff, and accommodations should be documented through the procedures and privacy safeguards that govern individualized plans (see Q316).

The evidentiary limits are clear. Few studies have directly measured how generative feedback tools score or rewrite neurodivergent writing, or how classroom speech systems handle autistic prosody. The concern rests mainly on analogy with documented disparities for race, accent and disability more broadly, together with what disabled participants report about language models. That inference is reasonable, but it is not yet demonstrated for these specific populations. How large and how consequential these effects are in schools remains unclear.

Mitigation starts with institutional practice rather than technical repair, because schools rarely control model training but always control deployment. The multi-level account of bias offered by Cicatiello and Fusco (2026) implies that interventions at the institutional and accountability levels are open to schools even when the data and architecture are not.

The first practice is local evaluation. Wojnar and colleagues (2024) show that general-purpose ASR performance varies across speaking styles and recording conditions that standard benchmarks underrepresent. Before adopting a captioning, dictation or voice-interaction tool, a school should therefore test it with consenting students whose speech reflects the actual

population: students who stutter, students with dysarthria, AAC users who also vocalize, and speakers of local dialects. Results should be reported by group, not as an average. This mirrors the wider case for independent audits of educational AI (see Q094).

The second practice is to keep humans accountable for consequential decisions. A misrecognized utterance should never alone produce a reading score, a participation grade, a behavioural flag or an integrity accusation. Speech-based assessment and automated writing feedback should stay advisory where students with communication differences are involved. Teachers also need enough understanding of how models generate output to recognize when a system is likely to fail. Kalota's (2024) primer argues that educators need grounding in machine learning, deep learning and large language models precisely so they can judge these tools rather than defer to them.

The third practice is to preserve alternatives and student control. Students should be able to decline voice interfaces without penalty, switch off predictive suggestions, and have their own phrasing respected in assistive composition. For AAC users this includes the right to retain idiosyncratic vocabulary rather than accept normalized output. Where captioning serves deaf and hard-of-hearing students, schools should treat automated captions as provisional and provide correction routes. The broader landscape of multimodal access for these learners is discussed elsewhere (see Q315).

The fourth practice is participatory governance. Guo and colleagues (2020) and Trewin and colleagues (2019) ground their recommendations in the experience of people with disabilities. Gadiraju and colleagues (2023) show that disabled users can identify subtle model harms that developers may miss. Schools can apply the same principle by including disabled students, families and AAC specialists in procurement panels, pilot reviews and incident reporting. Reports of misrecognition or harmful outputs should go back to vendors as contractual obligations rather than informal complaints.

Several cautions temper both alarm and optimism. Research on generative text-to-image systems offers an analogy. Currie and colleagues documented gender-skewed depictions of medical students (2024) and of cardiologists (Currie, Chandra and Kiat, 2024) in a widely used image generator. Those studies concern gender rather than disability or speech. Together with the disability-specific findings of Gadiraju and colleagues (2023), they show that generative models can reproduce societal patterns even where reality has moved on, and that

representational bias needs checking case by case rather than assuming it away. Schools that use generative tools to produce materials depicting disabled people should review those outputs as carefully as they review transcription accuracy.

The central unresolved question is whether newer, larger speech and language models narrow the gaps for atypical speakers or only shift where they appear. The documented racial disparities in ASR (Koenecke et al., 2020) and the concern about rare generative factors (Haider et al., 2025) suggest that scale alone does not guarantee equity. Optimistic accounts of personalization (Lopez-Gazpio, 2025) suggest that adaptation may eventually help. The current evidence does not show which tendency will prevail for students with communication disabilities. Nor does it show the longer-term educational effects of repeated machine misunderstanding on these students' confidence, participation or language development. Jeon and colleagues' (2024) attention to learner attitudes points toward that question but does not settle it for disabled learners.

The defensible position for schools is to treat speech and generative AI as accommodations whose fairness must be shown for each student and each tool. Equitable performance should be presumed only once local evidence supports it. Students who communicate differently must not be the last to be tested and the first to be misjudged.

Q226 How should AI-mediated laboratory simulation and coding assistants be designed and evaluated in STEM education?

13 citations · 13 sources · 5 cross-references

Claim 1 emerging

AI-mediated laboratory simulations and coding assistants in STEM education should be designed to scaffold students' own inquiry and reasoning rather than to supply answers. They should be combined with physical, hands-on and social learning, not substituted for it. And they should be evaluated with designs that measure independent competence, differences between groups of learners and the continuing accuracy of the underlying models, rather than engagement or task completion alone. This prescription rests on a field that is developing quickly but unevenly.

AI applications in science, technology, engineering and mathematics now include intelligent tutoring systems, adaptive platforms, virtual laboratories, AI-powered coding assistants and learning analytics tools. Reviews in several languages describe a broad pedagogical shift away from static, teacher-centred instruction toward adaptive, data-driven and inquiry-based learning environments. One example is a French-language synthesis of simulation, virtual laboratories and coding assistants in STEM teaching. Its more ambitious framing casts AI as a "cognitive mediator" rather than an automation tool. On this view, AI could move students from procedural correctness toward metacognitive regulation and critical evaluation of algorithmic outputs. That framing is best read as an aspiration that current evidence supports only in part.

Two recent syntheses widen the frame without settling it. Yáñez León, Lipuma and Oviedo Torres (2025) systematically reviewed 41 peer-reviewed publications on how AI has been integrated into STEM educational ecosystems. They report that AI has influenced instructional design, learner agency and ethical frameworks. They also report that integration raises unresolved questions of pedagogical coherence, assessment reform and algorithmic ethics.

Pacheco Olea and Villacís-Macías (2026) analysed the STEM literature from 2016 to 2025, tracing productivity patterns, leading countries and journals, thematic clusters and the integration of machine learning, virtual and augmented reality and generative language models. Their analysis foregrounds methodological gaps alongside applications. That such reviews now exist shows the field is maturing. Their emphasis on gaps and open questions shows how far it still has to go.

Confident claims about a single pooled effect size for AI-supported STEM instruction are not yet warranted. Tian (2026) conducted a PRISMA-guided scoping review of 37 studies of generative AI coding tools in university computing education, published between 2022 and July 2026. Evidence on educational effects was scattered across studies that differ in interaction patterns, instructional designs, assessment practices and learning contexts. That heterogeneity makes aggregate statements about "what works" hazardous.

Farooq, Morganti and Anwar (2026), in a narrative review, set interest in AI code assistants against a practical pressure. Programming is now taught across the humanities, social sciences and engineering as well as computer science. Enrolments are rising, and instructors struggle to support students from diverse backgrounds at scale. For younger learners, Yusvana and Papadakis (2026) observe that the importance of foundational computational thinking skills is well established: decomposition, pattern recognition and algorithmic thinking. Effective strategies for teaching those skills, however, remain fragmented. Whether AI is most effective at particular educational levels or in particular disciplines therefore remains unclear rather than settled.

The field's methodological limitations matter as much for design as its findings. Much of the research relies on non-experimental designs, small samples and short interventions, often lasting less than four weeks. Recent work illustrates the pattern. Zhao and colleagues (2026) studied 78 eighth-grade students aged 13 to 15 at a single public secondary school during a four-week Python course supported by an AI coding assistant. The study is valuable because it examines process-level mechanisms, including learning performance, behavioural patterns and cognitive patterns, rather than outcomes alone. Its scale and duration nonetheless limit what it can show about durable learning.

Ali and colleagues (2025) surveyed 311 undergraduate computer science students in Mexico across different semesters. They used an extended technology acceptance model to examine

trust, learning motivation and perceived reliability. Designs of this kind illuminate why students adopt these tools. They cannot show whether adoption improves learning, and associations between trust and acceptance are correlations, not causal effects on competence. The global distribution of this research is also poorly mapped. Bibliometric work such as that of Pacheco Olea and Villacís-Macías (2026) begins to identify which countries dominate output, but whether findings transfer across education systems remains unclear.

A second persistent problem is the gap between technical capability and pedagogical integration. Alanazi and colleagues (2026) studied faculty perspectives on AI coding assistants. They argue that the tools' educational value depends on pedagogical alignment, institutional readiness and faculty practice, not merely on what the technology can do. They also find that existing adoption frameworks inadequately address these pedagogical and institutional dimensions in domain-specific contexts, and they propose an AI Coding Assistant Adoption Framework in response. The STEM-wide review by Yáñez León and colleagues (2025) reaches a compatible conclusion at a broader level. Pedagogical coherence and assessment reform are open problems of integration, not side effects that capable tools resolve on their own.

A third problem is rarely addressed in STEM-specific work: the reliability of the AI models themselves. Verma and colleagues (2025) evaluated an AI model designed to identify the characteristics of engaging teaching videos. They argue that AI models used in education must be rigorously evaluated to ensure reliability and effectiveness. That evaluation must also continue, because model accuracy cannot be assumed to remain stable over time. Simulations diagnose misconceptions and assistants explain code. A model whose accuracy drifts would quietly degrade the feedback on which learning depends, and neither teacher nor student would necessarily notice. The algorithmic ethics concerns raised by Yáñez León and colleagues (2025) point in the same direction, since a tool whose behaviour is opaque is harder to hold to account when it errs. Wider systemic risks to model quality, including degradation from synthetic training data, are discussed in Q161 (see Q161).

Virtual laboratories are digital platforms that replicate real-world laboratory environments, and they are among the most significant applications of AI in STEM education. Simulations let students explore phenomena such as molecular interactions, physical forces and chemical reactions in safe, repeatable environments. They support inquiry that would be costly, dangerous or impossible with physical apparatus. Platforms such as Labster, PraxiLabs and PhET are widely discussed as having positive effects on motivation, engagement and learning

outcomes. Readers should distinguish carefully, however, between independent research and efficacy claims published by or for platform providers. Much of the favourable evidence concerns motivation and engagement rather than demonstrated conceptual gains, and no vendor figures should be treated as research findings.

The most consistent conclusion is that virtual laboratories work best as complements to physical laboratory work, not as complete replacements. Virtual labs can teach procedural knowledge, theoretical concepts and analytical skills well. They cannot reproduce the tactile experience of handling physical apparatus, which is educationally valuable in its own right. That experience includes calibrating instruments, coping with messy data, noticing anomalies and developing the practical judgement that experimental science requires. The design implication is a sequence rather than a choice. Simulation first prepares students for the bench, so that scarce laboratory time goes to investigation rather than orientation. It then extends physical work beyond what resources allow: more trials, wider parameter ranges, and phenomena at scales or speeds no school laboratory can reach. The broader near-term prospects for AI in embodied, laboratory and practical subjects are assessed in Q159 (see Q159).

AI-enhanced simulations aim to add value beyond traditional virtual labs through adaptive guidance, real-time feedback on student reasoning and personalised scaffolding. In principle, intelligent agents within a simulation can detect misconceptions, offer targeted explanations, and adjust difficulty and complexity in response to performance. Simulation would then shift from a static microworld to a responsive tutor. The evidence for this AI layer is thinner than for virtual laboratories in general. Whether adaptive agents improve learning beyond well-designed but non-adaptive simulations remains unclear. Their diagnostic value also depends on the accuracy concerns raised by Verma and colleagues (2025). A misconception detector that misfires may entrench the very errors it was built to correct.

Generative AI is also changing who can build simulations. Munoz and Rook (2026) present a case study of a postgraduate operations management course redesigned around simulation-based learning to strengthen analytical and decision-making skills. Educators used large language models to generate and test the simulation code, a practice described as "vibe coding". The authors note that practical guidance on such uses remains limited. This is a single case from management education rather than a controlled evaluation. It nonetheless suggests that the cost of producing bespoke, curriculum-aligned simulations may be falling. Instructors who can build and adjust their own simulations may integrate them with physical laboratory sequences

and local goals more readily than those relying on off-the-shelf products. The same process makes validation more pressing, because AI-generated simulations may contain modelling errors that neither educator nor student detects.

Integration with physical and social activity matters especially for younger learners. Yusvana and Papadakis (2026) identify hands-on inquiry and game-based learning among effective strategies for early computational thinking and coding. AI-mediated simulation is then one strand in a pedagogy that remains materially and socially grounded, not a substitute for it. Parallel questions about AI and embodied practice in physical education are discussed in Q232 (see Q232).

AI coding assistants provide real-time code completion, error detection and explanation. They are ubiquitous in professional software development and increasingly used in computing education. Alquran and Banitaan (2026) describe large language model tools such as GitHub Copilot, ChatGPT and DeepSeek as introducing a new form of human–AI collaboration, offering code suggestions, debugging assistance and design support. The authors stress that effects on learning, trust, productivity and coding practices remain underexplored. Their own study approaches the question through student perspectives rather than outcome measures.

The central design risk is that an assistant completes the cognitive work the exercise was meant to elicit. A student who accepts a working suggestion without understanding it may pass the assignment without acquiring the decomposition, tracing and debugging skills the course targets. For this reason, Tian's (2026) scoping review treats three matters as distinct questions: student–AI interaction patterns, task-level instructional strategies, and assessment and academic integrity. The same tool can support or undercut learning depending on how tasks are framed and work is assessed. Several design choices follow. Assistants can be configured to explain errors and ask guiding questions before offering code. Tasks can require students to critique or extend generated solutions. Assessments can include oral explanation or unassisted components.

Learner differences complicate any single design. Zhao and colleagues (2026) examined how students' computational thinking levels shape performance, behaviour and cognition with an AI coding assistant. Their premise was that overall outcomes can conceal different process-level mechanisms for different learners. A tool that accelerates students who already reason algorithmically may encourage dependence among those who do not. Ali and colleagues (2025)

identify trust and perceived reliability as conditions of adoption. This implies that calibrated trust is itself a learning goal, avoiding both blanket acceptance and blanket suspicion. Farooq and colleagues (2026) frame code assistants as a response to supporting diverse students at scale. Scale benefits learners only if support reaches weaker students in forms that build competence rather than bypass it. Alanazi and colleagues (2026) add that these choices rest with faculty and institutions as much as with tool designers.

Evaluation should follow from these design commitments. The first requirement is to measure independent competence. Engagement, satisfaction or completion of assisted tasks say little about what students can do once the assistant or simulation is removed. Delayed post-tests, transfer tasks, unassisted practical assessments and, for laboratory work, performance at the physical bench give a truer picture. The second requirement is to report outcomes for subgroups, including prior attainment, computational thinking level, and access to devices and connectivity, so that average gains do not mask widening gaps. Process data of the kind Zhao and colleagues (2026) collected, such as behavioural and cognitive patterns during assisted work, can show how differences arise rather than only that they exist.

The third requirement is continuing technical evaluation. Verma and colleagues (2025) argue that educational AI models need ongoing scrutiny of their accuracy. In STEM, that scrutiny applies to the explanations an assistant gives and the diagnoses a simulation makes, not only at launch but after every model update. The fourth requirement is attention to pedagogical and ethical implications alongside effectiveness. Alazemi and Alenezi (2026), reviewing AI for academic writing and speaking in higher education, observe that research often focuses on effectiveness without fully addressing these implications. They propose a mediated AI-pedagogy cycle in response. Their domain differs, but the lesson transfers to STEM. An evaluation that shows a tool raises scores without asking what students stopped practising is incomplete. Yáñez León and colleagues (2025) reinforce the point from within STEM by identifying assessment reform and algorithmic ethics as integral to integration rather than downstream of it.

Finally, claims about AI-mediated simulation and coding support cannot move from emerging to established without stronger designs. These require longer interventions, multi-site samples and comparison conditions that include well-designed non-AI alternatives. Tian's (2026) mapping of heterogeneous designs and the methodological gaps that Pacheco Olea and Villacís-

Macías (2026) identify across a decade of STEM research both show how much of that work remains.

Q232 How is AI transforming physical education and sports science pedagogy in schools and universities?

12 citations · 12 sources · 5 cross-references

Claim 1 emerging

AI is changing physical education (PE) and sports science pedagogy mainly by turning human movement into analysable data. Computer vision and pose estimation now offer feedback on technique. Machine learning promises personalised training prescription and injury-risk prediction. Wearable sensors feed instructional dashboards. More recently, generative AI has entered the cognitive side of the subject as a study and research tool. The change is real but uneven, and the evidence behind it is considerably thinner than the enthusiasm.

PE and sports science are a distinctive frontier because learning there is embodied, kinetic and social. What is being taught is the moving body in a shared space, not a text or a problem set. That makes the field both promising and difficult terrain for systems built largely around data that can be captured, quantified and compared.

Much of the technology arrives from elite sport. Mănescu (2025) describes AI as a constant presence in elite training, where it enables performance analysis, personalised training and injury prevention. He judges its transfer to school sport to be still at an early and insufficiently

documented stage, although it has begun to gain visibility. That judgement frames everything that follows.

Two strands of development should be kept apart. The first is analytic AI: systems that sense, model and predict physical performance, drawing on biomechanics and exercise physiology. The second is generative AI: large language models that students and staff use to read, write, plan and synthesise evidence. Shahzad and colleagues (2025) analysed Web of Science and Scopus records from 2015 to 2025. They frame generative AI as reshaping education through personalised learning and changed teaching methods. A bibliometric study, however, maps publication trends and thematic clusters. It shows where scholarly attention has gone rather than demonstrating learning gains, and it does not single out PE.

This answer therefore separates three things: what is technically feasible, what is being piloted, and what has been shown to improve learning. In this field the three diverge sharply. Several widely circulated claims, including some made in an earlier version of this answer, rest on evidence that could not be verified. They are treated here as open questions rather than findings.

The most visible change is in movement analysis. Pose-estimation technologies analyse student movement from ordinary video, increasingly in real time. Some are built on open frameworks such as MediaPipe and OpenPose; others are proprietary platforms. They give feedback on technique, form and efficiency that was previously available only through expert coaching. Work on computer vision for movement analysis in PE, published in the Journal of Science and Medicine in Sport in 2024, documents this capability and its application to school settings.

In principle, such systems can flag biomechanical errors in running gait, throwing mechanics or swimming stroke, and return corrective feedback to the student, the teacher or both. The appeal is clearest for complex motor skills, where visual feedback is hard to deliver in the moment. A single teacher supervising a full class cannot watch every attempt at a javelin throw or a tumbling sequence, let alone slow it down and annotate joint angles. A camera-based system can. This is one instance of the broader multimodal turn in learning beyond text (see Q095).

Zhang (2025) describes a web-based university PE platform that combines motion capture and machine learning. It delivers real-time biomechanical feedback and adapts training through what the author calls a closed-loop mechanism. The abstract reports significant improvements in skill acquisition and in the optimisation of physiological load. It does not state the sample

size, the comparison condition or the effect sizes. The study therefore suggests benefit but cannot settle the comparative question.

That question is whether AI-assisted biomechanical feedback speeds up motor learning compared with traditional instruction alone. An earlier version of this answer stated that research demonstrates such acceleration. On the verifiable evidence, that claim cannot be sustained, and the comparative effect in school and university PE remains unclear. There are further reasons for caution. Motor-learning scholarship has long debated whether frequent, immediate augmented feedback supports durable learning or creates dependence on the feedback source. In crowded gymnasia and pools, the accuracy of pose estimation also depends on camera placement, lighting and occlusion.

The firmest evidence for AI feedback comes from a quite different domain, and the contrast is instructive. Duan and Wang (2026) studied 400 undergraduate English-as-a-foreign-language learners at Guangdong University of Foreign Studies. They used a sequential explanatory mixed-methods design, followed by interviews with 30 purposively selected students. After generative-AI-assisted writing feedback, mean post-test scores far exceeded pre-test scores: 94.84 against 65.12 for grammar, and 94.16 for sentence structure. These are pre–post gains, and the available abstract describes no comparison group. More fundamentally, verbal feedback on written text is not perceptual-motor feedback on a moving body. Such results cannot be transferred to motor learning by analogy, which is precisely why PE-specific controlled trials are needed.

A second set of applications concerns training prescription and injury risk. In principle, AI systems can combine individual performance data to generate personalised training prescriptions meant to optimise development while minimising injury risk. The data include heart rate, movement patterns, strength metrics and recovery indicators. The same personalisation rationale runs through the wider literature: Shahzad and colleagues (2025) identify personalised learning as a dominant theme in research on generative AI in education. In sports science, though, personalisation targets physiological adaptation rather than content sequencing, and that raises the stakes of getting it wrong.

Mănescu (2025) places personalised training and injury prevention among the core elite applications whose school transfer is only beginning. AI-driven prescription is reportedly being built into practical coursework in university sports science programmes, so that future

practitioners gain experience with tools they will meet professionally. In school PE it is more nascent, though growing, particularly where wearable technology is available. Neither trajectory is measured in the verified sources, so both are best read as descriptions of practice rather than documented trends.

Injury-risk prediction follows similar logic. Machine-learning models trained on large datasets of athlete performance and injury records look for patterns that precede injury. Coaches can then intervene early through training-load management. These models are being applied to student athletes in school and university sport programmes. Earlier claims that they reduce overuse injuries could not be verified, so whether they do so in these populations remains unclear. Injuries are relatively rare events, school and university cohorts are small and heterogeneous, and models trained on elite or professional athletes may not generalise to adolescents or recreational students. The elite-to-school pipeline that Mănescu describes makes this generalisation problem central rather than incidental.

The pedagogical implications reach beyond injury prevention. Sports science students increasingly learn to interpret and act on AI-generated risk assessments. Taught well, this builds critical data literacy. A risk score is a probability conditioned on its training data, not a diagnosis. Acting on false positives also costs an athlete participation and confidence. Arguably the most defensible educational use of these models is as objects of critical study, examined for their assumptions, rather than as authorities to be obeyed.

Affordable wearable sensors, including heart-rate monitors, GPS trackers and inertial measurement units, have opened new possibilities for data-driven instruction. AI systems that aggregate and interpret wearable data can give teachers real-time dashboards of class physical activity. Such dashboards could support differentiated instruction, for instance by identifying students who are under-challenged or over-exerted. They could also support more evidence-based assessment of effort and fitness.

Movement-analysis outputs from computer vision, of the kind described in the 2024 Journal of Science and Medicine in Sport work, can in principle feed the same dashboards. The result would be an integrated sensor-to-feedback loop combining physiological and technical information.

Students can also see their own data, and advocates argue that this supports self-regulated learning and metacognitive development. Consider a student who watches her heart rate

recover across a term, or who compares her sprint mechanics before and after practice. She has material for reflecting on her own learning that PE has rarely provided. This is a plausible mechanism, but it has not been demonstrated. The claims of dashboard benefit in earlier versions of this answer rested on sources that could not be verified.

Using wearable data for assessment needs particular care. Heart-rate and activity metrics reflect body size, maturation, health conditions and disability as well as effort. Grading against them risks penalising students for their physiology rather than their learning. Real-time dashboards also change the social dynamics of a lesson by making exertion publicly visible, which may motivate some students and alienate others. Deciding what to display, to whom, and for what purpose is therefore a design question as much as a technical one.

A less discussed but fast-growing change is happening in the lecture theatre and the library rather than on the field. Generative AI is now part of how PE and sports science students study.

Alecu and Onea (2026) surveyed 1,084 full-time PE undergraduates aged 19 to 28. They examined associations between how often students reported using generative AI, their reported VARK learning-preference patterns, their attitudes toward AI, and their beliefs as framed by the Technology Acceptance Model. The authors note that PE combines embodied practice with cognitive learning, and that generative AI is increasingly used there as an academic support tool. The study is cross-sectional and based on self-report, so its findings describe associations rather than effects. It cannot show that generative AI use changes how students learn, only that use frequency travels alongside particular attitudes, acceptance beliefs and reported preferences. Even so, it locates generative AI inside PE degree programmes as an everyday reality rather than a speculative future.

The study also exposes a tension. VARK-style preferences are contested, and designs that match instruction to supposed preference types have weak support in the broader learning sciences. Reported preferences are better treated as descriptions than as prescriptions.

Önal and colleagues (2026) extend this survey tradition. In a correlational design, they studied 407 students (54.8% female, 45.2% male) in physical education teaching, coaching education and recreation at a state university's Faculty of Sports Sciences. They examined how attitudes toward AI relate to critical thinking tendencies and social intelligence, and whether these differ by gender and department. The design again permits associations only. Its significance lies in

treating critical thinking and social capacities, central to coaching and teaching, as relevant to how future practitioners approach AI.

Generative AI also touches the research-facing side of the curriculum. Oettl and Mudford (2026) argue that research communication is moving from the static linear manuscript toward 'living publications'. These are interactive platforms that use large language models and vector databases to synthesise new findings and map interdisciplinary connections as evidence accumulates. Theirs is a position piece about scholarly communication rather than an evaluation of teaching, but its relevance is direct. Sports science students are trained to appraise a fast-moving evidence base on training, nutrition and injury. If that evidence is increasingly reached through AI-mediated synthesis, appraisal must extend to how a system retrieved, weighted and summarised the underlying studies.

Such tools promise faster access to evidence. They also risk confident summaries that flatten disagreement between studies, a concern sharpened by synthetic-content saturation (see Q161). Teaching students to trace a synthesised claim back to its primary sources is a reasonable response to both possibilities.

Several questions cut across all of these applications, and the verified evidence on them is thinnest of all.

The first is equity. Camera systems, wearables and analytics subscriptions cost money, so AI-enhanced PE is likely to arrive first in well-resourced schools and universities, potentially widening existing gaps in provision. Systems calibrated on narrow populations may also perform worse for students whose bodies, movement patterns or disabilities differ from the training data. Claims about equity effects in earlier versions of this answer could not be verified, so these are risks to monitor rather than documented outcomes. Alecu and Onea's (2026) finding that use frequency is associated with attitudes and acceptance beliefs is a reminder that engagement with AI tools is not uniform. Uneven uptake may itself shape who benefits.

The second is datafication. Turning movement and exertion into continuous data streams changes what counts as achievement in PE. It privileges the measurable over enjoyment, creativity, cooperation and movement for its own sake. It also raises questions of consent, retention and surveillance, especially for minors whose biometric data are collected in compulsory lessons.

The third is teacher capacity. Every application described here assumes teachers who can interpret model outputs, recognise their limits and decide when to override them. Wang and Wang (2024) argue in a review that AI can participate in formulating teaching strategies, tracking teaching processes and evaluating outcomes in PE. They also argue that this places new demands on PE teacher quality and requires dedicated teacher-training strategies. Evidence on current readiness is sparse and not PE-specific. Bohara and Rana (2024) interviewed twenty teachers in ten urban Nepali schools and found mixed perceptions of AI, spanning both challenges and opportunities for pedagogical change.

Personalisation engines add a further demand on teacher judgement. Recommendation systems that learn from user feedback, such as those Aribas and Daglarli (2024) describe for personalised travel planning, refine themselves over time. In PE, someone must judge whether that refinement serves learning or merely engagement. Professional development in data literacy for PE teachers, and AI competencies in sports science curricula, are widely discussed but scarcely documented. Shahzad and colleagues (2025) record rapid growth in research on generative AI in education, yet growth in publications is not growth in classroom competence.

Taken together, AI is transforming the tools available to PE and sports science far faster than the evidence about their pedagogical value. The most defensible stance for schools and universities is to pilot carefully, evaluate against non-AI instruction, protect student data, and teach students to question these systems as much as to use them. Santi and colleagues (2025) offer one model for such evaluation. Their researcher–practitioner protocols co-design experimental training set-ups that test theory-derived hypotheses by deliberately disrupting ordinary practice. Approaches of this kind could turn today's pilots into the weak signals worth watching (see Q100).

Q319 In K–16 Computer Science education, how must introductory programming shift from syntax-writing to code reading, architectural specification, testing, and debugging when AI coding assistants generate boilerplate code?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

When AI coding assistants can produce boilerplate on request, introductory programming should not abandon code writing. It should move the centre of instruction from producing syntax to judging code. Students need to learn to read programs they did not write, to state what a program must do before any code exists, to write tests that settle whether it does so, and to diagnose failures in code whose origin they cannot trust. Hand-written code stays in the curriculum, but as one way of building understanding rather than as the main thing being assessed. The computing education community saw this pressure early. Becker and colleagues (2023), in a position paper titled "Programming Is Hard - Or at Least It Used to Be," argued that freely available AI code generators create immediate opportunities and challenges for the introductory sequence. They urged the field to act quickly in deciding which opportunities to use and how to mitigate the challenges. Prather, Denny, Leinonen and colleagues (2023), reporting for an international working group, described the urgent questions these tools raise about how educators should adapt their pedagogy, given that large language models can now interpret and generate both natural language instructions and source code. The research has expanded quickly since then. Kamalı-Arslantaş and Yürüm (2026) analysed 1,186 Scopus-indexed articles on AI in programming education published between 1977 and 2025 using semantic topic modelling, which shows how long-standing and how recently intensified the scholarly interest is. Farooq, Morganti and Anwar (2026) add a structural reason the shift matters beyond computer science majors. Programming is now taught across the humanities, social sciences and engineering, and enrolments keep rising. Instructors must therefore support students with diverse backgrounds at scale, which is exactly where AI code assistants are being proposed as aids.

The first problem is that tools which save experts effort can remove the effort that novices need in order to learn. Kazemitabaar and colleagues (2023) framed their CHI study around this tension. They noted that AI code generators can help novices by turning natural language

descriptions into code, but that over-reliance might harm learning and retention. Their design is instructive for the reorientation argued here. Sixty-nine novices aged 10 to 17 worked through 45 Python code-authoring tasks, half of them with access to Codex. Each authoring task was followed by a code-modification task completed without generation. The modification task was the real test of learning, because changing code requires reading it and understanding how it is built. The study is also one of the few controlled experiments in this area with school-age learners rather than undergraduates.

Evidence from outside computing points the same way. Bastani and colleagues (2025) ran a field experiment that gave nearly a thousand high school mathematics students access to generative AI tutors. Their title states their conclusion: generative AI without guardrails can harm learning. Their framing matters for computing. Because generative AI is fallible and users must check its outputs, learning remains critical even as productivity rises. A student who cannot check generated code is not saved effort. They are handed a liability they cannot see. Chakraborty (2026) reports a related split within a programming course. Across four experiments testing AI in different roles, students who used AI as a tutor reported higher motivation, programming self-efficacy and computational thinking, yet AI use did not improve examination performance. Students feeling more capable without performing better is exactly the risk a syntax-light curriculum must guard against.

The practical conclusion is about sequence. Manual coding should come first, and assistance should be introduced in a deliberate order. The argument parallels the case made for manual exposure control in photography before AI-assisted editing (see Q291). Novices need enough experience of writing loops, conditionals and functions by hand to have a mental model against which generated code can be judged. How much hand-coding is enough remains unclear, and the evidence cannot yet answer that question for any particular age group.

If students will meet far more code than they write, code reading has to become a core literacy rather than an incidental skill. Goodfellow and colleagues (2026) start from a familiar observation: students often understand only part of the code they produce, and the gaps may not surface until later in their studies, when misconceptions are harder to correct. They argue that deep code understanding becomes more critical once learners can use tools such as GitHub Copilot. Their response builds on an established practice, posing targeted questions about a student's own submission, and uses generative AI to support that questioning. This turns the generator from a source of answers into a source of comprehension probes. The student must

explain why a branch exists, what a variable holds at a given point, or what would happen if an input changed.

Sarmento and Reis (2026) take a similar approach with younger learners. Their exploratory mixed-methods study in vocational secondary education used code comments as a pedagogical scaffold for novices who had trouble understanding code structure, identifying errors and turning problem statements into algorithmic solutions. Commenting is a low-tech practice, but its value grows when code is machine-generated. Annotating someone else's program, line by line or block by block, is a disciplined form of reading that makes a student's understanding visible to teachers. The study is exploratory, and it shows that the approach can be done rather than that it causes better outcomes.

Code reading can also be framed more broadly as critical literacy. Burriss and Leander (2024) argue that critical literacy theory, combined with posthumanist ideas and some technical knowledge, can ground how people read, write and live ethically with everyday AI. Applied to programming, this means treating generated code as a text with an author, assumptions and possible errors, rather than as a neutral artefact. Literature teaching is defending close reading against instant summarisation in much the same way (see Q323). In both fields, the reader who can only accept a machine's output has lost the interpretive work that defines the discipline.

The second part of the shift is architectural specification: deciding, before generation, what the program is for, how it divides into parts, and what each part must guarantee. This was always part of good introductory teaching, but it was often crowded out by the work of getting syntax to compile. Once generation removes much of that friction, decomposition and interface design can become an explicit focus earlier. Students can be asked to write function signatures, describe inputs and outputs, and set out constraints in plain language, which is effectively the prompt. They then judge whether the generated code honours that design. A vague specification produces vague code, and students can learn this directly by comparing results.

Testing is how a specification becomes enforceable, and it should move from a late-semester add-on to a habit taught from the first weeks. Zampirolli and colleagues (2025) show one infrastructure for this. Working in an interdisciplinary science and technology bachelor's programme, they used the Virtual Programming Lab plugin for Moodle to give students parameterised exercises that generate unique problem instances and test cases for each individual. An embedded system drawing on seven widely used large language models then

analysed student code and gave automated feedback on each correction request. Individualised test cases make simple copying less useful, and they keep the test suite, rather than the code, as the measure of correctness. A natural next step, not yet well studied, is to have students write the tests themselves before asking a tool for an implementation. The quality of a student's tests would then become evidence of how well they understand the problem.

Project-based structures may give specification work a real setting. Omeh and Ayanwale (2025) ran a quasi-experiment with a non-equivalent pretest–posttest control group of 87 second-year undergraduates in computer robotics programming courses at Nigerian universities. They examined whether AI-supported problem-based learning improves engagement, intrinsic motivation and academic achievement. Robotics makes specification concrete, because a robot that does the wrong thing physically shows that the requirements were misunderstood. Educators using AI in project work still face the risk, discussed elsewhere in this volume, that the tool shortens the messy inquiry phase where problems are actually framed (see Q328). Specification is that inquiry phase in computing, and it should not be handed to a tool.

Debugging is the third part, and generated code changes its character. A novice debugging their own code is usually tracing errors they made themselves. A novice debugging generated code faces programs that look fluent and idiomatic and may be subtly wrong in ways their own code would never be. The skills involved are forming hypotheses about failure, isolating a minimal failing case, reading error messages, and stepping through state. These skills are largely independent of who wrote the code, which makes them durable targets for instruction. The difficulties Sarmento and Reis (2026) document among vocational secondary students, especially identifying errors, are the same difficulties a debugging-centred curriculum would address directly. Exercises can be built around deliberately flawed generated code, where the student's job is to find the defect, explain it, and write a test that would have caught it.

Assessment has to change to match, or the curriculum will not change in practice. If marks reward working code, and working code can be generated, grades will measure access to tools rather than competence. The comprehension questioning Goodfellow and colleagues (2026) describe offers one alternative: asking students to account for submitted code, so that understanding rather than output becomes what is evaluated. Chakraborty's (2026) finding that AI-as-tutor improved self-reported motivation and self-efficacy without improving examination performance is a warning against relying on students' own views of their learning. Measures must capture what students can actually do without assistance, or with assistance whose

contribution can be separated out. The broader argument that rubrics should shift weight away from surface fluency once fluency is free applies directly to code (see Q309). Points should move from correct syntax and passing output toward the quality of specifications and tests, the accuracy of explanations, and the soundness of debugging reasoning.

Automated feedback systems such as the one Zampirolli and colleagues (2025) describe raise a further design question. Feedback generated by language models is itself a form of assistance. Whether it builds students' own diagnostic ability, or simply replaces it with a faster external check, depends on how the feedback is designed and timed. Current evidence does not settle this.

The case for this reorientation is strong in principle, but the empirical base is thinner and more uneven than the confidence of the debate suggests. Yalçın and colleagues (2026) systematically reviewed 46 peer-reviewed empirical studies of generative AI in programming education following PRISMA guidelines. They describe the research as fragmented, and their review is limited to higher education, which shows where most of the evidence comes from. Farooq, Morganti and Anwar's (2026) narrative review of AI code assistants likewise sets the research mainly in the context of scaling instruction for diverse learners. For the K–12 end of the K–16 range, the evidence comes from a small number of studies. These include the controlled experiment with learners aged 10 to 17 by Kazemitabaar and colleagues (2023), the exploratory vocational secondary study by Sarmento and Reis (2026), and, by analogy from mathematics, the high school field experiment by Bastani and colleagues (2025). This is not enough to set age-specific sequences with confidence.

Several questions remain open, and they should be named directly. It remains unclear how much hand-written code novices need before code reading and specification can carry the main learning load. The answer probably differs between a ten-year-old and a university first-year. It also remains unclear whether gains in motivation and self-efficacy from AI support turn into lasting competence. Chakraborty's (2026) results suggest they may not, at least as examinations measure it. The literature is genuinely divided between those who emphasise the risks of over-reliance and those who emphasise opportunities for scale and personalisation. Prather and colleagues (2023) and Becker and colleagues (2023) both hold these views together rather than resolving them. Few studies yet follow students over time to see whether those taught through reading, specifying, testing and debugging become stronger programmers later than those taught mainly through writing.

The defensible position for curriculum designers is a deliberate sequence. Students should first build a foundation in hand-written code sufficient to support judgement. Code reading and explanation should become regular, assessed practices. Specifications and tests should be required before generation is allowed. Debugging should be taught explicitly on code students did not write. Assessment should be redesigned so that understanding, not output, earns credit. The aim is not to protect old skills from new tools, but to make sure students can still check whether a program is right when a machine has written it.

Q320 In Mathematics education, how do neuro-symbolic solvers and step-by-step tutoring models affect conceptual number sense, proof construction, and productive struggle?

12 citations · 12 sources · 3 cross-references

Claim 1 disputed

Neuro-symbolic solvers and step-by-step tutoring models can sustain procedural learning gains. Their effects on conceptual number sense, proof construction and productive struggle depend far more on when and how they intervene than on how well they solve problems. The evidence is uneven. On one side, controlled studies suggest that machine-generated hints can match human-authored hints for short-term skill acquisition, and a large body of research demonstrates that students who struggle with a problem before receiving instruction tend to learn new concepts better. On the other side, field evidence suggests that unguarded generative assistance can depress learning when the assistance is removed. Machine provers can now solve olympiad-level geometry problems, but there is very little classroom evidence about what such systems do to a learner's own capacity to construct an argument. The resulting picture is consistent but uncomfortable. The pedagogical value of an AI system in mathematics is inversely related to how readily it closes the gap between a learner's question and the answer, at least during the phase in which understanding is being built.

The question's three outcomes sit at different distances from the available evidence. Conceptual number sense covers flexible reasoning about magnitude, decomposition, estimation and the structure of operations. It is the least directly studied, because most efficacy trials measure performance on algebra or statistics items rather than the quality of quantitative intuition. Proof construction involves selecting representations, generating auxiliary constructions and justifying inferences. It has attracted spectacular demonstrations from automated reasoning but little learning research. Productive struggle is well theorised and well tested, but mostly with human-designed tasks rather than AI tutors. A responsible synthesis must therefore combine strong evidence about learning design with emerging evidence about AI tools, without letting the strength of the former lend false authority to the latter.

The architectures matter, because the claims made on behalf of neuro-symbolic systems are partly pedagogical claims in disguise. Sinha and colleagues (2026) characterise neuro-symbolic frameworks as combining neural representation and learning with symbolic representation and reasoning. Their aim is to pair the reasoning capacity, explainability and interpretability of symbolic processing with the flexibility of neural computation, and so to solve complex problems more reliably and data-efficiently. They also observe that the field still lacks user-friendly tools, libraries and unifying frameworks, and that it imposes a steep learning curve on developers. Bougzime and colleagues (2026) make a parallel case that such architectures can

improve generalisation, reasoning and transparency in generative AI. De Boer and colleagues (2025) argue that neuro-symbolic systems built around large language models can make explicit use of expert knowledge and can be inspected by humans. Unlike purely statistical generative models, they can therefore offer explanations, though the proliferation of approaches makes them hard to compare.

For mathematics education, the attraction is obvious. A tutor whose steps are licensed by an explicit symbolic engine is less likely to assert a false algebraic identity than a fluent language model. Such a tutor can, in principle, expose why each step follows. Confalonieri and Guizzardi (2025) show how explicit knowledge structures such as ontologies can support intelligible explanations through reference modelling, common-sense reasoning and the management of complexity. Michel-Delétie and Sarker (2026) review how neuro-symbolic methods have been used to improve trustworthiness, particularly interpretability. Mileo (2025) proposes a neuro-symbolic cycle aimed explicitly at human-centred explainability.

None of this work, however, evaluates mathematics learners. Interpretability for a developer or a domain expert is not the same as an explanation that builds a fourteen-year-old's conceptual understanding. A correct, fully transparent derivation can still be a worked solution that pre-empts the learner's thinking. The neuro-symbolic literature therefore establishes a plausible engineering route to more reliable and inspectable mathematical assistance. Whether that reliability translates into deeper understanding remains unclear, because no study in this line measures student learning.

The most direct evidence on step-by-step tutoring concerns hints. Pardos and Bhandari (2024) randomly assigned 274 participants to one of three hint conditions: no hints, human tutor-authored hints, or hints generated by ChatGPT. They crossed these conditions with four subject areas spanning elementary, intermediate and college algebra and statistics. They report that ChatGPT-generated help produced learning gains equivalent to those from human tutor-authored help. The finding matters for practice because authoring hints is labour-intensive. It suggests that generative models can lower the cost of supplying stepwise support at scale.

The study's scope also defines its limits. It compares two sources of hints within a hint-based design. It does not test whether hints themselves, delivered on demand, help or hinder conceptual development relative to designs that withhold support. It measures skill gains on

problem types rather than number sense in the broader sense of flexible, estimation-rich reasoning.

Bastani and colleagues (2025) complicate the optimistic reading. In a field experiment that gave nearly a thousand high school mathematics students access to generative AI tutors, they conclude that generative AI without guardrails can harm learning. They frame the problem in terms of skill acquisition: generative AI is fallible, and users must still check its outputs. Read together, the two studies are not strictly contradictory. One isolates the quality of help content under controlled conditions. The other examines what happens when students have open access to a capable assistant during practice. But they point in different directions for policy. The disagreement turns on the conditions of use, including how much of the reasoning the tool performs and whether students can bypass their own attempts, rather than on whether the hints are accurate.

For number sense specifically, this distinction is decisive. Estimation, mental decomposition and judgements of reasonableness develop through the learner's own repeated generation of quantitative relationships. A tutor that supplies the next step forecloses exactly the moments in which a student might notice that an answer is implausible. Schindler, Cevikbas and Lilienthal (2026) find that review-level research on AI in mathematics education is fragmented across AI paradigms, system types and methods. That fragmentation helps explain why so few studies isolate conceptual outcomes of this kind. Claims that step-by-step tutors build or erode number sense should therefore be treated as hypotheses, plausible on theoretical grounds but not yet demonstrated.

Proof is where the gap between machine capability and learning evidence is widest. Trinh and colleagues (2024) report a system that solves olympiad geometry problems without human demonstrations. They note that proving theorems at that level has long been regarded as a milestone in automated reasoning. Progress has been slowed by the cost of translating human proofs into machine-verifiable form, a problem especially acute in geometry because of its unique translation difficulties and the resulting scarcity of training data. The achievement is a canonical neuro-symbolic case: neural generation proposes candidate constructions and symbolic deduction verifies them. This is precisely the division of labour that the framework literature describes in general terms.

The educational implications cut two ways. A verifier that checks each inference could serve as a patient interlocutor for students drafting proofs. It could confirm that a step is valid without supplying the next one, and so make the logical structure of argument more visible than red ink alone does. Explanation-oriented neuro-symbolic designs of the kind Mileo (2025) and Confalonieri and Guizzardi (2025) describe point towards such feedback, grounded in explicit relationships rather than opaque pattern-matching.

Yet the hardest part of proof for most learners is not verification. It is invention: deciding which auxiliary line, which case split or which representation will make the problem tractable. A system that excels at producing these constructions automates the very decision through which proof competence is acquired. If students meet such systems as answer generators, the risk resembles the fixation effects described for generative tools in the visual arts (see Q281). Learners may adopt the machine's first construction and never search the space of alternatives themselves.

No study here measures whether exposure to automated provers improves or weakens students' proof construction. The appropriate stance is therefore cautious. Machine theorem proving demonstrates what is computationally possible. What it does to the formation of mathematical argument in classrooms remains unclear.

Productive struggle supplies the strongest evidence in this discussion, and it bears directly on how AI tutors should be timed. Kapur (2008) set out the case for Productive Failure. Students first attempt novel problems they cannot yet solve, and only then receive instruction that builds on their attempts. Kapur also delineated boundary conditions for how, when and why the approach succeeds. Sinha and Kapur (2021) put the question on a quantitative footing. Their meta-analysis of 53 studies with 166 comparisons found a significant, moderate effect favouring problem solving followed by instruction over instruction followed by problem solving (Hedges' g = 0.36, 95% CI 0.20 to 0.51). Effects were stronger, with g ranging from 0.37 to 0.58, when designs adhered closely to Productive Failure principles. The authors acknowledge that the design of initial learning remains the subject of passionate debate. The meta-analysis demonstrates a reliable average advantage, but it does not settle the question for every learner, topic or level of prior knowledge.

This evidence reframes the AI question. A step-by-step tutor available from the first moment of a novel problem converts a problem-solving-first design into an instruction-first one, often

without the teacher intending it. The learner's failed attempts are what make later instruction meaningful, and an always-on assistant can pre-empt them. The concern Bastani and colleagues (2025) raise about unguarded generative AI fits this mechanism, although their abstract-level reporting does not establish that the mechanism was the cause. The equivalence result of Pardos and Bhandari (2024) is compatible with it too. That study shows that AI hints can be as good as human hints, not that hints should arrive early.

The practical upshot is that the pedagogical design question is mainly one of sequencing. Interdisciplinary inquiry faces the same problem of preserving the messy exploratory phase (see Q328). In mathematics, a well-supported principle is available: support should be withheld or kept minimal during initial generation, then used to consolidate, contrast and formalise what students have attempted.

Two cautions apply. First, the productive failure studies concern human-designed tasks and instruction; few studies have tested AI tutors deliberately programmed to delay help. Second, struggle is productive only within boundary conditions. Unbounded frustration, particularly for students with low prior success, can damage persistence and self-efficacy. The developmental evidence on agency and self-efficacy under AI tutoring is therefore directly relevant here (see Q245).

Several design commitments follow from this evidence, and several gaps remain. First, symbolic reliability should be treated as necessary but insufficient. Neuro-symbolic architectures plausibly reduce mathematical error and improve inspectability, as the framework and interpretability literatures argue (Sinha et al., 2026; de Boer et al., 2025; Michel-Delétie & Sarker, 2026). But an accurate tutor that thinks for the student offers little gain for conceptual understanding.

Second, the timing and granularity of help should be explicit design parameters, informed by the productive failure evidence (Sinha & Kapur, 2021). On this view, an AI tutor first elicits and records students' own attempts and only afterwards offers contrasting solutions or targeted hints. Schools should also use deployment guardrails that prevent wholesale answer extraction, the condition that Bastani and colleagues (2025) associate with harm. Third, verification and generation should be separated in proof tools. Systems that check a student's inference without proposing the next construction preserve the inventive work in which proof competence grows.

The gaps are substantial. Few studies have measured conceptual number sense as an outcome of AI tutoring. Most efficacy work, including the controlled comparison by Pardos and Bhandari (2024), measures performance on skill items over short horizons. Few studies have examined automated provers as instructional tools rather than as research achievements. Schindler and colleagues (2026) find that the review literature is fragmented across paradigms and system types, which makes cumulative claims difficult. The available research also does not show whether the equivalence of AI and human hints holds for open-ended reasoning, how effects differ by prior achievement, or whether early losses from unguarded use persist or reverse. Until such evidence exists, the field should resist both enthusiasm driven by solver benchmarks and blanket prohibition. It should instead test, under controlled conditions, tutors designed to protect the struggle through which mathematical understanding is formed.

Q321 In the Natural Sciences (Biology, Chemistry, Physics), how can AI simulations and data-analysis tools augment—without replacing—wet-lab experimentation, sensory observation, and messy empirical measurement?

13 citations · 13 sources · 3 cross-references

Claim 1 disputed

AI simulations and data-analysis tools augment rather than replace laboratory science when they are placed on either side of the bench. Before measurement, they help students form predictions and see mechanisms that cannot be observed directly. After measurement, they help students analyse, visualise and interrogate data the students gathered themselves. They should never sit in the place where hands, eyes, instruments and stubborn materials meet. That placement matters because what is distinctive about the natural sciences is not information about the world but disciplined contact with it. That contact includes a precipitate that will not form, a pendulum whose period drifts with a loose clamp, a leaf whose discolouration resists easy classification. The argument that follows treats the laboratory as the anchor and asks what AI can add to it. It also asks under what conditions AI begins to hollow the laboratory out, and where the evidence is still too thin to settle the matter.

The starting point is a long-standing claim about the laboratory itself. Hofstein and Lunetta (2003) revisited, twenty years on, their own frequently cited critical review of school science laboratory research. They noted that the laboratory has been given a central and distinctive role in science education, and that educators have suggested rich learning benefits accrue from it. They situated that reassessment in an era of dramatic new technology resources and renewed emphasis on inquiry. Their framing is useful precisely because it is cautious. The benefits of laboratory work have often been asserted more confidently than they have been demonstrated, and each wave of technology reopens the question of what the bench is for. Any defence of wet-lab experimentation against AI substitution therefore has to rest on a clear account of what physical investigation affords, not on nostalgia.

De Jong, Linn and Zacharia (2013) supply the most widely used vocabulary for that account. Writing in Science, they describe two routes by which students can investigate phenomena using the tools, data collection techniques, models and theories of science. One is physical laboratories, which support interactions with the material world. The other is virtual laboratories, which take advantage of simulations. The distinction is worth holding onto

because it locates what each environment offers rather than ranking them. Physical laboratories carry the friction of the material world: measurement error, instrument calibration, contamination, the smell of a reaction, the tactile resistance of a dissection. Virtual laboratories offer control, repeatability, safety, and access to scales of time, size and danger that no school bench can reach. Examples include molecular collisions, evolutionary change over thousands of generations, and electric fields made visible.

The pedagogical risk of AI is that it blurs this distinction. A conventional simulation is transparent about being a model: its parameters are fixed by its designers, and its idealisations are, at least in principle, inspectable. Generative and machine-learning tools can produce plausible outputs that look like data, narrate an experiment that was never run, or 'clean' a messy dataset into the curve the textbook predicts. When that happens, the virtual is no longer a complement to the physical. It becomes a counterfeit of it. The design task is therefore to keep the epistemic status of every representation visible to the learner. Students should know at each point whether they are looking at a measurement, a model prediction, or a machine inference. They should also know which of these is allowed to overrule the others.

The framing offered by de Jong and colleagues is well established as a way of thinking about physical and virtual investigation. How AI-driven simulations, as opposed to conventional ones, alter the balance between the two remains unclear. Few studies yet compare learning from AI-generated or AI-adaptive simulations with learning from conventional simulations paired with bench work.

The case for keeping measurement sovereign over model output is strengthened by what is known about AI's modelling limitations. Spreitzer and colleagues (2024) examined the mathematical modelling capabilities of successive ChatGPT versions: GPT-3.5, GPT-4.0, and a more instructed variant they call GPT-MM. All versions demonstrated basic mathematical problem-solving skills, but effectiveness varied with increasing task complexity. GPT-4.0 and GPT-MM showed only marginal improvements in providing detailed solutions. Significant challenges persisted in moderate to complex modelling contexts, where comprehending the nuances of a task becomes difficult. Their study concerns mathematical modelling rather than laboratory science. Even so, the implication for natural-science teaching is direct, since the hard part of modelling a real experiment is exactly the nuance: deciding which variables matter, what to idealise away, and when a discrepancy signals error rather than new physics. A tool that

handles textbook cases but falters on open, context-laden ones cannot be the arbiter of what an experiment 'should' have shown.

Research practice outside education points to a more productive arrangement, in which data-driven and physics-based models are coupled to fieldwork rather than substituted for it. Wu, Li and Zou (2026) developed a vulnerability assessment framework for houses built against cut slopes by combining multiple machine-learning algorithms with SPH–FEM numerical simulations. The two kinds of evidence played different roles. Field geological investigations identified the rear wall of such houses as the primary element at risk. Data-driven analysis then identified slope-cutting height and toe distance of slope as the key factors controlling vulnerability. This is a geohazard study, not a teaching intervention, and it should not be read as evidence about student learning. Its value for the classroom is as an image of mature practice. Observation in the field establishes what matters, physics-based simulation explores mechanisms, and machine learning finds patterns across cases. Each checks the others.

Translated into the teaching laboratory, the arrangement suggests a cycle with four steps. Students first predict with a simulation, then measure at the bench, then use analytical tools to fit and explore their data. Finally they reconcile any mismatch by returning to the apparatus rather than to the model. The reconciliation step is where scientific reasoning is most visible and where AI shortcuts are most tempting. It is the laboratory analogue of the 'messy inquiry phase' that project-based learning must protect from premature closure (see Q328).

Where AI-enabled analysis has its clearest educational promise is in working with real data at scales students could never collect themselves, provided that this extends rather than displaces their own observation. Marín Díaz (2025) presents a project-based framework for astronomy education. It integrates exploratory data analysis, fuzzy logic and explainable AI so that students learn to extract and interpret scientific knowledge from real astronomical data. Learners retrieve, process and visualise dynamic datasets of comets, asteroids and stars from open resources such as NASA's JPL Horizons and ESA's Gaia DR3, using Python libraries such as Astroquery and Plotly. The design is notable for insisting on explainability: students are asked to interpret what the model is doing, not merely accept its classifications. Astronomy is also a discipline where direct wet-lab manipulation is impossible, which makes it an honest test case for data-centred pedagogy. The paper, however, presents a framework. Its abstract does not report learning outcomes, so its effectiveness remains to be established.

The situation is more delicate in disciplines where sensory observation is itself the skill being learned. Qu and Yu (2026) review AI image-recognition technologies in agricultural education. These include virtual simulation systems, intelligent pest and disease diagnosis, adaptive learning platforms and smart field teaching. The authors discuss their pedagogical value in terms of experiential learning, digital competence and instructional innovation. Automated diagnosis of a diseased crop can widen access to expertise and offer immediate feedback in the field. Yet the trained eye of the agronomist, biologist or field naturalist is built through repeated, effortful looking. That means noticing texture, distribution and context, and holding several candidate explanations open. If the classifier speaks first, the student's perception may never develop.

A defensible sequence is 'observe, record, then consult'. Students sketch, describe and tentatively identify before the tool offers its judgment, and the disagreements become material for discussion. Who trained the model, on which crops and in which ecosystems, also matters. Local ecological knowledge held by farming and Indigenous communities may diverge from what a globally trained classifier has learned (see Q329).

How users weigh such tools against conventional ones is itself an open question. Šumak and colleagues (2025) compared a traditional qualitative data analysis tool, Taguette, with ChatGPT and Gemini among 85 master's students in electrical engineering and computer science. The students performed sentiment analysis and annotation tasks, and the researchers examined usability, user experience, mental workload, trust and emotional impact. The domain is qualitative analysis rather than laboratory science. The study's dimensions nonetheless mark exactly what natural-science educators should monitor when students analyse data with AI: not only whether they get answers faster, but whether their trust is calibrated to the tool's actual reliability.

Whether any of this reaches laboratories depends on teachers. The current evidence suggests a gap between familiarity and disciplinary use. Kumar, Zhuang and Thomas (2024) examined the initial perspectives of five instructors who took part in a five-day workshop on using ChatGPT 4.0 for natural-science course development, framing their findings as a strengths, weaknesses, opportunities and threats analysis. The sample is very small, and the focus is course planning and content generation rather than laboratory pedagogy. Still, the study signals that natural-science educators are beginning to treat generative AI as a design partner.

López Costa (2025) surveyed teachers in rural Catalan schools. More than half reported moderate to high AI knowledge, but classroom implementation remained limited. Teachers used AI primarily for text generation and content detection, and less often for video generation or simulations. If that pattern generalises, the simulation-rich, data-literate uses most relevant to science laboratories are precisely the ones least taken up.

Student use follows a similar pattern of convenience. Hershkovitz, Tabach and Lurie (2025) analysed 825 open-ended responses from students at a large multidisciplinary university in Israel and inductively coded the academic tasks for which they used generative AI. Their task-centred lens is valuable for laboratory educators. The question is not whether students use AI but at which step of the work: hypothesis formation, procedure planning, data analysis, or the write-up of the lab report. Each carries different risks of substitution. Palmer and colleagues (2026) found that students in agricultural leadership, education and communications held diverse perceptions of AI as an educational tool. This is a reminder that enthusiasm and suspicion coexist within the same cohort.

Structured intervention appears to help. Leahy, Ozer and Cummins (2025) report a multicentre, teacher-led programme across three cohorts in different subject areas. It aimed to support engagement, examine effects on learning efficiency and skill development, and build awareness of generative AI's strengths and limitations. Salinas-Navarro and colleagues (2024) argue that generative AI can be used to explain and enhance experiential learning in service of authentic assessment. They position experiential and authentic designs as a response to integrity concerns. For the laboratory, the lesson converges: assessment should reward what AI cannot fabricate. That includes annotated raw data, records of failed runs, error analyses tied to specific apparatus, and oral defence of anomalous results. Parallel arguments about AI diagnostics in skilled manual training (see Q327) reach a similar conclusion: the tool earns its place by sharpening, not bypassing, embodied judgment.

Several design principles follow from this evidence, though most are inferences from adjacent findings rather than results of controlled trials in science laboratories. First, simulations should precede or follow physical work, not stand in for it, except where physical access is genuinely impossible, as with stellar data or hazardous reactions. In those cases the model's idealisations should be made explicit. Second, the measurement should be given authority over the model. When bench data disagree with a simulation or an AI fit, students return to the apparatus, not the prompt. Third, AI analysis should be used on data students produced, or on authentic public

datasets with documented provenance, never on synthetic data presented as real. Fourth, independent observation should come before machine judgment in observational disciplines. Fifth, explainable tools should be preferred, and students asked to articulate what the algorithm assumed.

The field should be candid about what the evidence does not yet show. The physical-versus-virtual debate predates generative AI and has never been fully settled. Researchers continue to disagree about how far simulations can substitute for hands-on experience in developing manipulative skill and a feel for measurement uncertainty. The AI-specific studies available are largely surveys of perception, small workshop cohorts, framework proposals, or capability tests of chatbots on mathematical tasks. They do not demonstrate that AI-augmented laboratories improve conceptual understanding, experimental skill or scientific identity compared with well-designed conventional laboratories. Few studies follow students from AI-supported prediction through bench measurement to AI-supported analysis and examine what changes in their reasoning about error and evidence.

The defensible position, for now, is a conditional one. AI simulations and analytics extend the reach of laboratory science when they are kept honest about their status and subordinate to measurement. They erode it when they allow students to skip the encounter with recalcitrant material reality that makes science an empirical discipline at all.

Q322 In History and Social Studies, how can students use LLMs to interrogate archival bias, historiography, and competing primary sources while avoiding anachronistic "historical role-play" hallucinations?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Students can use large language models productively in history and social studies only if the model is treated as an object of source criticism, never as an oracle and never as a ventriloquist for the dead. Four disciplined moves make this possible. Students interrogate what the model knows and does not know, so that it becomes a kind of archive with silences. They test its claims laterally against documents and scholarship. They use it to map historiographical positions and then check those positions against the historians who actually hold them. And they replace open-ended historical role-play with tightly bounded exercises in which any synthetic 'voice' is labelled, annotated, and dismantled as a manufactured source.

The case for this design rests on a mismatch between what generative systems do well and what historical thinking requires. Fan and Liu (2026), surveying humanities and social science students in China at scale, start from the observation that learning outcomes in these fields are commonly expressed in written and interpretive forms that align closely with the capabilities of generative AI. That alignment is both the opportunity and the danger. A model can produce a fluent interpretive paragraph about the causes of a revolution in seconds. Fluency, however, is not evidence, and the historian's craft lies in the warrant behind the paragraph rather than its surface.

Saúde, Barros and Almeida (2024) combined a bibliometric analysis and systematic review of 64 publications with student perception data. They characterise generative AI's effect on the pedagogical aspects of higher education as disruptive. Disruption in history teaching need not be purely corrosive. It can force educators to make explicit the evidentiary reasoning that well-written essays once allowed to stay implicit.

The 'historical role-play' problem deserves precise diagnosis. When a student asks a model to speak as a medieval peasant, an enslaved person, or a nineteenth-century factory owner, the output is not a primary source of any kind. It is a contemporary text generated to sound like one. Its vocabulary, moral framing, and assumptions about what such a person would notice or care about are drawn from present-day writing about the past, not from the past itself. Anachronism is therefore built into the genre. The more convincing the performance, the harder it is for a novice to detect.

Research on synthetic text in political communication shows why convincingness should worry history teachers. Kreps, McCain and Brundage (2020) ran three experiments on whether text generated by GPT-2, which can mimic the style and substance of human-written news, was perceived as credible and could influence opinions on foreign policy. They also examined how partisanship interacted with responses to such text. Goldstein and colleagues (2024), in a preregistered survey experiment with US respondents, found that GPT-3 could produce highly persuasive text, measured by participants' agreement with propaganda theses. They also investigated whether a fluent English speaker could improve that persuasiveness.

Neither study concerns historical documents, and the transfer should be stated cautiously. Still, both suggest that machine-generated prose can carry persuasive weight with ordinary readers. A fabricated 'eyewitness' account of a historical event plausibly inherits the same rhetorical force. It adds a further hazard: students may later recall the invented testimony as though they had read an authentic document.

The pedagogical response is not prohibition but reclassification. Any simulated historical voice should enter the classroom explicitly labelled as a twenty-first-century artefact. Students should then be asked to treat it the way they would treat a forgery or a Victorian historical novel. That means asking who produced it, from what materials, with what interests, and where it betrays its own date of composition.

Archival bias offers the richest opening for genuine inquiry, because the model itself is an archive with a history. Its training data overrepresents some languages, regions, social groups, and genres of writing, and underrepresents others. The resulting silences echo, and sometimes amplify, the silences historians already confront in state records, missionary reports, and colonial correspondence. Students can investigate this directly. They might ask the model about a well-documented elite figure and then about a contemporaneous laundress, dockworker, or village healer, comparing the specificity, confidence, and sourcing of each answer. Where the model fills gaps with generic plausibility, students learn something about how both machines and earlier chroniclers write over absences.

Evidence of representational skew in generative systems, though drawn from other domains, supports this exercise. Currie and colleagues (2024) noted that 54.3% of Australian medical students are women, yet women remain under-represented in stereotypical images of medicine. On that basis they evaluated how DALL-E 3, accessed through GPT-4, depicted Australian undergraduate medical students, warning that text-to-image generation could reinforce gender bias. The study concerns images and a single profession. It cannot establish how language models portray historical populations, and teachers should not imply otherwise.

Currie and colleagues' approach nonetheless offers a usable classroom protocol. Compare a known distribution with the model's representation of it, then ask what produced the gap. In history the 'known distribution' is often contested, which is precisely the point. Students must first establish from census data, parish registers, or secondary scholarship what the past population looked like before they can judge the model's portrait of it.

These silences are not culturally neutral. Models trained predominantly on English-language and Western scholarship may present one national or imperial historiography as the default narrative. That problem is particularly acute in non-Western classrooms and is treated at length elsewhere (see Q243). The interrogation of archival bias should therefore include the model's own geography of knowledge, not just the biases of the documents students bring to it.

Working with competing primary sources requires corroboration, and here the most transferable evidence comes from research on evaluating digital information. Wineburg and McGrew (2019) set out to understand what skilled online evaluation actually looks like, because prior research offered few concrete ideas on the matter. They sampled 45 experienced Internet users, including ten holders of the Ph.D. Their account of 'lateral reading', captured in their subtitle as

reading less and learning more, describes leaving an unfamiliar source to find out what others say about it rather than scrutinising it in isolation.

Applied to language models, lateral reading becomes the default response to every substantive claim. When a model asserts that a treaty contained a particular clause, that a pamphlet circulated in a given city, or that two accounts of a massacre disagree on casualty figures, students leave the chat. They go to digitised archives, critical editions, and peer-reviewed scholarship to confirm, qualify, or refute the claim. Any citation the model supplies is treated as a lead to be verified, not as a reference.

A productive classroom structure pairs two or three authentic documents that disagree about a single event with a model-generated synthesis of 'what really happened'. Students audit the synthesis line by line. They mark which claims are traceable to the documents, which come from elsewhere and need lateral checking, and which smooth over genuine contradictions. Students quickly discover that the model tends to harmonise conflicting testimony into a single narrative, while historical reasoning often requires holding the conflict open and explaining it through each author's position, audience, and purpose.

Teaching notes from other professional disciplines point the same way. McMullen (2026) describes integrating generative AI into a contract negotiation exercise for undergraduates, where teams used the tools for idea generation, drafting, and evaluation. He is explicit that the resulting agreements are not ready for use without legal review. The parallel for history is direct. A model's account of contested sources may be a useful first draft of the problem. It is never a finished interpretation, and the student's task is to supply the expert review the output lacks.

Historiography, the study of how interpretations of the past change, is where models can be most helpful and most misleading at once. Asked to outline schools of thought on the origins of a war or the nature of an empire, a model can produce a serviceable map of positions. Such maps routinely misattribute arguments, flatten disagreements between scholars, and present a contemporary consensus as though it had always existed. Students can turn these errors to advantage. The assignment is to take the model's historiographical summary, identify the historians it names, consult their actual work, and write a correction explaining where the summary distorts the debate and why such a distortion might arise.

The most defensible use of simulated voices may be one that inverts role-play rather than indulging it. Roozenbeek and van der Linden (2019) designed a browser game in which players take the role of a fake news producer and master six documented techniques of misinformation: polarisation, invoking emotions, spreading conspiracy theories, trolling, deflecting blame, and impersonating fake accounts. They report that the game conferred psychological resistance against online misinformation.

By analogy, students might deliberately commission a model to produce a pastiche 'primary source' from a specified period. They then annotate every anachronism, unsupported detail, and modern moral framing they can find, and compare it with a genuine document of the same type. Producing and dissecting a fake may build resistance to fakes, in the way the game's design intends. Whether the inoculation logic transfers from contemporary news to historical documents remains unclear, and few studies have tested it in history classrooms.

The persuasion findings cut both ways. If machine-generated text can shift agreement with propaganda theses, as Goldstein and colleagues (2024) found, then a vivid synthetic testimony might leave impressions that outlast the annotation exercise meant to neutralise it. Teachers should therefore keep such pastiches short and clearly marked, and always pair them with authentic material. The wider civic challenge of synthetic media and manufactured consent belongs to media literacy curricula (see Q324). History classrooms contribute a distinctive capacity to that work: the habit of dating a text by its assumptions.

Assessment, equity, and the limits of current evidence complete the picture. Nantaburom (2026) examined Thai secondary students' perceptions of ChatGPT-supported summative assessment in social studies. That study frames generative tools as offering new possibilities for explanation, synthesis, and written response, while raising concerns about academic integrity, overreliance, accuracy, and fairness in subject-specific contexts. Those concerns map closely onto the risks described here. Overreliance becomes outsourced interpretation. Inaccuracy becomes hallucinated evidence.

Assessments that reward the audit trail rather than the polished essay address both risks. Annotated transcripts, verification logs showing which claims were checked laterally and against what, and written reflections on where the model's account diverged from the sources make students' reasoning visible. They also align with emerging norms for disclosing and documenting AI use (see Q083). Reimer (2024), writing on social work curricula, argues that

educators must prepare students to use generative AI thoughtfully, skillfully, and ethically through deliberate curriculum and assessment design. The argument transfers readily to history, though it is a conceptual case rather than an empirical demonstration.

Students also differ in how they approach these tools. Aloud, Alotaibi and Al-khalifa (2026) modelled awareness, desire to use, and fear of using generative AI among 652 university students. They examined whether these perceptions differed by gender, age, major, and level of study. Some students will resist or be unable to use such tools. Every model-based exercise described here can therefore be redesigned around a teacher-supplied model transcript, so that no student needs an account to practise the critique (see Q111).

The evidence base is thin precisely where history teachers most need it. Yavich and Davidovitch (2026) found correlations between AI use and learning motivation among 207 Israeli middle and high school students using self-report instruments. Those associations are correlational and say nothing about whether AI use causes motivational change, still less about historical reasoning. Much of the surrounding literature measures perceptions and intentions rather than learning.

What the evidence does not yet show is whether model-audit tasks improve students' sourcing, contextualisation, and corroboration more than conventional document-based instruction does. It also does not show whether exposure to synthetic testimony leaves lasting distortions in historical memory. Until rigorous classroom studies address these questions, the approach outlined here should be read as a reasoned design argument. It rests on established habits of historical source criticism and lateral reading, not on demonstrated outcomes.

Q323 In Literature and Rhetoric, how does close reading, stylistic voice development, and hermeneutic interpretation survive when commercial tools offer instant text summarization?

12 citations · 12 sources · 3 cross-references

Claim 1 disputed

Close reading, stylistic voice and hermeneutic interpretation survive instant summarization only when literature and rhetoric teachers make explicit what was always implicit: these practices were never mainly about extracting a text's content, so a tool that extracts content well does not replace them. It does remove much of the visible labour that once stood in for them. A summary reports what a text says. Close reading attends to how it says it: the turn of a line, the pressure of a repeated word, the gap between what a narrator asserts and what the syntax lets slip. Voice development asks a student to find a manner of saying that is answerable to a particular mind. Interpretation asks the reader to account for why a text means one thing rather than another, and to defend that account before others who read differently. None of these is delivered by a paragraph of paraphrase. All of them, however, have historically been taught and assessed through artefacts, such as essays, annotations and response papers, that a language model can now approximate.

The core problem is therefore not that summarization makes literary skill obsolete. The problem is that the discipline's habitual evidence of skill has come apart from the skill itself. Soderstrom and Bjork (2015) give this predicament its most useful frame. They distinguish

learning, meaning relatively permanent changes in comprehension and skill that support retention and transfer, from performance, the observable behaviour during instruction, and they warn that performance is often an unreliable index of whether learning has occurred. A polished reading of a sonnet produced with machine assistance is performance without any guarantee of learning. A halting, partly wrong annotation done unaided may carry more of the durable change teachers actually want. The survival of literary pedagogy depends on designing for that second kind of evidence.

Jarmy (2026) sharpens the stakes by returning to Plato. Socratic teaching aims at truth, whereas the sophists and orators Plato criticizes aim at plausibility and winning arguments. Jarmy argues that generative AI resembles the latter because it works by sounding plausible. For a discipline built on reading against the grain, this is a precise diagnosis. The summary is the most plausible reading, and plausibility is exactly what literary interpretation exists to interrogate.

The empirical case for concern comes mostly from adjacent domains rather than from literature classrooms, and it should be read with that limit in view. The most direct evidence concerns writing. Kosmyna and colleagues (2025) assigned 54 participants to LLM, search-engine or unaided ('brain-only') conditions across three essay-writing sessions. They used electroencephalography to assess cognitive load and analysed the essays with natural language processing and with scoring by human teachers and an AI judge. In a fourth session, completed by 18 participants, the conditions were swapped. The authors frame their results as an accumulation of 'cognitive debt' when writers rely on an AI assistant. The design is suggestive, especially the crossover, which tests whether prior reliance carries forward once the tool is removed. The samples are small, though, and the work was released as a preprint, so it supports caution rather than settled conclusions.

Survey and field evidence points in a similar direction while remaining correlational. Gerlich (2025) surveyed and interviewed 666 participants across age groups and educational backgrounds. He examined the relationship between AI tool use and critical thinking, with cognitive offloading as a mediating factor, using ANOVA, correlation analysis and thematic analysis. Such a design can show association, not that tool use causes diminished critical thinking. Lee and colleagues (2025) surveyed 319 knowledge workers, who supplied 936 first-hand examples of generative AI use. Their analysis found that a user's task-specific self-confidence and confidence in the AI predicted whether critical thinking was enacted and how

much effort it required. The study title reports self-perceived reductions in cognitive effort. Fan and colleagues (2024) studied motivation, learning processes and performance when learners receive support from generative AI alongside other agents. They warn of 'metacognitive laziness', a disposition to let the tool carry the monitoring and regulating that learning requires.

Taken together, these studies suggest a plausible mechanism for what summarization does to literary study. The tool takes over effortful processing, and students' confidence in the tool may lower their sense that checking is necessary. What the evidence does not yet show is equally important. None of these studies measured close reading of literary texts, development of a personal prose style, or interpretive argument about ambiguous works. The extrapolation is reasonable but untested. The findings also come largely from adults and knowledge workers, not from adolescent or undergraduate readers.

Close reading is, among other things, a discipline of attention. It slows the eye, keeps the reader in contact with particular words, and refuses the economy of the gist. Instant summarization optimizes for the gist. It offers the reader a way around the text in the very form, the condensed paraphrase, that close reading was designed to resist. The relevant question is therefore what conditions sustain sustained attention, and here the reading research offers a useful, if indirect, warning.

In a meta-analysis of studies from 2000 to 2017, Delgado and colleagues (2018) compared comprehension of comparable texts read on paper and on digital devices. They included 38 between-participants and 16 within-participants designs, together involving 171,055 participants. Both designs yielded the same advantage for paper over digital reading, a Hedges' g of −0.21. This is among the more robust findings in reading research. Its relevance here is analogical rather than direct. The meta-analysis concerns reading medium, not AI summaries, and its effect is modest. Still, it demonstrates that the conditions under which reading happens shape comprehension, and that the convenience of a technology does not guarantee depth. A pedagogy of close reading that takes this seriously would protect slow, situated encounters with the full text before any machine-generated condensation enters the room. The summary would be treated as a later object of critique, never as a substitute for first contact.

Practically, this means returning some reading and annotation to spaces where the work itself is visible: in-class marking of passages, oral explication of a few lines, and commonplace books kept over a term. These forms leave a trace of attention that a summary cannot fabricate. They

also make the learning–performance gap that Soderstrom and Bjork (2015) describe more legible to the teacher. The parallel with programming education is close. There, the argument for shifting instruction from code-writing toward code reading and debugging rests on the same insight: when production is automated, the capacity to scrutinize becomes the skill worth teaching (see Q319).

Students' own beliefs matter here too. Baldrich, Pérez-García and Santamarina-Sancho (2025) note that AI has transformed academic reading and writing in higher education. They also note that empirical research with validated instruments for measuring students' beliefs, perceptions and practices in this area is still incipient. Their contribution is a reminder that teachers currently know rather little, in measurable terms, about how students actually read when summaries are a click away.

Stylistic voice faces a subtler threat than close reading. A summarizer does not replace a student's voice so much as offer a default one: fluent, balanced, hedged, and recognizably average. Jarmy's (2026) reading of Plato is again apt. Among the areas she considers is how plausibility is established by wide consensus, with consequences for bias in AI. Prose generated from consensus tends toward the centre of what has been written before. For a student still discovering how she sounds on the page, this default is seductive because it already looks like competent academic English. Voice develops through friction: drafts that are awkward, sentences that try something and fail, and the slow accumulation of a writer's habitual choices. A tool that removes the friction may also remove the formation.

The writing study by Kosmyna and colleagues (2025) is relevant because it measured the essays themselves, through natural language processing and scoring by human teachers and an AI judge, alongside participants' neural activity. Its crossover design makes it possible to ask whether writers who began with assistance carried anything different into unaided work. That is precisely the question voice pedagogy needs answered at scale and over longer periods. Given the small sample, the finding should be read as a prompt for classroom research, not a verdict.

The rhetorical tradition suggests a constructive response. Classical rhetoric taught style through imitation, variation and conscious departure from models. Generated prose can serve as a model to depart from. A student can be asked to rewrite a machine paragraph in the cadence of a writer she admires, then to explain each change, or to identify what the paragraph refuses to risk. Exercises of this kind turn the consensus voice into a foil and make stylistic choice

explicit. They work only if the explanation, not the polished output, is what earns credit. The findings of Lee and colleagues (2025) caution that confidence in the tool can reduce critical engagement. Voice pedagogy therefore has to cultivate a writer's task-specific self-confidence deliberately, so that students have grounds to overrule the machine's suggestions.

Hermeneutic interpretation may be the most resilient of the three practices, because it is the least reducible to a single correct output. A summary can state a theme. It cannot account for why a poem's closing image unsettles the theme it seems to confirm, or adjudicate between a feminist and a formalist reading of the same scene. Interpretation is argumentative and situated. It is also social, since it is tested in seminar discussion against other readers. These features offer the discipline real leverage.

The reviews of generative AI in higher education identify both openings and obstacles. Abedin, Hayajneh and Raahemi (2026) reviewed 30 peer-reviewed articles and found five opportunities, among them the deliberate fostering of critical thinking. The word 'deliberate' is the important one: the benefit does not arrive on its own. Batista, Mesquita and Carnaz (2024) synthesized empirical studies from January 2023 to January 2024, identifying 102 articles and including 37. They trace effects on teaching, learning and institutional practice. Yang and colleagues (2026) used an AI-assisted mining of 1,998 education-relevant articles to catalogue barriers to classroom use. Their method is exploratory, and it shows how fast the field is producing claims that remain hard to evaluate.

For literary interpretation, the most promising designs use the summary as a provocation rather than a shortcut. Students can receive a machine reading of a text and be asked where it flattens ambiguity, what it omits, whose reading it reproduces, and what evidence in the text resists it. This inverts the tool's function. Its plausible, consensus account becomes the position an interpretation must argue against. Fan and colleagues (2024) caution that learners may hand over metacognitive work, so these designs need explicit checkpoints. Examples include annotated evidence, oral defence and reflective commentary on how a student's reading changed. Such checkpoints keep the regulating activity with the student. The same logic protects the open-ended inquiry phase of project-based learning from premature closure (see Q328). It also echoes the case against instant translation in language learning, where meaning-making must remain the learner's (see Q325).

Several matters remain unresolved, and honesty about them should shape policy. First, the strongest cognitive evidence is correlational or small-scale. Gerlich (2025) establishes association, not causation, and the crossover sample in the study by Kosmyna and colleagues (2025) is 18 participants. It is not yet clear whether summarization degrades literary capacities, merely displaces them, or affects some students and not others. Second, few studies have examined literary reading or interpretation specifically. Most work concerns general writing tasks or knowledge work, and the validated instruments that Baldrich and colleagues (2025) call for are only beginning to appear. Third, the ethical dimensions are broader than academic integrity. Creely (2026) traces, through a consequentialist lens, how scholarship on generative AI in education from 2022 to 2026 has moved across ethical, social and environmental concerns. Literary pedagogy inherits all of these, including questions about whose interpretive traditions dominate the consensus a model reproduces. That question resonates with concerns raised elsewhere about the distortion of oral and Indigenous traditions.

What can be said with confidence rests on the learning–performance distinction rather than on AI-specific findings. Soderstrom and Bjork (2015) show that observable performance often misleads about durable learning, and that principle holds whatever the technology. If literature and rhetoric courses continue to grade polished products, summarization tools will hollow out their evidence of learning. If they assess the visible processes of attention, stylistic choice and argued interpretation, the core practices remain teachable, and arguably become more distinctive. The discipline's oldest claim, that how a thing is said is part of what it means, is the claim a summary cannot accommodate. The task now is to build that claim into assessment and to test, with properly designed classroom studies, whether doing so preserves the capacities it was meant to protect.

Q324 In Civic Education and Media Literacy, how should curricula prepare students to navigate synthetic deepfakes, astroturfed public comment campaigns, and algorithmic polarization?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

Curricula should prepare students to navigate synthetic deepfakes, astroturfed comment campaigns and algorithmic polarization through three habits. Students should first establish who stands behind a piece of content before judging how it looks. They should learn the manipulator's techniques in advance rather than meeting them for the first time in the wild. And they should treat the information environment as a system shaped by incentives and power, not as a stream of individual true-or-false claims. The underlying shift is from inspection to investigation. For most of the history of media education, students were taught to scrutinise a single artefact for internal signs of bias, error or tampering. That approach was already weak before generative AI, and it is weaker now that synthetic text, images, audio and video can be produced at scale. Voinea (2026) defines synthetic media as artefacts wholly or partly generated or materially manipulated by AI. Their form, source, identity signal or evidentiary relation to recorded events thereby becomes partly or wholly artificial. The final element of that definition matters most for civic education. What is at stake is not merely whether a clip is fake. It is whether recordings, testimonies and public submissions can still serve as evidence in democratic deliberation.

Two research traditions offer the most usable foundations. The first comes from Wineburg and McGrew (2019), who sampled 45 experienced internet users, among them 10 PhD holders, to characterise what skilled evaluation of digital information looks like. The practice their title captures, reading less and learning more by reading laterally, means leaving a page to find out what others say about its source rather than dwelling on the page itself. This transfers naturally to synthetic media, where the artefact may be engineered to look flawless. The second tradition is inoculation. Roozenbeek and van der Linden (2019) designed a browser game in which players take the role of a fake news producer. Players learn six documented techniques: polarisation, invoking emotions, spreading conspiracy theories, trolling, deflecting blame and impersonating fake accounts. The authors report that this conferred psychological resistance against misinformation. Together these traditions suggest a curriculum built on provenance and technique recognition rather than artefact forensics. That conclusion is emerging rather than settled for AI-generated content specifically.

Deepfakes illustrate why civic education cannot simply aim at better detection. Kietzmann and colleagues (2020) note that manipulation of visual and auditory media is as old as the media themselves. They argue nonetheless that deepfakes mark a turning point, because automated procedures now produce content that is harder and harder for human observers to detect. Their prescription, written for organisations, is that people need to understand how the underlying techniques work, along with their strengths and limitations. That prescription applies with equal force to classrooms. Voinea's (2026) taxonomy widens the frame further. Deepfakes include audio-only voice clones and still images as well as video, so a unit centred on spotting glitches in faces will miss much of the threat surface.

The most consequential finding for curriculum designers concerns trust, not deception. In an experiment with a large representative sample of the UK population, Vaccari and Chadwick (2020) found that people were more likely to feel uncertain than to be misled by deepfakes. That uncertainty in turn reduced trust in news on social media. If the primary civic harm is corrosive doubt rather than outright belief in falsehoods, then teaching students to distrust everything they see may reproduce the very damage the technology causes. A well-designed unit must therefore pair scepticism with procedures for restoring warranted trust. Students need to know whom to consult, which corroborating records to seek, and how to say with calibrated confidence that a recording is probably authentic.

There is encouraging evidence that targeted instruction helps. In a two-wave online experiment among US residents, Huang and Hu (2025) compared interventions that varied by content (a warning, technique tips, or both) and by format (text, infographic, video). Technique tips on how to identify deepfakes improved detection, perceived AI literacy and self-efficacy. The video format was most effective in raising perceived AI literacy. The study's title, a participant's plea that a warning is not enough, captures the practical lesson that generic alerts should give way to concrete strategies. Two limits deserve emphasis. First, gains in perceived literacy and self-efficacy are not the same as durable competence. Second, cues that work against today's generators may fail against tomorrow's. Detection tips should therefore be taught as perishable, nested inside the more durable habit of verifying provenance. Film and media courses that have students build synthetic video themselves offer a complementary route into how such artefacts are constructed (see Q287).

Astroturfing, the manufacture of apparent grassroots opinion, poses a different problem, because the deception lies in the aggregate rather than in any single item. A regulatory docket or a city council's comment portal flooded with thousands of fluent, varied submissions can simulate public sentiment that does not exist. Generative text models lower the cost of producing that variety. Kreps, McCain and Brundage (2020) ran three experiments asking whether news-style text generated by GPT-2 was credible and could influence opinions on foreign policy. They also examined how partisanship interacted with responses to AI-generated news. Goldstein and colleagues (2024) went further in a preregistered survey experiment with US respondents. GPT-3 could create highly persuasive text, as measured by participants' agreement with propaganda theses, when compared against articles written by foreign propagandists. They also tested whether a person fluent in English could improve that persuasiveness. Together these studies suggest that fluency and persuasiveness can no longer serve as markers of human authorship or authentic grassroots origin. Neither study, however, examined public comment processes directly. Their relevance to astroturfing is an inference about capability rather than a measured effect on deliberative institutions.

The pedagogical implication is that students need to reason about patterns and provenance across a body of content. Lateral reading extends naturally here (Wineburg & McGrew, 2019). Faced with a seemingly spontaneous groundswell, students can ask who organised it, whether the named commenters and organisations can be found elsewhere, and whether funding or coordination is disclosed. The impersonation of fake accounts, one of the six techniques in the

inoculation game of Roozenbeek and van der Linden (2019), gives teachers a ready entry point. Students who have practised building a fake persona are better placed to recognise one. Civic education adds a dimension that media literacy alone does not. Students should understand why public comment exists, how agencies are meant to weigh submissions, and why the volume of comments differs from the weight of argument. Simulated exercises can make this concrete. In one, students act as agency staff confronted with a mixed docket and must decide how to read it. In another, they design a comment campaign transparently and compare it with a covert one. Few studies have evaluated such exercises. Their effectiveness against AI-scaled astroturfing therefore remains unclear and should be treated as a research priority rather than an established practice.

Algorithmic polarization is the hardest of the three to teach, because it is not a deceptive artefact at all but an emergent property of recommendation systems interacting with human attention. Here the evidence base for pedagogy is thinnest. Polarisation appears as a deliberate manipulation technique in the inoculation work of Roozenbeek and van der Linden (2019), where players learn to exploit it. That treats polarization as something bad actors do. It does not address the structural sorting that ranking systems may produce without any actor intending it. Curricula should keep these two meanings apart. Prebunking can help students recognise content engineered to inflame. Understanding how feeds, engagement metrics and personalisation shape what different citizens see requires a more conceptual, systems-level treatment.

The higher-education evidence suggests such treatment currently remains abstract. In a document and thematic analysis of course catalogues, syllabi and institutional reports from 72 universities in Türkiye, Babacan and colleagues (2025) found that AI education in journalism and new media programmes was predominantly theoretical. It emphasised AI ethics, media algorithms and the impact of automation on news production. Theory is a reasonable start, but civic competence likely also requires experiential work. Examples include auditing one's own feed, comparing results across differently configured accounts, or tracing how an emotionally charged post gains reach. A critical AI media literacy framework, which Stewart (2026) applies to faculty discussion of AI in higher education, offers a useful orientation because it foregrounds power, agency and access rather than individual vigilance alone. On this view, the goal is not merely students who resist polarizing content. It is citizens able to ask who designs ranking systems, whose interests they serve and what public oversight would look like.

What the evidence does not yet show is decisive. It remains unclear whether any classroom intervention measurably reduces students' susceptibility to algorithmically amplified polarization. The same is true of whether understanding recommendation systems changes how students engage with them. Social studies teachers working with competing narratives already have tools for this kind of perspective-taking. The parallel challenge of using AI to interrogate historiographical bias without inviting fabricated historical voices is treated elsewhere (see Q322).

Schools need not carry this work alone, and the most promising models connect classrooms to wider civic infrastructure. Fernández Chapou and Frias Deniz (2026) examined how civil society and academic actors in Mexico developed media and information literacy, fact-checking and digital media observation in response to AI-mediated disinformation during electoral processes. Their cases were the fact-checking organisation Verificado and the monitoring initiatives of the Digital Media Observatory at Tecnológico de Monterrey. They framed the analysis through UNESCO's media and information literacy approach, complemented by media ecology and general semantics. The case is a reminder that verification is a social practice sustained by institutions. Students benefit from knowing these institutions exist, how they work, and how to contribute to them, not only from acquiring individual skills. School librarians and media specialists are natural brokers of such partnerships, and their evolving role is discussed separately (see Q165).

The learner-side evidence is largely correlational and should be read accordingly. Saklaki and Gardikiotis (2024) surveyed 310 Greek students in an exploratory study. They examined how general attitudes toward AI, attitudes toward AI ethics, and media and digital literacy levels relate to one another. Such designs can identify associations but cannot show that literacy instruction shifts attitudes or behaviour. In a cross-sectional survey of 500 journalism and communication students across five Chinese universities, Chen and Chen (2026) used structural equation modelling to test a sequential mediation model. They concluded that AI integration in journalism education operates through a developmental pathway, via learning engagement and media literacy, rather than through direct skill transfer. Because the data are cross-sectional, this pathway remains a plausible model rather than a demonstrated causal sequence. Still, it points to something curriculum designers should take seriously. Exposure to AI tools does not by itself produce discernment, and engagement and reflective literacy may be the mechanism through which competence develops.

One domain demands special care. Synthetic media are not only a matter of distant political actors. Students can themselves be targets or authors of deepfakes in school communities. Civic and media literacy units that teach students to create synthetic content for analysis must be bounded by clear ethical norms. They should also connect to school policies on AI-enabled harassment (see Q220).

Taken together, the evidence supports a curriculum organised around durable reasoning rather than perishable tricks. Its core is lateral reading and provenance inquiry, with skilled evaluators' habits as the model (Wineburg & McGrew, 2019). Prebunking through active, game-like exposure to manipulation techniques should supplement this core (Roozenbeek & van der Linden, 2019). Deepfake detection tips belong in a third layer, valuable but explicitly time-limited (Huang & Hu, 2025). Students should understand that persuasive, fluent text is cheap to produce (Goldstein et al., 2024; Kreps et al., 2020). They should also understand that the creators of synthetic media profit as much from generalised doubt as from successful deception (Vaccari & Chadwick, 2020). Civic content should then do what media literacy alone cannot. It should explain how deliberative institutions, from comment dockets to elections, are supposed to work, so that students can recognise when manufactured opinion or engineered division is corrupting them.

Several tensions remain unresolved. The first is between scepticism and trust. Interventions that heighten vigilance may deepen the uncertainty and loss of trust that deepfakes already produce, and few studies measure this cost alongside detection gains. The second concerns individual and structural framings. Inoculation and detection research centres the individual user, while critical AI media literacy insists that responsibility also lies with platforms and the designers of ranking systems (Stewart, 2026). The third is between theory and practice. Where AI appears in media curricula, it is often taught conceptually (Babacan et al., 2025), and few studies show how conceptual understanding translates into everyday behaviour. Most of the experimental evidence also comes from adult samples in the United States and the United Kingdom, and most of the curricular evidence from higher education. Whether these findings hold for adolescents in secondary civic education, the setting this question chiefly concerns, remains unclear. Programmes adopting these approaches should build in evaluation, and should measure trust calibration and civic participation alongside detection accuracy. A student who flags every video as fake has not been well educated. Neither has one who verifies diligently but no longer believes that public deliberation is worth joining.

Q325 In World Language and Second-Language Acquisition (SLA), why does instant neural translation threaten communicative fluency, and how can conversational AI serve as a low-anxiety Zone of Proximal Development (ZPD) partner?

14 citations · 14 sources · 4 cross-references

Claim 1 disputed

Instant neural translation threatens communicative fluency because it hands the learner a finished utterance. It removes the effortful, real-time work of formulating meaning in the second language, and that work is the very process through which fluent production is thought to develop (Zheng and colleagues, 2025). Conversational AI can work the other way. When it is

configured to withhold ready-made answers, adjust its language to the learner, and respond without social judgement, it can act as a patient, low-stakes interlocutor (Godwin-Jones, 2024). Such an interlocutor keeps learners producing language at the edge of their current ability, which is roughly what Vygotsky's Zone of Proximal Development describes. Both halves of this answer need qualification. The evidence that translation erodes oral fluency is still largely inferential (Lee, 2021). The evidence that chatbots reduce anxiety and sustain growth comes mostly from short, small-scale studies with mixed findings on whether benefits endure (Fryer and colleagues, 2017; Miao and Hu, 2026). This essay therefore treats translation and conversation as two contrasting ways of distributing linguistic labour between learner and machine. The central pedagogical question is which way keeps the learner doing the cognitive and interactional work that acquisition requires.

The case for concern starts with what fluency is. Zheng, Ortega, Pekarek Doehler and colleagues (2025) argue for a praxeological view of second language acquisition. On this view, L2 grammar and interactional competence emerge from humans acting jointly with others, in and through the language, across many social situations. If competence is built in that joint action, a tool that replaces the learner's own formulation with a polished target-language rendering does more than save time. It removes the occasions on which competence would have emerged. Speaking under real-time pressure requires the learner to retrieve vocabulary, assemble morphosyntax, monitor output, and repair breakdowns, all at once. Neural machine translation lets learners skip that sequence entirely. The likely result is learners whose receptive and edited written performance runs well ahead of their ability to speak unaided.

The literature on machine translation does not, however, support a simple story of harm, and it should not be presented as if it did. Lee (2021) synthesised studies of machine translation in foreign language education in a systematic review and meta-analysis. The review starts from an observed tension: a growing number of studies report pedagogical benefits, yet teachers remain sceptical, chiefly because they have limited trust in output quality and doubt its effectiveness for learning. Klimova, Pikhart, Delorme Benites and colleagues (2022) followed PRISMA procedures in a systematic review of neural machine translation in foreign language learning. They framed their task as identifying approaches to efficient implementation and drawing pedagogical implications for best practice, not as asking whether the technology should be banished. Both reviews treat translation as a tool whose value depends on how it is integrated.

Lee's (2019) study of EFL writing shows what principled integration can look like. Students first translated their own L1 writing into English without machine help. Only then did they consult the machine translation as a point of comparison for revising their L2 text. That sequencing preserves the effortful production phase and positions the machine as a source of contrastive feedback rather than a substitute author. The design matters for the fluency argument. The threat does not come from translation technology as such. It comes from instant, default, pre-emptive use that removes the learner's own attempt. What the evidence does not yet show is a well-measured causal link between habitual machine translation use and reduced oral fluency over time. That claim remains a plausible inference from acquisition theory, not a demonstrated finding. The wider debate over whether translation supports or substitutes for acquisition is taken up elsewhere (see Q242), as is its bearing on the rationale for school language study (see Q176).

If translation risks removing productive struggle, conversational AI offers a way to keep learners struggling productively without the social costs that often silence them. Those costs are real and well described. Hsu, Chen and Yu (2021) begin from the observation that many EFL learners find spoken English frustrating and difficult, particularly with English-speaking foreigners. The reasons are unfamiliarity with the spoken mode and fear of grammatical errors, which leave learners scared to speak. They also note a structural difference between reading and speaking. A reader can stop, consult a dictionary, and reread a passage. A speaker has no such recourse. Their response was a task-oriented chatbot for speaking practice, designed around this anxiety and the real-time demands of oral interaction.

The hope that chatbots create a low-anxiety space recurs across the field, but its empirical status is uneven. Jeon (2022) notes that the assumed benefits of chatbots include more chances to interact and an anxiety-free atmosphere. Jeon then stresses that little was known about how learners actually use chatbots in class or how chatbots affect motivation, and addressed this through young learners' experiences and perspectives. Huang, Hew and Fryer (2021) reviewed chatbot-supported language learning across first, second, and foreign language contexts. They organised what chatbots enable into technological, pedagogical, and social affordances, a framework that usefully separates the machine's availability from its instructional design and its role as a social partner.

Newer studies address anxiety directly. Kasap (2026) used an explanatory sequential mixed-methods design to examine how AI-integrated pedagogy affects English proficiency and

anxiety among adult learners. The study's rationale was that evidence for such learners, who face time constraints and foreign language anxiety, has been lacking. Miao and Hu (2026) studied beginners of Spanish rather than English, using intact classes in a small sample. They examined how AI-assisted speaking practice with a commercial conversational tool affected foreign language enjoyment, anxiety, boredom, and willingness to communicate, drawing on positive psychology, control-value theory, and the willingness-to-communicate framework. These studies move the conversation beyond English and toward emotional outcomes. Their designs, though, limit how far their findings generalise: mixed methods, intact classes, and modest samples. The proposition that chatbots lower anxiety is therefore best described as emerging. Repeated observation suggests it, but it has not yet been established across populations, languages, and durations.

Lowering anxiety is necessary but not sufficient for a chatbot to function as a ZPD partner. The ZPD is a relational concept. It describes what a learner can do with calibrated assistance that they cannot yet do alone, and it implies assistance that is contingent, graduated, and withdrawn as competence grows. A conversational partner that simply produces fluent, idiomatic language on request reproduces the translation problem in conversational form. Generative AI is attractive here because its behaviour can be specified. Godwin-Jones (2024) observes that tools such as ChatGPT offer second language practice through written or voice chats. Learners set the conversational parameters through prompts, and the AI can be instructed to give corrective feedback and generate practice exercises. Godwin-Jones frames this as distributed agency. Learning outcomes then arise from how learner, instructor, and machine share control, not from the tool alone. The same affordance supports autonomous and instructed learning.

That configurability is what turns a chatbot from an answer engine into something closer to a scaffold. A learner or teacher can instruct the system to simplify its vocabulary, slow its turn-taking, recast errors rather than correct them explicitly, ask follow-up questions that push for elaboration, and refuse to switch into the learner's first language unless asked. Each instruction approximates a feature of skilled human scaffolding. The default behaviour of general-purpose language models, however, tends toward helpful completion rather than instructional restraint. The technical reasons, and the prompting and training methods developers use to counteract them, are examined elsewhere (see Q338). In language learning terms, an unconstrained model will often supply the word the learner was reaching for, finish the sentence, or produce a model answer. Each of these closes the zone rather than working within it.

Kohnke, Moorhouse and Zou (2023) reviewed ChatGPT for language teaching and learning. Alongside its affordances, they set out the debates and drawbacks, and they emphasised that teachers and learners need particular digital competencies to use the chatbot ethically and effectively. That emphasis on competence is decisive for the ZPD argument. Few studies have tested whether learners left to their own devices configure chatbots in ways that preserve productive difficulty. Without guidance, the path of least resistance is to ask the machine to do the hard part. Whether a chatbot acts as a ZPD partner therefore depends less on the model than on the pedagogical design around it. That design covers task framing, prompt templates, feedback policies, and teacher monitoring.

Three limits temper enthusiasm. The first is durability. Fryer, Ainley, Thompson and colleagues (2017) designed a twelve-week experiment with 122 foreign language students. In a counterbalanced design, learners completed speaking tasks with a human partner and with a chatbot partner at three-week intervals, with pre- and post-course interest measures and repeated task-interest measures. The study was built to ask whether interest sparked by novel technology lasts and whether it carries over to interest in the course itself. As the authors put it, sustainability remains unclear. Any claim that chatbots motivate learners must separate the appeal of novelty from engagement that persists. A ZPD partner is only useful if learners keep returning to it long enough for scaffolding to fade into independent performance.

The second limit is social. Zou, Guan, Shao and colleagues (2023) recruited 70 students from Chinese universities to practise speaking with AI apps over five weeks of summer vacation. Learners were divided into two groups to examine whether social network-based interaction changed the character of AI-assisted practice. The design acknowledges that solitary practice with a machine may be incomplete, and that peer sharing and social accountability may matter alongside the AI interaction itself. This fits the praxeological claim of Zheng and colleagues (2025) that interactional competence emerges across varied social situations and in transnational and translingual spaces. A chatbot can rehearse turn-taking. It cannot fully supply the unpredictability, identity work, and mutual stakes of human interaction.

The third limit is a matter of theory. Sato, Thorne, Michel and colleagues (2025) argue that instructed second language acquisition, generative linguistics, and ecological perspectives should be combined, and that researchers with different theoretical commitments can and should work together. From an instructed acquisition standpoint, a chatbot is a source of input, output opportunities, and feedback whose effects can be measured. From an ecological

standpoint, it is one participant among many in a learner's semiotic environment, and its value depends on its relations with the others. These lenses yield different success criteria. One asks whether accuracy and fluency gains appear on tests. The other asks whether the learner is becoming a more capable participant in real communities. Current chatbot research leans heavily toward short-term affective and perceptual outcomes and satisfies neither fully. Questions of which languages and learners these tools serve well, and which they serve poorly, are treated separately (see Q228).

Taken together, the evidence supports a practical stance rather than a verdict. Instant neural translation is best kept out of the moment of production and brought in afterwards, as Lee's (2019) design illustrates, for comparison, noticing, and revision. Here the reviews by Lee (2021) and Klimova and colleagues (2022) point toward structured integration rather than prohibition. Conversational AI is best treated as a configurable rehearsal partner. It is valuable because it lowers the social stakes that silence anxious speakers, but only when prompts, tasks, and teacher oversight prevent it from collapsing into a fluent answer service. Its role is a bridge toward human interaction, not a replacement for it, and the drawbacks and competency demands identified by Kohnke and colleagues (2023) apply in full.

The open questions are considerable. It remains unclear whether anxiety reductions in chatbot practice transfer to willingness and ability to speak with humans. It also remains unclear whether gains outlast the novelty that Fryer and colleagues (2017) set out to probe, and whether adaptive scaffolding by large language models is genuinely contingent on learner performance or only appears so. The field would benefit from longitudinal designs that measure unaided oral fluency directly, compare constrained and unconstrained AI configurations, and track learners' translation habits alongside their speaking development. Until such evidence accumulates, the most defensible claim is modest. Translation threatens fluency when it replaces the learner's attempt, and conversation supports fluency when it requires one.

Q326 In Physical Education, Kinesiology, and Youth Athletics, what are the pedagogical benefits and biometric privacy risks of computer-vision movement analysis and wearable load tracking?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Computer-vision movement analysis and wearable load tracking offer physical education, kinesiology, and youth athletics something the field has long lacked: objective, individualised, near-real-time feedback on how bodies move and how much stress they absorb. The same capability makes the body a continuous stream of biometric data, and that data is unusually intimate, durable, and open to repurposing. The pedagogical case rests on two technical lineages. On the sensing side, Seshadri and colleagues (2019) describe how advances in semiconductors, physiology, and predictive analytics allow wearables to capture metrics of physical performance, physiological status, biochemical composition, and mental alertness. They report that applying such metrics has been shown to reduce injury risk, improve performance, and support athlete-centred protocols built by team physicians and trainers. On the vision side, Cao and colleagues (2018) present OpenPose, a bottom-up method using Part Affinity Fields that estimates the two-dimensional poses of multiple people in real time, with high accuracy regardless of how many people are in the image.

These capabilities are now being proposed for ordinary classrooms and playing fields, not only elite programmes. Zhou and Wu (2025) argue that physical education is under pressure from the need to monitor children's physical parameters in real time and to provide individual feedback and performance analysis. They position artificial intelligence as a means of meeting that demand. The broader arc of this transformation in schools and universities is treated elsewhere (see Q232). This answer concentrates on the specific trade-off between what movement and load data can teach and what collecting it exposes. That trade-off is sharpest where the people being measured are minors, where participation is compulsory, and where the institution doing the measuring also grades, selects, or recruits.

The strongest pedagogical argument for computer-vision movement analysis concerns feedback scarcity. A single teacher supervising a large class cannot watch every learner's squat, throw, or landing mechanics closely enough to give specific corrective feedback. Multi-person pose estimation of the kind Cao and colleagues (2018) demonstrate is designed to track many bodies at once without slowing as group size grows. In principle, every student could receive information about joint angles, timing, and symmetry that was previously reserved for athletes with access to a biomechanics laboratory. Zhou and Wu (2025) frame this as the core promise of AI-reformed physical education: individualised feedback and performance analysis at the scale of a whole cohort. Systematic work on AI in higher education points the same way. Abedin, Hayajneh and Raahemi (2026), synthesising 30 peer-reviewed articles under PRISMA 2020, identify tailored and adaptive education and enhanced accessibility for varied learners among the principal opportunities. Their review concerns generative tools rather than motion capture, however, and its transfer to embodied learning should be treated as analogy rather than evidence.

Three cautions temper the promise. First, technical accuracy is not pedagogical validity. A pose estimator can locate a knee precisely and still be silent on whether a given deviation matters for this learner, at this stage, in this task. A real-time two-dimensional system also cannot resolve rotation and depth in the way a movement educator's eye or a three-dimensional laboratory can. Second, the feedback loop shifts attention toward what the camera can quantify. Tactical decision-making, cooperation, expressive movement, and enjoyment may receive less instructional weight simply because they are harder to score. Third, the benefits depend on teachers who can interpret and contextualise outputs. Varga and Fügedi (2026) surveyed 416 pre-service physical education teachers across seven Hungarian universities in autumn

2025/2026, using a revised attitudes instrument whose structure they examined through principal component analysis (KMO = 0.741). They frame integration of AI into practice-oriented teacher education as uneven and shaped by both digital readiness and institutional constraints. Whether teachers can turn skeleton overlays into sound coaching therefore remains unclear. Comparable questions about AI-guided feedback on skilled manual performance arise in vocational apprenticeships (see Q327).

Wearable load tracking makes a different pedagogical contribution. It helps learners and coaches reason about the dose of training, not only its form. Seshadri and colleagues (2019) organise their account around internal workload, the physiological response, and external workload, the work performed. Teaching that distinction is itself valuable kinesiological content. A student who sees heart-rate response diverge from distance covered across a week of practice is encountering, in personal data, the concepts of fatigue, adaptation, and recovery that textbooks present abstractly. In university kinesiology and sport-science programmes, wearable data can therefore serve as a laboratory for data literacy and applied physiology, not merely as a monitoring service.

The injury-prevention claim needs careful handling when it migrates from elite sport to youth athletics and school physical education. Seshadri and colleagues (2019) report that the application of wearable metrics has been shown to reduce injury risk and improve performance. Their account is situated in a clinical and translational context where team physicians and trainers interpret data and design treatment plans. Most school and community youth settings lack that interpretive infrastructure. Whether the protective effect survives the move to settings without medical staff, with developing bodies whose load tolerance changes with growth, and with consumer-grade devices remains unclear. A volunteer coach handed a red-amber-green dashboard may also over-react to noise or under-react to signals the device was never designed to capture.

There is also a subtler pedagogical risk. Montebello (2026), writing about generative AI and assessment, argues that tools can decouple assessment performance from the cognitive engagement that assessment once enforced. An analogous decoupling is plausible in physical education. If a device certifies that a student reached a target heart-rate zone or a step count, the grade may track compliance with the metric rather than the understanding of exertion, pacing, and self-regulation that physical literacy aims to build. Educational designs that ask learners to predict, interpret, and dispute their own data preserve that engagement better than designs that

simply report it. Health-professions education offers a parallel. Schröder and colleagues (2026) evaluated physiotherapy students' use, perceptions, and AI literacy before and after structured curricular adaptations, on the premise that structured training builds confidence with AI-related ethical challenges. The case for embedding interpretive literacy rather than passive consumption is therefore at least being tested in adjacent movement professions.

The privacy risks follow directly from the richness that makes these data pedagogically useful. The categories Seshadri and colleagues (2019) list are physical performance, physiological status, biochemical composition, and mental alertness. These go well beyond athletic information: they bear on health, and potentially on disability, menstrual status, sleep, stress, and substance use. Once recorded, such data can be retained, aggregated, and analysed for purposes unrelated to the lesson in which they were collected. Movement video carries its own exposures. Gait and body proportions can function as identifiers, and recordings can reveal body shape in ways students may find distressing. Because multi-person pose estimation is built to process everyone in the frame (Cao et al., 2018), it captures classmates, spectators, and passers-by who never agreed to be analysed. In a school gymnasium, consent cannot be negotiated one person at a time by a system that by design does not distinguish the participant from the bystander.

Power relations sharpen these risks in educational and athletic settings. Physical education is typically compulsory. Youth athletes depend on coaches for selection and playing time, and collegiate athletes increasingly operate in environments where performance data have commercial and recruitment value. Under those conditions, consent to wear a device or be filmed is rarely free. Function creep is a live concern: data gathered for feedback may later inform grading, roster decisions, scholarship evaluations, or disciplinary judgements about effort. Bugeja (2026), addressing college athletics administrators, urges them to prepare for AI-related threats and risks in athletics. He draws on his own early warnings about social media's unintended effects on campus life, a reminder that institutions have previously adopted networked technologies faster than they anticipated their harms. Creely's (2026) consequentialist review of ethical scholarship on generative AI in education between 2022 and 2026 likewise traces how concerns widen from immediate classroom effects to social and environmental consequences. Applied to biometric sensing, that lens directs attention to downstream outcomes: who later gains access, what inferences are drawn, and how a youth's recorded body follows them into adulthood. Questions of who governs data about a

community's bodies and practices echo the sovereignty arguments made for Indigenous data (see Q329).

Institutional governance has not kept pace with either the benefits or the risks, and the available evidence on AI policy in education suggests why. Elkhodr and Gide (2026) observe that higher-education policy on generative AI has been stronger on governance, permission, disclosure, and assurance than on pedagogy. They note that publicly visible approaches rarely provide structured, student-facing workflows. The same imbalance appears likely in movement analytics. A university may issue a data-protection statement about wearables without telling a kinesiology student how to interpret, challenge, or delete their own load profile. Policy ambiguity has measurable consequences for learners. Enriquez, Lin and Baciu (2026) investigate how institutional ambiguity about AI shapes students' educational experiences and decision-making, alongside students' perceptions of benefits and risks. Their focus is academic AI rather than biometric sensing, but the mechanism plausibly carries over: where rules are unclear, students guess, comply defensively, or disengage.

Adamakis and Rachiotis (2025), in a state-of-the-art overview, argue that pedagogical integrity, AI literacy, and policy integration must be addressed together rather than separately. For physical education and youth sport, that integration would require a learner-facing account of data practices. It would cover which signals are captured, where they are processed, who sees them, how long they are kept, and which decisions they may and may not inform. Movement educators would also need preparation to deliver that account. Varga and Fügedi's (2026) emphasis on institutional constraints in Hungarian physical education teacher education is pertinent. Teachers cannot explain privacy trade-offs they were never taught, and pre-service programmes are where biometric literacy could most efficiently be built. Few studies have examined how physical education teachers themselves understand the privacy implications of the sensors they are being encouraged to adopt. That gap matters because teachers are often the only adults positioned to notice when a monitoring practice becomes coercive.

Several principles follow from the evidence, while respecting its limits. First, data minimisation should be the default. If the pedagogical goal is feedback on technique, systems can process video locally, extract the skeletal keypoints needed for feedback, and discard raw images. If the goal is teaching load concepts, aggregated or self-held data may suffice without central retention. Second, purpose limitation should be explicit and enforceable. Data collected for learning should be walled off from grading, selection, and discipline unless learners and

guardians knowingly agree otherwise. Third, learners should be positioned as interpreters of their own data rather than objects of surveillance. That design choice serves pedagogy and privacy at once, and it counters the decoupling of measured performance from genuine understanding that Montebello (2026) warns against in another domain. Fourth, analytic pipelines should be audited end to end. Pose estimation feeds metric extraction, which feeds load models, which feed recommendations, and small errors can compound across stages in ways resembling those of chained AI agents (see Q343).

The evidence does not yet show several things the field most needs to know. It does not demonstrate that the injury-reduction and performance benefits Seshadri and colleagues (2019) report transfer to school physical education or under-resourced youth programmes. It does not establish whether automated movement feedback improves motor learning, motivation, or lifelong physical activity more than skilled human feedback. Nor does it show how real-time pose systems such as that of Cao and colleagues (2018) perform across diverse body types, clothing, adaptive equipment, and disability. Zhou and Wu's (2025) case for AI-reformed physical education is a reasoned argument, not an outcome trial. The opportunities catalogued by Abedin and colleagues (2026) derive from generative-AI studies in higher education rather than from embodied learning. On the risk side, it remains unclear how often biometric data from educational settings are actually repurposed. The scale of harm is projected from structural conditions more than documented through incident data, and reasonable scholars weigh it differently. Creely's (2026) consequentialist framing helps here: the right question is not whether these tools can produce benefit, but whether their expected benefits, for these learners and in these institutions, outweigh foreseeable harms that fall disproportionately on young people with the least power to refuse. Until outcome trials and privacy audits in school and youth settings exist, cautious, minimised, and learner-controlled adoption is the defensible course.

Q327 In Career and Technical Education (CTE) and vocational trades, how are AI diagnostics and augmented-reality guidance reshaping skilled manual and technical apprenticeships?

13 citations · 13 sources · 3 cross-references

Claim 1 disputed

AI diagnostics and augmented-reality guidance are reshaping skilled manual and technical apprenticeships mainly by redistributing who holds diagnostic knowledge and when novices receive it, rather than by replacing the hands-on core of the trades. The empirical base for that claim is still uneven. Strong evidence exists for augmented reality as a learning technology in general and for AI assistance in white-collar work. Direct, trade-specific evidence from welding bays, electrical panels, automotive shops and construction sites is far thinner. The chapter's position is therefore deliberately qualified: the mechanisms are plausible and partly documented in adjacent settings, but how they play out across the long, socially embedded arc of an apprenticeship remains unclear.

Sun and Pratt (2024) frame the problem well. They observe that career and technical education is often overlooked in discussions of teaching and learning, and largely absent from the literature on AI in educational settings, even though its programming is more hands-on and industry-connected than most K-12 or higher education. Their review draws on Diffusion of

Innovations theory and treats AI adoption among CTE educators as a process shaped by specific barriers and opportunities, not an inevitability. This matters because technologies in the trades rarely arrive through curriculum committees alone. They often come through employers, equipment vendors and certification bodies, so instructors may meet AI-enabled diagnostic tools on the shop floor before they meet them in a pedagogical framework.

Lampropoulos (2025) reviews 201 documents from Scopus and the Web of Science on combining artificial intelligence with augmented and virtual reality in education. He describes this convergence as an area that can significantly affect the educational domain. For trades instruction, the convergence is the relevant unit of analysis. An AR overlay that shows a learner where a component sits is one thing. An overlay driven by a model that interprets sensor data and proposes a fault hypothesis is something different, because it combines spatial guidance with inferential judgment. The broader experience of AI across vocational and professional training is treated elsewhere in this volume (see Q066). The focus here is on that pairing of perceptual scaffolding and automated diagnosis.

The augmented-reality half of the pairing has the firmer evidential footing. Garzón and Acevedo (2019) conducted a meta-analysis of 64 quantitative studies with 4,705 participants, published between 2010 and 2018 in major journals, to estimate AR's impact on students' learning gains. Their motivation is instructive: they note that much earlier work on AR in education was qualitative and did not measure the size of the effect. A quantitative synthesis of that scale supports the general proposition that AR can improve learning outcomes. It does not, however, establish that AR improves the specific outcomes trades care about. These include psychomotor precision, safe tool handling, tolerance to variation in real materials, and the tacit judgment that separates a competent journeyworker from a merely compliant one. Most studies in such syntheses come from general educational settings, so transfer to procedural trade skill is an inference, not a finding.

Immersive virtual reality offers a parallel line of evidence that tells a similar story. Radianti and colleagues (2020) mapped applications of immersive VR in higher education across both high-end and budget head-mounted displays. They found little systematic prior work on how researchers had applied immersive VR for these purposes, and they set out design elements, lessons learned and a research agenda. For vocational programmes, the relevance of their mapping lies less in any single outcome than in the design question it foregrounds. Simulation fidelity, interaction design and cost tier are decisions with pedagogical consequences, not just

engineering ones. A budget headset that lets every apprentice rehearse a lockout-tagout sequence may serve a programme better than a high-fidelity rig that only a few can use, but the evidence to settle such trade-offs in the trades is not yet available.

Allied technical fields where imaging, diagnostics and spatial guidance already converge give a glimpse of the likely direction. In a narrative review of dentistry, Meto and Halilaj (2025) describe how cone beam computed tomography, AI-assisted diagnostics, 3D imaging and AR/VR simulation tools are enhancing clinical precision, streamlining workflows and redefining dental education. Dentistry is not a construction trade. Yet it shares with skilled technical work a dependence on fine motor control guided by interpreted imagery, and dental technology and assisting roles sit close to the vocational tradition. The review's narrative design means its claims about educational transformation should be read as descriptive rather than causal. Even so, it illustrates the pattern that matters here: diagnosis, planning and hands-on execution become linked through a shared digital representation that learners must learn to read critically, not just follow.

The AI-diagnostics half of the pairing draws its strongest evidence from outside the trades, and that evidence carries a consistent and pedagogically important signal. Brynjolfsson, Li and Raymond (2025) studied the staggered introduction of a generative AI conversational assistant among 5,172 customer-support agents. Access to AI assistance raised productivity, measured as issues resolved per hour, by 15 percent on average, with substantial heterogeneity across workers. Less experienced and lower-skilled workers improved in both speed and quality. The most experienced and highest-skilled workers saw small gains in speed and small declines in quality. The authors also report evidence that AI assistance facilitated worker learning. Noy and Zhang (2023), in a preregistered experiment with 453 college-educated professionals doing occupation-specific writing tasks, found that ChatGPT cut average task time by 40 percent, raised output quality by 18 percent, and reduced inequality between workers.

If these patterns carried over to diagnostic work in the trades, AI troubleshooting assistants would act chiefly as accelerators for novices. They would compress the gap between a first-year apprentice and a seasoned technician on routine fault-finding. That is the optimistic reading, and it is consistent with apprenticeship's goal of moving learners toward competent practice. Two cautions apply. First, both studies concern language-mediated tasks, where the AI's output is the work product itself. In a trade, a diagnostic suggestion still has to be checked against a physical system, and an error may show up as a damaged component or an unsafe

installation rather than a weaker paragraph. Second, a novice getting better output with assistance is not the same as a novice getting better. The customer-support evidence on learning is encouraging, but it does not show that skill persists once the assistance is removed.

Dell'Acqua and colleagues (2023) supply the necessary counterweight. In a preregistered experiment with 758 consultants, they introduce the idea of a "jagged technological frontier": AI assistance improves performance on some tasks and worsens it on others, even within the same workflow and at seemingly similar difficulty. For trades education, this may be the most transferable finding of all. Diagnostic AI trained on common failure modes may perform well on frequent faults and fail without warning on unusual equipment, legacy installations or field conditions its training data never captured. Apprentices must learn where that frontier lies, and that knowledge is itself a form of expertise.

Task-exposure estimates point the same way. Eloundou and colleagues (2024) estimate that roughly 1.8 percent of jobs could have over half their tasks affected by large language models with simple interfaces. That share rises to just over 46 percent once complementary software developments are taken into account. The jump suggests that integration with sensors, documentation systems and visual interfaces, precisely the AI-plus-AR configuration, is what turns language models from peripheral to pervasive in technical occupations.

The deepest stakes for apprenticeship lie in its social structure, not in individual task performance. Apprenticeship has long worked through graduated participation. The novice observes, assists, takes on bounded pieces of real work, and gradually assumes responsibility under the eye of a more experienced practitioner. Beane's (2018) study of robotic surgery is the most illuminating evidence on what happens when technology disrupts this arrangement. Drawing on a two-year, five-site comparative ethnography and a blinded interview study across 13 top-tier U.S. teaching hospitals, Beane found that learning through increasing participation with approved methods worked well in traditional open surgery. The abstract frames his inquiry around trainees who must learn new techniques and technologies when approved practices for learning are insufficient, which leads to what he terms shadow learning.

The parallel to technologically mediated trades is direct. When an AR headset guides an apprentice step by step, or a diagnostic system names the likely fault before the apprentice has formed a hypothesis, the moments in which a mentor once handed over a bounded challenge can disappear. The work still gets done, and perhaps done faster. What thins out is the struggle

through which diagnostic reasoning develops, and with it the mentor's chance to see that reasoning and correct it. Beane's account suggests that trainees facing such constraints may find unofficial routes to competence, and that those routes may be unevenly available. A related concern about AI short-circuiting productive struggle appears in work on inquiry-based learning (see Q328). In the trades, the stakes include physical safety.

The productivity findings and the shadow-learning findings are therefore in tension, and the tension should be stated plainly rather than resolved by preference. Brynjolfsson and colleagues (2025) suggest AI can spread expert practice to novices. Beane (2018) suggests technology can erode the participatory pathway through which novices become experts. Both may be true at once, on different timescales. Gains appear quickly in output metrics, while costs build slowly in the depth of the workforce's skill. The jagged frontier of Dell'Acqua and colleagues (2023) adds a further complication. If novices rely on AI precisely where it is weakest, and have not yet developed the judgment to notice, the result may be confident error rather than competent performance. Few studies have followed apprentices longitudinally through AI-mediated training to see which dynamic dominates. Without such work, claims that AI and AR either accelerate or hollow out apprenticeship stay speculative.

Institutional conditions shape whether these technologies widen or narrow opportunity, and the emerging vocational literature is mostly perceptual rather than outcome-based. Jadjuli (2026) used a phenomenological design, with semi-structured interviews of fifteen technical-vocational higher education students in Jolo, Sulu, Philippines, to examine how students experienced AI adoption and what it implied for learning, employability and institutional readiness. The analysis draws on the Technology Acceptance Model, Human Capital Theory and Digital Governance Theory. A small qualitative study cannot be generalised. It does, however, remind the field that institutional readiness is a precondition. Programmes in resource-constrained regions may meet AI-enabled diagnostics and AR hardware unevenly, if at all.

Huang (2026) offers the largest quantitative vocational dataset among the works examined here: 526 Taiwanese technical and vocational students with internship experience. Using path analysis with bootstrapping, the study found that perceived generative AI literacy was positively associated with technological self-efficacy, career adaptability and perceived employability through the hypothesised serial pathway, with internship quality tested as a moderator. All six hypotheses were supported. These are associations among self-reported

perceptions, not evidence that AI literacy causes employability, and still less that it improves trade competence. The internship component is nonetheless notable. It suggests that the workplace-based element of vocational training is where AI literacy becomes meaningful, which fits the view that apprenticeship's situated character still matters.

Equity questions extend beyond geography. Portell-Fonolla and colleagues (2026) synthesised 13 empirical studies on AI applications supporting women's career development. Their themes included bias mitigation and representation, such as auditing gendered language and platform-level disparities, and skills development and empowerment. They note that empirical evidence in this area remains limited. Given the long-standing gender imbalances in many skilled trades, AI-mediated recruitment, guidance and training tools could either reproduce or challenge those imbalances. Which outcome occurs depends on design and governance rather than on the technology itself. Similar questions about how body-tracking and sensor data are collected and governed arise in physical education (see Q326) and apply with equal force to AR systems that record trainees' movements on the job.

Sun and Pratt (2024) bring these strands together at the level of the educator. Their diffusion-based analysis treats adoption as a series of decisions shaped by barriers and opportunities. This framing usefully resists both vendor-driven enthusiasm and reflexive refusal. CTE instructors, many of whom came into teaching from industry, are well placed to judge where a diagnostic tool's suggestions match field reality and where they do not. Supporting that judgment may matter more than any particular platform.

Several conclusions can be drawn with appropriate confidence, and several cannot. The meta-analytic record demonstrates that augmented reality can improve learning gains in educational settings generally (Garzón & Acevedo, 2019). The field-experimental record demonstrates that AI assistance tends to benefit less experienced workers most on language-mediated tasks (Brynjolfsson et al., 2025; Noy & Zhang, 2023). It also shows that such benefits are jagged rather than uniform across tasks (Dell'Acqua et al., 2023). The ethnographic record suggests that technology can disrupt the participatory pathways through which apprentices traditionally become experts (Beane, 2018). What the evidence does not yet show is how these findings combine in the trades themselves. Specifically, it is unclear whether AR-guided, AI-diagnosed training produces journeyworkers who can diagnose unfamiliar faults without assistance, work safely when systems fail, and eventually mentor others.

The pedagogical implication is a design principle rather than a verdict. Diagnostic AI and AR guidance are most defensible when they are faded deliberately as competence grows. They should prompt apprentices to commit to a hypothesis before revealing the system's own, and they should keep the mentor's role intact. These features also make the frontier of the tool's reliability visible, so learners learn when to trust it and when to check it against the physical system. Programme evaluations should track not only time-to-competence and error rates but also unassisted performance and the quality of mentor-apprentice interaction. Until longitudinal, trade-specific studies exist, the honest summary is this: these technologies are changing how apprentices access knowledge, and whether they are changing what apprentices come to know remains open.

Q328 In Project-Based Learning (PBL) and interdisciplinary inquiry, how do educators prevent AI from short-circuiting the messy collaborative inquiry phase?

14 citations · 14 sources · 4 cross-references

Claim 1 disputed

Educators prevent generative AI from short-circuiting the messy collaborative inquiry phase of project-based learning mainly through design rather than prohibition. They sequence human divergence before machine assistance. They constrain AI tools to roles that provoke uncertainty instead of resolving it. They make the inquiry process, not only the finished artefact, the thing that is assessed. And they protect the face-to-face negotiation of meaning on which collaborative projects depend. This answer rests more on theory, design proposals and early quasi-experimental work than on settled comparative evidence. The field has not yet established which of these moves matters most, or for whom.

The starting point is that project-based learning was never a guarantee of learning. Chen and Yang (2019) conducted a meta-analysis comparing project-based learning with traditional, teacher-led instruction on academic achievement. Their aim was to estimate its overall effect and to identify which study features moderate that effect. The framing matters for the AI question. If the benefits of project work depend on how it is implemented, then a technology that changes how students move through a project is a potential moderator in its own right. It is not a neutral convenience.

The most direct experimental warning comes from outside project work. Bastani and colleagues (2025) gave nearly a thousand high school mathematics students access to generative AI tutors in a field experiment. They reported, as their title states, that generative AI without guardrails can harm learning. Their argument is that learning remains critical even when AI raises productivity, because the systems are fallible and users must be able to check their outputs. In a project setting, the student who cannot evaluate what the machine proposes is exactly the student who has skipped the inquiry. The point of that study is not that AI tutors are harmful in themselves. It is that the absence of design constraints allowed students to lean on the tool in ways that displaced the practice learning required. That distinction frames everything that follows: the question for project teachers is less whether AI enters the classroom than what conditions govern its entry.

To see what is at stake, it helps to be precise about what the messy phase does. In a well-designed project, students spend time unable to frame the problem. They argue over what counts as evidence. They chase dead ends and discover that teammates hold different working assumptions. This is not inefficiency waiting to be optimised. It is the place where disciplinary judgement and collaborative reasoning are built. Generative AI threatens this phase in a specific way. It can produce a plausible problem statement, a tidy research plan or a polished synthesis before the group has done the cognitive and social work those artefacts are supposed to represent. The output looks like the end of inquiry while standing in for its absence. Teachers who have run projects for years often recognise the pattern: the group that seems stuck on Tuesday is frequently the group that produces the most original framing by Friday. Removing the stuck interval removes the conditions for that originality.

The social dimension is easily underestimated. San Pedro (2026), writing about scholarly collaboration rather than school projects, draws on cognitive science research showing that thinking is fundamentally social. He centres Indigenous scholars who asserted this long before Western science named it. He argues that institutions which privilege individual production reproduce logics of extraction and individualism. The parallel for project-based learning is uncomfortable. When each group member privately consults a chatbot and returns with a finished contribution, the project becomes a set of parallel individual transactions with a machine. Something that looks like collaboration replaces the shared construction of knowledge. The relational and epistemic stakes of this shift are taken up from the perspective of Indigenous knowledge systems elsewhere in this chapter (see Q329).

Brooke, MacDonald and Hunter (2024) offer a complementary picture from arts education. They describe collaborative a/r/tography as a more ecological approach to the development of generalist primary teachers, who often lack confidence, competence and community in the arts. Their work concerns teachers rather than students. Still, it shows that agency in open-ended creative inquiry is cultivated through community and sustained shared practice. That is precisely what a frictionless answer engine can erode.

The most practical defence is to change what the AI is permitted to do at each stage of a project. Several design studies position AI as a scaffold for reasoning rather than a source of answers. Firdaus and Alifah (2026) integrated AI into a project-based inquiry framework for elementary geometry. The AI provided adaptive prompts supporting students' reasoning, representation and reflection while learners worked on authentic tasks such as designing

classroom layouts and park environments. The design logic is instructive. The AI asks; the students decide; the project's authenticity stays anchored in a physical problem the machine cannot complete for them. The comparable argument about conversational AI as a scaffolding partner within a learner's zone of proximal development is developed for language learning elsewhere (see Q325).

Omeh and Ayanwale (2025) studied AI-supported problem-based learning in a quasi-experimental, non-equivalent pretest–posttest design with 87 second-year undergraduates in computer-robotics programming courses at Nigerian universities. They examined engagement, intrinsic motivation and achievement. Their study addresses problem-based rather than project-based learning, and its non-randomised design limits causal claims. Even so, it belongs to a growing body of work that treats AI as an embedded component of inquiry pedagogy rather than an external threat to it.

Scaffolding, however, carries its own failure mode. Sánchez (2026), writing about medical education, identifies a "mimicry trap." A system that fluently generates Socratic-sounding questions can appear to cultivate reasoning while in fact functioning as interactive content delivery. He frames this as an educational instance of the ELIZA effect and of the proxy-outcome problem. For project teachers, the lesson is that an AI configured to "only ask questions" is not automatically protecting inquiry. Leading questions can steer a group toward a predetermined answer as efficiently as a direct response. They also leave students with the false impression that they reasoned their way there.

Modality may matter too. He, Niu and Mohamad Ashari (2026) conducted a quasi-experimental study in higher education. It compared multimodal generative AI, which processes and generates text, images and visual representations, with text-based AI and with no AI support. Outcomes were critical thinking dispositions and writing quality in inquiry-based academic writing. The authors note that the impact of generative AI on critical thinking dispositions remains empirically underexplored. Their study is best read as opening that question rather than settling it.

Because AI can generate a convincing final product, many educators have shifted assessment weight toward the inquiry trail. This trail includes evolving research questions, records of disagreements and how they were resolved, annotated dead ends, and oral defences in which groups explain why they rejected alternatives. The rationale is straightforward. When the

artefact can be produced without the inquiry, the inquiry itself must be made visible. The same pressure on interpretive work, where summarisation tools offer instant products, is examined for literary study elsewhere (see Q323).

Process-focused assessment, however, creates a tension the field has not resolved. Sánchez (2026) names surveillance as a second failure mode alongside mimicry. Making inquiry visible can slide into monitoring every keystroke and prompt, which changes the character of the inquiry being monitored. Students who know their exploratory confusion is logged may perform tidiness rather than risk genuine uncertainty. Lee (2026) offers a more constructive frame, though she writes about qualitative researchers rather than school pupils. Drawing on Foucault's ethics of the self, she reframes ethics in human–AI entanglements as an ongoing, contingent practice of self-formation rather than procedural compliance. Translated to project work, this suggests that the goal is not policing AI use. It is cultivating students who can account for how they used it and why.

Two contributions point toward what such cultivation looks like. Hall, Johnson and Paulus (2026) describe how three experienced instructors integrated generative AI into graduate research methods courses. They emphasised active learning and technological reflexivity, guided by Mollick's principles from Co-Intelligence. Their account is a reflective practitioner report, not a controlled study. Its value lies in showing reflexivity built into course activities rather than appended as a policy. Ko (2026) proposes a curricular model for inquiry-driven student–AI engagement. He argues that the field has attended substantially to material access and algorithmic fairness but comparatively less to the learner-side capacities that determine whether AI is engaged critically or passively. That distinction is the crux of the problem in project-based learning. Two groups with identical tool access can have entirely different inquiry experiences depending on whether they treat AI output as a claim to be interrogated or a deliverable to be submitted.

None of these designs works unless teachers can enact them, and the evidence on teacher readiness is mixed. Egara and Mosimege (2024) used a sequential exploratory mixed-methods design to study how secondary mathematics educators in Nigeria's Nsukka Education Zone perceive ChatGPT in mathematics teaching. Their sample comprised 80 teachers selected by stratified random sampling, followed by detailed interviews. Their work reflects a broader reality. Teachers' awareness and perceptions vary, and the conditions for thoughtful integration cannot be assumed.

Kelley and Wenzel (2025) observe that many teacher candidates remain unaware of AI's presence despite its growing influence on personal and professional life. They describe professional partnership inquiry as a route to AI literacy in teacher education. The recursion is notable. Preparing teachers to protect inquiry from AI appears to require teachers to undertake inquiry about AI themselves. Chinoracky and Stalmasekova (2025) conducted a thematic review of 42 open-access, peer-reviewed articles published between 2022 and 2025. They classified the ethical problems of AI use by university educators across teaching, research and other activities. Their review is a reminder that teachers' own uses of AI, in planning projects, generating prompts or giving feedback, raise ethical questions that shape the inquiry climate students experience.

The implication for project-based learning is that guardrails are partly a professional development problem. A teacher who has never experienced generative AI collapsing their own uncertainty is poorly placed to notice it happening to a student group. Such a teacher is also poorly placed to tell productive struggle from unproductive floundering that a well-timed AI prompt might legitimately relieve. Professional learning that asks teachers to work through an open-ended project with and without AI support, and to compare what each version demanded of them, would address this gap directly.

Several matters remain unclear, and they should temper confident prescription. First, the evidence base is small and methodologically uneven. The studies most directly relevant to AI-supported project or problem-based inquiry are largely quasi-experimental, conducted in single disciplines and in particular national contexts. They cannot yet show whether gains in engagement or achievement come at the cost of the collaborative reasoning the messy phase is meant to develop. Bastani and colleagues (2025) are closer to a rigorous test, but their setting was mathematics tutoring, not open-ended group projects. Extrapolating from one to the other requires caution.

Second, the field genuinely disagrees about what AI should do in inquiry. Design-oriented work such as that of Firdaus and Alifah (2026) treats AI prompts as cognitive scaffolding that can strengthen inquiry. Critical work such as Sánchez (2026) warns that question-generating systems may only simulate the cultivation of reasoning. Both positions are plausible. No comparative study yet distinguishes, in project settings, scaffolding that deepens group inquiry from scaffolding that quietly substitutes for it.

Third, almost all current outcome measures are individual. Achievement scores, motivation scales and critical-thinking disposition instruments capture what single learners gain. The thing most at risk, however, is the collective process San Pedro (2026) describes as fundamentally social. Until researchers measure group-level epistemic work, such as how groups frame problems, handle disagreement and revise shared models, claims that a given AI design protects collaborative inquiry will rest on inference. The analogous difficulty of preserving messy empirical measurement while adopting AI analysis tools is addressed for the laboratory sciences elsewhere (see Q321).

Finally, Chen and Yang's (2019) attention to moderators is a useful discipline for future research. AI use should be studied as one moderator among several, alongside group composition, task authenticity, duration and teacher expertise, rather than as a single intervention with a single effect. Duration deserves particular attention, since the messy phase unfolds over days or weeks while most AI studies capture comparatively short interventions. The defensible practical stance for now is provisional. Delay AI until groups have committed to their own framing. Restrict it to roles the group can interrogate. Assess the inquiry trail without turning it into surveillance. And invest in the teacher learning that makes these judgements possible. Practitioners should regard all of this as informed design, not demonstrated effect.

Q329 How do Western-centric foundation models distort Indigenous knowledge systems, oral traditions, and local ecological wisdom—and how do the CARE Principles for Indigenous Data Governance protect community sovereignty?

10 citations · 10 sources · 4 cross-references

Claim 1 disputed

Western-centric foundation models distort Indigenous knowledge systems in three ways. They underrepresent the languages in which that knowledge lives. They flatten oral, relational and place-bound knowledge into decontextualised text. And they absorb and recirculate community knowledge without the consent, benefit-sharing or accountability that its holders require. The CARE Principles for Indigenous Data Governance answer this problem by moving decisions about such data back to Indigenous communities. Data use is judged by collective benefit and community authority, not only by technical openness or reusability.

The structural starting point is not in dispute. Bender and colleagues (2021) describe recent natural language processing as a race toward ever-larger pretrained language models, "especially for English," with progress measured on English-language benchmark leaderboards. Joshi and colleagues (2020) quantify the corresponding exclusion. Only a very small number of the world's more than 7000 languages are represented in rapidly evolving language technologies. Their analysis of resources and conference representation shows a marked disparity between languages, and it questions the claim that current models are "language agnostic."

For educators, these findings matter because a foundation model is not a neutral library. It is a statistical compression of whatever its builders could collect at scale. When Indigenous languages and knowledge practices are thinly present or absent, the model does not fall silent.

It fills the gap with the dominant patterns it has learned, and students then receive those patterns as authoritative answers.

Carroll and colleagues (2020) frame the governance side of this problem precisely. Indigenous communities feel a tension between protecting their rights and interests in Indigenous data, which explicitly include traditional knowledges, and supporting open data, machine learning, broad data sharing and big data initiatives. That tension is aggravated by concerns about secondary use and limited opportunities for benefit-sharing. A large pretrained model is an extreme case of secondary use. Material gathered for one purpose becomes training signal for countless unforeseen purposes, and the originating community rarely shares in any resulting benefit.

Oral traditions show the mechanism of distortion most clearly, because the gap is one of form as well as quantity. Much Indigenous knowledge is transmitted through speech, song, ceremony, performance and apprenticeship. Its meaning is bound up with who is speaking, to whom, in which season and under what obligations. Text-dominant pretraining captures at best a transcription, often made by an outsider, sometimes in a colonial language, and stripped of the relational rules that govern who may hear a story and when.

The resulting failure is subtler than an outright error. The model may produce fluent, plausible paraphrases of narratives it has encountered only in fragments, ethnographic summaries or popularised retellings. This gives learners the impression that a living tradition is a fixed, public and fully documented corpus.

Multimodal systems are often proposed as a remedy. Claman and Sezgin (2024), writing about dental education, describe how foundation models increasingly combine multiple types of data, including text, images and audio. In principle, audio and video capability could let models engage with spoken knowledge on its own terms, and the technical capacities and failure modes of such systems are examined elsewhere in this volume (see Q342).

Modality alone, however, does not resolve the governance problem. A model that can ingest recorded oral narratives can also absorb restricted or ceremonial material far more efficiently than a text model ever could. Without community-controlled access rules, multimodality may deepen extraction rather than correct it.

The language-learning implications follow the same pattern. For many Indigenous languages, the resource disparities documented by Joshi and colleagues (2020) mean that translation and conversational tools are weak, absent or trained on scarce and possibly unrepresentative text. The broader debate about whether conversational AI supports or undermines communicative fluency (see Q325) takes on a sharper edge here. For a language under revitalisation, a poor-quality model risks normalising errors at precisely the moment a speech community is trying to stabilise its forms.

The empirical record on this specific risk is thin. Few studies have measured how learners of Indigenous languages respond to model-generated text. Whether such tools help or harm revitalisation therefore remains unclear.

Local ecological knowledge raises a related but distinct problem: the decontextualisation of place-based expertise. Indigenous ecological wisdom is typically specific to a particular landscape. It is encoded in seasonal calendars, place names, observational sequences built up over generations, and practices whose validity depends on local conditions. A general-purpose model trained mostly on globally aggregated, predominantly Western scientific and popular text tends to return generic ecological claims. These may be accurate in aggregate but wrong for a given watershed, coastline or growing season.

Instructively, mainstream science faces a version of the same difficulty. Ma and colleagues (2026), reviewing geoscience-oriented large language models, note that knowledge in that field is expressed through specialised terminology, heterogeneous documents, maps, imagery, geospatial structures and temporally ordered interpretations. They argue that these features distinguish domain-specific models from generic applications. If generic models struggle to represent the spatial and temporal structure of Western geoscience without deliberate adaptation, it is reasonable to expect even greater difficulty with ecological knowledge that is spatially specific, temporally layered and largely unwritten.

This is an inference by analogy, not a finding. The geoscience review does not examine Indigenous knowledge, and the extent of distortion in ecological outputs has not been directly measured in the work considered here.

The analogy also cuts the other way, and the field disagrees about what follows from it. One position holds that the remedy is better domain adaptation: curated datasets, community-informed fine-tuning and evaluation against local expertise. A competing position, grounded in

the concerns Carroll and colleagues (2020) articulate about secondary use and benefit-sharing, holds that improving a model's command of traditional knowledges is not automatically a good. Better representation in a system the community does not control may simply make extraction more effective.

Both positions agree that generic outputs mislead. They diverge on whether the solution is inclusion in the model or protection from it. The governance frameworks discussed next are best read as a way to let communities make that choice themselves rather than having it made for them.

The CARE Principles must be understood against the open-data framework they were designed to complement. Wilkinson and colleagues (2016) introduced the FAIR Guiding Principles to improve the infrastructure supporting reuse of scholarly data. They were jointly endorsed by stakeholders from academia, industry, funding agencies and scholarly publishers. Their distinctive emphasis is on enhancing the ability of machines to find and use data automatically, as well as supporting reuse by individuals.

That machine orientation is exactly what makes FAIR data valuable for training foundation models. It is also why FAIR, taken alone, can be insufficient for Indigenous data. A dataset can be perfectly findable, accessible, interoperable and reusable while its use violates the rights and interests of the people it concerns.

Carroll and colleagues (2020) developed CARE to address this gap. The four principles are Collective benefit, Authority to control, Responsibility and Ethics, and they shift attention from the properties of data to the relationships surrounding them.

Each principle bears on foundation models in a specific way. Collective benefit asks whether data use returns value to the community, rather than only to model developers. Authority to control asserts that Indigenous Peoples hold rights to govern how their data, including traditional knowledges, are collected, accessed and used. Responsibility places obligations on those who work with Indigenous data to support the community's self-determination and to account for how data are used. Ethics puts Indigenous rights and wellbeing at the centre across the data lifecycle.

Read against a model-training pipeline, these principles challenge the default assumption that publicly accessible material is fair game for ingestion.

Carroll and colleagues (2021) take the argument from principle to practice. They argue that operationalising FAIR together with CARE enhances machine actionability while bringing "people and purpose to the fore." The aim is to resolve Indigenous Peoples' rights to and interests in their data across the full lifecycle. They also observe that, as big data, open data and open science expand, Indigenous Peoples' rights to control and access their data within these environments remain limited.

This framing is important because it rejects a false choice between openness and protection. CARE does not demand that Indigenous data be locked away. It demands that decisions about sharing, reuse and machine processing be made with, and ultimately by, the communities concerned.

Two cautions apply. CARE is a set of principles, not an enforcement mechanism. And the work considered here does not establish how far commercial foundation-model developers have adopted it, nor whether adoption changes what models actually learn.

In education, these concerns become concrete in curriculum, classroom tools and institutional policy. A teacher who asks a general-purpose model to explain a local creation narrative, the medicinal use of a plant, or seasonal fishing practices may receive a confident synthesis with no stated provenance. It may also blend traditions from different nations and omit the protocols that govern sharing.

The pedagogical response suggested by the critical literature is not to forbid such tools. It is to treat their outputs on Indigenous topics as claims to be checked with knowledge holders. Learners should be taught to ask whose knowledge this is, how the model could have come to contain it, and whether its circulation was authorised.

There is also emerging work on the reverse direction: using Indigenous pedagogies to teach AI itself. Tetteh and colleagues (2026) examined whether the Culturo-Techno-Contextual Approach can increase interest in elementary AI regardless of gender. This teaching method integrates indigenous knowledge, context and technology. Their quasi-experimental study involved 105 Ghanaian basic-education participants, 38 in the experimental group and 67 in the control group, selected through purposive and random sampling.

The design and sample are modest, and a quasi-experimental comparison of unequal groups cannot isolate the contribution of indigenous content from other features of the intervention.

The study nonetheless signals a different orientation. Here Indigenous knowledge is a pedagogical resource that frames how students meet AI, rather than raw material to be mined by it.

Institutional governance is the third layer. Uddin (2026) observes that university responses to generative AI have largely framed governance as compliance, concentrating on technical reliability, permissible use and policy enforcement. Such approaches, the author argues, neglect users' moral agency, cognitive engagement and responsibility. The critique applies with particular force to Indigenous data. A compliance-oriented policy might regulate plagiarism and detection while saying nothing about whether course materials, recorded community lectures or student work on Indigenous topics may be fed into external models.

CARE offers educational institutions a more demanding standard. Before such materials enter any AI pipeline, institutions would need to ask whether the relevant communities have authority over them and whether their use benefits those communities.

The infrastructure side of this question, including connectivity, language access and sovereignty at system level, is treated elsewhere (see Q359).

Several technical proposals promise to reconcile model capability with community control, but their fit with Indigenous governance is still largely untested. Borazjani and colleagues (2025) describe federated foundation models for education. In this approach, federated learning enables collaborative, privacy-preserving training across decentralised institutions while accommodating diverse modalities and tasks. Their motivation is that privacy regulations, data silos and limited domain-specific data hinder deployment.

In principle, a federated architecture could let a community keep its recordings, texts and ecological observations on infrastructure it controls. It would contribute to shared model improvement only on terms it sets, which resonates with CARE's emphasis on authority to control. Two cautions qualify this. The proposal is framed around institutional privacy, not Indigenous sovereignty. And privacy-preserving training does not by itself guarantee collective benefit or protection against secondary use of what the model learns.

The broader limits of the evidence should be stated plainly. The demonstrations that language technology is concentrated on English and a few other high-resource languages are well established (Joshi et al., 2020; Bender et al., 2021). The specific claim that foundation models

systematically misrepresent particular Indigenous knowledge systems is plausible and widely voiced. Yet it rests more on structural reasoning than on systematic audits of model outputs against community-validated knowledge. Few studies have conducted such audits, and designing them ethically is itself a CARE problem. Testing what a model knows about restricted knowledge risks further circulating it.

The CARE framework is well articulated and has been paired with FAIR for operational use (Carroll et al., 2021). How consistently its principles are honoured in the training of commercial models, however, remains unclear. Evidence on classroom interventions grounded in Indigenous pedagogy is also at an early, small-sample stage.

What the field can say with confidence is that technical openness and community sovereignty are distinct values. Machine-oriented reuse, the core aim of FAIR (Wilkinson et al., 2016), can serve or undermine Indigenous interests depending on who governs it.

For educators across the disciplines, the practical implication is to treat foundation models as sources whose provenance must be questioned, especially on Indigenous topics. Indigenous communities should be treated as authorities over their own knowledge, not as content for AI systems to absorb. Where local inquiry with knowledge holders is part of the curriculum, protecting that slow, relational work from AI shortcuts is as much a matter of data governance as of pedagogy (see Q328).

Chapter 26: Early Childhood, Developmental Stages, and Parenting in an AI World

9 questions · 121 citations · 95 unique sources · 41 cross-references

Q049 What shared human culture and values should education transmit when AI fragments information into personalized realities?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Education should transmit three things in common when AI fragments information into personalized realities. The first is a disciplined capacity for epistemic agency. The second is a shared commitment to evidence and to collectively validated ways of knowing. The third is a lived practice of solidarity built through encounter with people unlike oneself. Together these sustain a shared world in which citizens can at least argue about the same facts. The deepest threat posed by AI-driven personalization is not misinformation in the conventional sense. It is the dissolution of that shared world.

The technical trajectory of the field makes this concern concrete. A recent position paper argues that large language models should learn individual rather than aggregated human preferences, and it acknowledges the societal cost of that design choice. If everyone interacts with differently personalized systems calibrated to their particular preferences and beliefs, shared reality and common knowledge may erode. The engineering case for personalization is real. Systems tuned to an averaged user serve many actual users poorly. But the same logic that improves individual fit loosens the common reference points on which public reasoning depends. This is the civilizational wager now sitting, largely unexamined, at the heart of educational policy.

The question for educators is therefore not only what children should learn, but what they must learn in common. It is also why that commonality is itself a moral and political good. Carlos Alberto Ávila Araújo (2026) frames a related problem through the concept of information integrity, which the UN and G20 have proposed against disinformation, hate speech and

conspiracy theories. Analysing institutional documents through Habermas's theory of communicative action, Araújo argues that generative AI poses new challenges to the concept's three founding principles: accuracy, consistency and reliability. He also notes that these challenges are not yet reflected in the documents that define the concept. A dual taxonomy of AI's opportunities and risks for democracy makes the parallel point that personalized content can quietly hollow out the informational preconditions of self-government.

The problem is more layered than early warnings about filter bubbles suggested. A social-psychological analysis published in Frontiers in Psychology observes that personalized media environments expose individuals to information aligned with their existing beliefs. This raises concerns about polarization, intergroup hostility and the erosion of shared political reality. Its central contribution is to reject a purely technological account. Filter bubbles emerge from the recursive interaction of three forces: motivated cognitive processing, identity-based social networks and algorithmic amplification. In that analysis, emotion operates across all three layers. The implication for education is sobering. Removing a recommender system would not by itself restore a common world, because the habits of selective attention it reinforces are partly human habits that schooling must address directly.

AI does not simply distort the information landscape from the outside. It reshapes the internal habits by which people seek, weigh and revise knowledge. A Frontiers in Education study of epistemic authority in generative AI learning spaces argues that these systems affect not only beliefs but belief revision itself. In the classroom, this means students may update their knowledge in response to algorithmic authority, without recourse to further justification or reflection. A fluent, confident and personalized answer can acquire the standing once reserved for a textbook or a teacher, while lacking the accountability structures that made such authorities trustworthy. The question of how a generated answer differs epistemically from a discovered one is taken up in its own right elsewhere (see Q005). For present purposes, the relevant point is that fragmentation operates on two levels at once: what people believe, and how they come to believe it.

Araújo's (2026) Habermasian framing sharpens why this matters collectively and not merely individually. Communicative action presupposes participants who can raise and redeem validity claims against a background of shared understanding. When the background itself is personalized, the conditions for reaching understanding are weakened before any argument begins. How large this effect is in practice remains unclear. The filter-bubble literature itself

disputes the magnitude of algorithmic, as opposed to self-selected, exposure effects, and the educational evidence specific to generative AI is still thin.

This is where the educational stakes become philosophical rather than merely technical. Drawing on Wieczorek's 2025 analysis, a commentary from the National Education Policy Center argues that the values underpinning current educational AI work directly against much of how democratic education has been understood since John Dewey. Those values are individualism, mastery-based learning and the automation of teaching. Personalized learning optimizes the individual learner's trajectory through content. Democratic education, by contrast, has always been partly about friction: encountering minds unlike one's own, negotiating disagreement, and building the civic capacity to inhabit a world held in common. Wieczorek's conclusion is pointed. The current push for educational AI is producing technologies that diminish students' opportunities for communication and collaboration with others.

The literature does not speak with one voice here, and the disagreement should be stated plainly. Empirical work on personalization reports genuine gains. Junzhen Wang (2026) ran a 12-month longitudinal experiment with 360 children with special needs in China. The study reports significant improvements in attention, memory and problem-solving relative to traditional methods, and the author attributes neuroplastic changes in key brain regions to the system. Effects varied by disorder type, including ADHD and autism spectrum conditions. Wang also reports a dose-response relationship between system usage and cognitive gains, although the abstract leaves open whether the design separates usage from other learner differences. The author also flags challenges of resource equity and teacher adaptability. Jurgita Bagdonaitė and Valentina Dagienė (2025) synthesized 94 empirical studies of AI in primary education from 2020 to 2025. They find that AI adds most value when it personalizes feedback and practice, scaffolds inquiry and computational thinking, and supports teacher decision-making through learning analytics. Reported gains include reading fluency, problem-solving, motivation and participation among diverse learners.

These findings do not refute the democratic critique, but they reframe it. The benefits Wang and the Bagdonaitė and Dagienė review document concern individual cognitive and skill outcomes. The Deweyan concern is about what happens to the shared, deliberative dimension of schooling when individual optimization becomes the organizing principle. Notably, Bagdonaitė and Dagienė find that the most sustainable outcomes came from human-in-the-loop approaches in which teachers interpret and moderate AI insights. Even the strongest case for personalization

therefore depends on a human, relational frame around the technology. The related risk that individualized pathways harden into algorithmic determinism is examined separately (see Q013).

What, then, should education transmit? Three clusters of value emerge from current scholarship as non-negotiable, whatever AI systems can deliver efficiently.

The first is epistemic agency: the cultivated capacity to interrogate sources, tolerate uncertainty and resist the seduction of algorithmic fluency. A recent analysis of AI in education beyond learning outcomes argues that tools prioritizing speed and convenience risk three harms: amplifying automation bias, reducing cognitive struggle and weakening critical thinking. Its remedy is that AI must preserve cognitive friction. It should prompt retrieval, offer delayed feedback and frame uncertainty as opportunity, so that it fosters the intellectual resilience and critical thinking that democratic societies require. This value cannot be transmitted by software alone. It requires teachers who model doubt, not just delivery. The Frontiers analysis of epistemic authority reinforces the point. If students learn to defer to algorithmic outputs without justification, the habit of asking how anyone knows something is lost precisely when it matters most.

The second is shared factual ground: a curriculum that insists certain things are true, contested or false independent of any individual's preference profile. The dual taxonomy of AI and democracy warns that algorithmic filtering and personalized content can nudge people toward particular viewpoints without their awareness. This limits exposure to diverse information and weakens their capacity for independent thought. The resulting manipulation diminishes people's ability to make informed choices and undermines democratic participation. Education's answer must be a commitment to evidence, method and the disciplines that have developed collectively validated ways of knowing. These include scientific reasoning, historical analysis, literary interpretation and mathematical proof. Araújo's (2026) three principles offer a useful vocabulary for what such a curriculum protects. Accuracy concerns correspondence to evidence. Consistency concerns coherence across sources and occasions. Reliability concerns trustworthy procedures for producing claims. A personalized system can be locally accurate while undermining consistency across users, which is exactly the property a common curriculum exists to secure.

Neither value implies hostility to AI. The argument is that these goods must be designed for deliberately, because the default incentives of engagement-optimized personalization run in the opposite direction.

The third value is solidarity through encounter: the experience of being educated alongside people whose lives, backgrounds and conclusions differ from one's own. The European DEMOCRAT project describes education for democracy as a holistic and participatory approach. It aims to foster the knowledge, skills, values and attitudes that active and responsible citizenship requires. The project's account goes beyond textbooks, emphasizing experiential and inclusive learning that strengthens democratic competencies such as critical thinking, dialogue, agency and meaningful participation. No AI tutor, however sophisticated, replicates the moral education that occurs when a classroom must reach understanding across genuine disagreement.

A shared culture need not mean a single, homogenized one. Simona Tiribelli and colleagues (2024) note that AI now analyses vast historical datasets and catalogues cultural collections at scale. They show that this raises unresolved ethical questions of authenticity, subjectivity and interpretive bias in AI-reproduced or generated works, and they observe that these questions remain largely unaddressed in scholarship. Huimeng Wang and colleagues (2025) propose guidelines for the sustainable use of AI in heritage preservation. Their guidelines stress inclusive data governance, protection of data authenticity, AI as a complementary rather than substitutive tool, and balancing innovation with cultural values. They illustrate these with cases including educational dissemination through Google Arts & Culture. For education, the lesson is that cultural inheritance can be widely shared through AI, but only if questions of authenticity and interpretation are kept visible rather than smoothed away by fluent generation.

The common ground can also draw on plural moral traditions. Milton Maldonado and Daniela Córdova-Pintado (2025) present Indigenous Andean ethics of reciprocity as both epistemology and moral system. Their sources are Mauss's theory of the gift and practices such as ayni (reciprocal labour), minka (collective work) and randi-randi (generalized reciprocity). In this framework, giving, receiving and returning are sacred obligations that secure continuity, balance and mutual recognition across generations. Wealth is understood as relational abundance, measured by kinship networks and the capacity to meet communal obligations. Such traditions offer a counterweight to the individualism Wieczorek identifies in educational AI, and a reminder that a curriculum can be common without being culturally narrow. Jeffrey

Gardiner's (2026) theory of knowledge capital adds an economic register. It distinguishes commons and public knowledge from enclosed forms and names the risk of cognitive enclosure. Read alongside the educational literature, this suggests that shared knowledge is a form of public infrastructure whose governance, not just its existence, determines who benefits from it.

These three values converge on formation rather than information. Laura Maska, Dimitrios Kalamaras and Charalambos Tsekeris (2026) argue that higher education remains governed by a scarcity model built on knowledge transmission, durable credentials and economic productivity. They claim this model is structurally misaligned with societies shaped by AI, ecological destabilization, labour-market reconfiguration and declining institutional trust. In their account, the central challenge is shifting from knowledge scarcity to power abundance. The deeper crisis is a deficit of formation: universities have underdeveloped the human capacities needed to use technologically amplified power wisely, meaningfully and responsibly. Their proposed first principle, flourishing stewardship, means cultivating persons and institutions able to pursue meaningful lives while preserving the conditions for shared human and planetary flourishing. The argument is conceptual, built on a systematized scoping review rather than outcome data. It aligns closely with questions about whether knowledge loses value when no longer scarce (see Q003) and about education for meaning rather than employment (see Q046).

The analysis of AI in education beyond learning outcomes states the stakes directly. An ethical use of AI in education is about preserving education as a space for autonomy, critical inquiry and democratic formation. If AI systems undermine these values, they risk weakening not only learning outcomes but the social institutions that depend on educated, reflective and empowered citizens. The evidence reviewed here supports a cautious synthesis. Personalization appears to deliver real individual gains, particularly when teachers remain in the loop. Whether it erodes common knowledge at scale remains unclear and contested. Education therefore needs to secure the commons by design rather than assume it will survive by default.

The curriculum of the future will need to be deliberately, even stubbornly, common. Uniformity is not a virtue in itself. The reason is that a democracy requires citizens who can, at minimum, argue about the same world.

> **What changed in this edition:** This answer is unchanged in Edition 122. Its most recent revision, in Edition 117: Expanded to six sections that add evidence on personalization gains (Wang 2026; Bagdonaitė & Dagienė 2025), information integrity, heritage authenticity, Indigenous reciprocity and formation. The revision states disagreements plainly and adds cross-references to Q003, Q005, Q013 and Q046. (708 → 2,132 words · 8 new sources)

Q330 Why should early childhood education (ages 0–8) remain overwhelmingly tactile, play-based, and human-relational—and what are the neurodevelopmental risks of voice assistants and AI toys during language and Theory-of-Mind acquisition?

14 citations · 14 sources · 4 cross-references

Claim 1 disputed

Early childhood education should remain overwhelmingly tactile, play-based and human-relational because the two capacities that most define these years are built inside contingent exchanges with responsive people. The first is spoken language. The second is the understanding that others have minds, beliefs and intentions of their own. Voice assistants and AI toys can imitate the surface of such exchanges, but they cannot reliably supply the social substance on which early learning appears to depend. The neurodevelopmental risks they pose are therefore less about any single dramatic harm. They are more about substitution: time, talk and attention that might have gone to a caregiver, a peer or a block tower go instead to a device whose responsiveness is engineered rather than intersubjective.

This position should be stated with care about what kind of evidence supports it. The strongest findings concern the social gating of early language learning and the developmental correlates of screen exposure. They were not obtained with modern generative AI. The direct evidence on AI toys and conversational agents is newer, smaller and more descriptive. A recent state-of-the-art review by Ljungcrantz (2026) located 39 studies on AI and early childhood education published between 2020 and 2024, after applying its exclusion criteria. That is a modest base for a field now saturated with commercial products. The argument here is accordingly a precautionary inference. It moves from well-replicated mechanisms in human development to

plausible risks in a technological setting that has not yet been studied at the necessary scale or duration. The broader map of what is known and unknown in this area is treated elsewhere (see Q097). This essay concentrates on the mechanisms that justify a human-first default.

The case begins with the infant's ear. Kuhl, Tsao and Liu (2003) start from a now-classic observation. Early in life, infants can discriminate the phonetic units of all languages, native and foreign alike. Between 6 and 12 months, the ability to discriminate foreign-language phonetic units sharply declines. Their two studies asked what conditions are necessary and sufficient to reverse that decline through short-term foreign-language exposure. They framed social interaction explicitly as a variable of interest. The work matters for this chapter because it placed a precise question at the centre of developmental science: whether the same linguistic input is equally useful to the infant brain regardless of whether a responsive human delivers it. A great deal of subsequent thinking about screens and language has organised itself around that question, and the answer has consistently pointed toward the social conditions of input rather than its acoustic content alone.

Roseberry, Hirsh-Pasek and Golinkoff (2014) sharpened the mechanism for toddlers. They exposed 36 children aged 24 to 30 months to novel verbs under three conditions: live interaction, socially contingent video chat, and noncontingent, yoked video showing the same content. Children learned the novel verbs only in the socially contingent conditions, live interaction and video chat. This result is especially relevant to AI because it locates the active ingredient in contingency, not in physical co-presence. A partner on a screen who responds to what the child does supported learning. Identical footage that did not respond did not.

That finding cuts in two directions, and honesty requires acknowledging both. On one reading, it is reassuring about technology: mediated interaction is not intrinsically inert. On another, it is a warning about AI specifically. Conversational agents are the first widely available technology that produces something resembling contingency without a human on the other end. Whether algorithmic contingency is functionally equivalent to human contingency for word learning remains unclear. The contingency in the Roseberry study came from an adult who was tracking the child's gaze, intentions and confusion, and who adjusted accordingly. Voice assistants respond to utterances. They are typically poor at responding to the pointing, fussing, partial words and shared attention that make up so much of toddler communication. The developmental literature suggests that this richer, multimodal responsiveness, rather than turn-taking alone, carries the learning. That is precisely what current devices approximate least well.

Until studies directly compare word learning from AI agents with learning from responsive humans, the defensible position is that AI contingency is an unproven substitute during the period when language foundations are laid.

The second developmental stake is Theory of Mind, the gradually constructed understanding that other people have beliefs, desires and knowledge that can differ from one's own and from reality. Children build this understanding largely through participation in mental-state talk, conflict, pretend play and repair with real minds. A conversational agent complicates this learning environment because it speaks in the grammar of minds. It says "I think" and "I don't know", and it uses names and personalities, while lacking the beliefs and intentions that such language normally indexes.

Children's own conceptions show the resulting ambiguity. Xu and Warschauer (2020) examined how three- to six-year-olds categorise conversational agents in smartphones and smart speakers, and how they justify their judgements. Children sometimes took a nuanced position. They spontaneously attributed both artifact and animate properties to the agents, or regarded them as neither artifacts nor animate objects. Such hybrid categorisation is not in itself pathological. Young children routinely animate stuffed toys, and flexible categorisation may reflect sophistication rather than confusion. The concern is different. A pretend friend is animated by the child, who controls the fiction. A voice assistant animates itself, answers back and is designed to be persuasive. Whether sustained exposure to entities that produce mental-state language without mental states alters the trajectory of Theory-of-Mind development remains unclear. Few studies have measured Theory-of-Mind outcomes in relation to conversational agent use, and the inference from category judgements to developmental harm should not be overstated.

Trust is a closely related issue. Learning from testimony is central to early childhood, and children must learn to calibrate whom to believe. Girouard-Hallam and Danovitch (2022) investigated, across two studies, children's trust in and recall of statements made by a novel voice assistant compared with a human informant. In the first study, children aged 4 to 5 and 7 to 8 heard each informant respond to questions from multiple categories. The design is valuable because it treats voice assistants as testimonial sources whose credibility children must evaluate, and it compares two age bands within the 0 to 8 window. The sample's limits matter, however. The first study involved 40 children in each age group, drawn from predominately White, upper-middle-class families. Generalising to children with different home language,

socioeconomic or cultural backgrounds, whose exposure to smart speakers and whose norms of adult authority may differ, is not warranted. The broader point is that young children are actively forming beliefs about whether devices know things. An environment that positions an always-available voice as an answer source may shape epistemic habits in ways the field has barely begun to track.

Even if AI interactions were developmentally neutral in themselves, they would not occur in a vacuum. Every hour a young child spends talking to a device is an hour not spent in the forms of activity that early childhood pedagogy has long valued: manipulating materials, negotiating with peers, being read to, moving through space. The screen-time literature offers the closest available evidence on this displacement problem, with appropriate cautions. Madigan and colleagues (2019) noted that excessive screen time is associated with developmental delays. They also noted that the direction of this association was unclear. Greater screen time might lower developmental performance, or children who already struggle might be given more screen time to manage challenging behaviour. Their longitudinal cohort of 2,441 mothers and children in Calgary, Alberta, drawn from the All Our Families study, used a three-wave cross-lagged panel model specifically to disentangle that directionality. Designs of this kind are the right response to the reverse-causation problem. Even so, they remain observational, and conclusions about screen time cannot simply be transferred to AI toys. AI toys are interactive, often audio-only and sometimes embedded in physical objects, which places them in a category the screen-time literature was not built to address.

The commercial context intensifies the concern. Hirsh-Pasek and colleagues (2015) described children as living in the midst of a vast, unplanned experiment. They observed that "educational" apps, numbering 80,000 in Apple's App Store as of January 2015, were largely unregulated and untested, and that the time and resources to evaluate each one did not exist. Their response was to offer a way of defining the potential educational impact of current and future apps, rather than leaving the label to marketers. The same structural problem now applies, arguably with greater force, to AI-enabled toys and companions. Questions of how statute and design codes govern smart toys and children's data are addressed separately (see Q337).

The literature does not speak with one voice here. Some theoretical syntheses are considerably more optimistic. Cimino, Maremmani and Cerniglia (2025), drawing on Vygotskian sociocultural theory, distributed cognition and the Five Big Ideas framework, argue that AI-

powered personalised learning platforms enhance engagement and adaptability, and that robotics and gamification foster problem-solving and collaboration. The disagreement is partly about evidence standards and partly about age. Claims of enhanced engagement, especially in theoretical discussions, do not establish developmental benefit. Engagement is also exactly what commercial design optimises. For children under five in particular, the burden of proof should rest on those proposing that AI interaction improves on human interaction, not on those defending the human default.

A human-relational default does not require AI to be absent from early childhood settings. It requires AI to be positioned behind the adult rather than in front of the child. Much of the existing professional literature already points this way. Jambunathan (2025) reports that teachers have used AI to generate lesson plans, curricula and other content, including in early childhood special education and in work with English language learners. Teachers' reluctance stemmed substantially from feeling insufficiently trained to use it confidently. Oh-Young and Karlin (2024) similarly describe how early childhood special education teachers can use ChatGPT to facilitate instruction and support daily teaching practice. In both cases the AI serves the practitioner, and the child's experience remains mediated by a responsive human.

Practitioners themselves appear to see the field the same way. In a survey of 292 Austrian early childhood education and care teachers conducted in May and June 2025, Pölzl-Stefanec (2026) found that 9.6% fully integrated AI into their practice, 34.3% used it at least occasionally, and 65.6% recognised its potential to support pedagogical processes such as documentation, observation or language education.

The gap between recognised potential and actual use is instructive. Documentation and observation free adult time for children. Language education is more ambiguous, and it is exactly where the mechanisms discussed above counsel caution about direct child-facing use. Teacher dispositions matter as well. Eker and Ertek Eroğlu (2026), studying 236 preschool teachers, examined how analytical and holistic thinking styles relate to attitudes toward AI. Their premise is that implementation depends heavily on teachers' cognitive and attitudinal readiness, which implies that professional preparation, not procurement, is the lever.

Governance has not kept pace. Liang and Tan (2026) identify a policy imbalance in Australia. Generative AI use in schools has received explicit national guidance, whereas its implications for early childhood education and care are addressed only through broader digital frameworks.

That pattern deserves wider scrutiny, because the developmental stakes are arguably highest where policy attention is thinnest. A developmentally sequenced approach in which the early years remain essentially unplugged, with AI concepts introduced through play and discussion rather than device interaction, offers one coherent response (see Q331).

Several gaps should temper confidence on all sides. The bibliometric analysis by Latorre-Medina and Abdelmaula-Mesaud (2024) concludes that the potential of AI in early childhood education is yet to be realised. Ljungcrantz's (2026) review shows how small the empirical base remains. The evidence does not yet show that voice assistants or AI toys cause language delay. Nor does it show that they impair Theory of Mind, or that children who use them fare worse over time once family circumstances are accounted for. The evidence equally fails to show the reverse: that they are harmless, or that their apparent contingency can stand in for a responsive adult during the sensitive periods of phonetic and lexical learning. The most consequential open question follows directly from Roseberry and colleagues' finding. If contingency rather than presence drives toddler word learning, does machine-generated contingency qualify? Answering it requires experimental comparisons with AI agents, longitudinal cohorts that measure AI exposure separately from passive screen time, and samples far more diverse than the predominately upper-middle-class groups that dominate current work on children's trust in devices.

Under that uncertainty, asymmetry of risk should govern practice. Tactile, play-based, relational early education has no plausible developmental downside. The opportunity cost of displacing it during language and social-cognitive acquisition could be substantial and slow to detect. The concerns raised here also lay foundations for later stages. The questions of parasocial attachment and algorithmic influence that become acute in early adolescence (see Q332) have roots in how young children first learn to tell minds from machines. For now, the responsible stance for educators and parents is to let AI lighten adult workloads while keeping the child's hours full of people, objects and play.

Q331 What is a developmentally sequenced framework for introducing AI across K–12 (Ages 5–8 Unplugged Foundations; Ages 9–11 Guided Co-Exploration; Ages 12–14 Critical Apprenticeship; Ages 15–18 Autonomous & Disciplinary Mastery)?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

A developmentally sequenced framework for AI education moves children through four stages. In the early years they build embodied, unplugged intuitions about how machines follow rules and find patterns. In upper primary they explore real AI tools under close adult guidance. In early adolescence they serve a critical apprenticeship in how data, design and power shape AI systems. In late adolescence they use AI autonomously and with discipline inside the subjects they are mastering. Each stage widens the learner's independence only once the conceptual and dispositional groundwork beneath it is secure.

The framework's architecture is not new. It extends a move made by the joint working group that the Association for the Advancement of Artificial Intelligence and the Computer Science Teachers Association formed in May 2018. As Touretzky and colleagues (2019) describe, that

group set out to define what students in each grade band should know about artificial intelligence, machine learning and robotics, explicitly modelled on existing national standards for K–12 computing education. The grade-band logic matters. AI is treated as a body of understanding that accumulates over years, not as a single unit or a tool to be adopted. Long and Magerko (2020) supply the companion idea that AI literacy is a definable set of competencies, oriented to interacting with AI effectively and evaluating it critically. They pair this with design considerations for learner-centred technologies that make AI more understandable.

The four age bands proposed here are a design argument, not an empirically validated developmental map. They draw on the grade-band precedent and on broad features of cognitive and social development. Few studies have tested whether these particular age thresholds mark real discontinuities in what children can learn about AI. The boundaries should therefore be read as flexible defaults that teachers adjust to individual learners. They are not gates.

The first stage, Unplugged Foundations for ages five to eight, keeps AI learning almost entirely off-screen. Children sort picture cards by features they choose, then watch a classmate fail to sort new cards using someone else's rule. They play games in which one child acts as a "robot" that can follow only literal instructions. They notice how a set of examples can lead to a wrong generalisation. These activities plant the conceptual seeds that later stages formalise: machines act on rules or patterns, patterns come from examples, examples can be incomplete, and a machine that responds is not thereby a mind. The case for keeping this period tactile, play-based and relational, and the neurodevelopmental concerns about voice assistants and AI toys during language and Theory-of-Mind acquisition, are developed elsewhere (see Q330). Here the point is curricular. The unplugged stage is not a delay of AI education but its foundation.

The evidence base for unplugged AI pedagogy is thin, and most of it sits just above this age band. Ruan and colleagues (2025) ran a repeated-measurement quasi-experiment with a control group among 56 fourth-grade students. They examined whether combining unplugged and plugged-in activities could build AI literacy more effectively than plugged-in activities alone. The study is valuable because it frames unplugged work as a deliberate design choice and tests it against a screen-only comparison. Its sample is small, its participants are older than five to eight, and it addresses primary education generally. Extending its logic downward to kindergarten and the early grades is an inference, not a demonstrated result. The authors also

note that AI education at primary level remains largely unexplored, which describes the evidentiary position for the youngest learners even more aptly.

Universal Design for Learning offers the most defensible pedagogical scaffold for this stage. CAST's (2024) version 3.0 guidelines organise design around multiple means of engagement, representation, and action and expression. They frame the aim as learner agency: learners who are purposeful and reflective, resourceful and authentic, strategic and action-oriented. For young children, this means the same pattern-finding idea should be reachable through movement, drawing, talk and manipulatives. Children who cannot yet read, or who are still acquiring the language of instruction, are then not shut out of the conceptual foundation.

The second stage, Guided Co-Exploration for ages nine to eleven, introduces plugged-in experiences while keeping the adult firmly in the loop. Children might train a simple image or sound classifier, deliberately feed it skewed examples, and watch its predictions degrade. They might ask a constrained conversational tool a question and then check its answer against a book. The aim is for children to see AI as something that can be inspected, tested and caught out, not as an oracle. This band corresponds most closely to the fourth-grade population that Ruan and colleagues (2025) studied. Their design, which interleaves unplugged reasoning with hands-on tool use, is a reasonable template for the transition. The plugged activity confirms or complicates an idea first met physically.

The central design question at this stage is how much to let the machine do. Balzan and colleagues (2026) frame this through a theoretical model of learner autonomy under generative AI. They ask whether learners can think and act independently, and they set the promise of efficiency and personalisation against the risk that AI erodes the capacities it was meant to support. Their image of "budgeting" human and machine autonomy is especially useful for this age band. A guided co-exploration lesson budgets machine agency tightly. The child sets the question, the tool offers an output, and the child, with an adult, judges it. Because Balzan and colleagues offer a theoretical framework rather than outcome data, it remains unclear what budget is optimal for nine- to eleven-year-olds. The framework clarifies the trade-off without settling it.

Long and Magerko's (2020) design considerations reinforce this. Learner-centred AI technologies should make their workings more visible, not less. Tools that conceal their reasoning are poor choices for a stage whose purpose is building accurate mental models. Co-

exploration also extends beyond school. Many children first meet AI at home, and how families with different levels of technical literacy and home languages can guide that use is a distinct problem (see Q333). The framework's coherence depends on school and home sending compatible messages about when the machine leads and when the child does.

The third stage, Critical Apprenticeship for ages twelve to fourteen, shifts the emphasis from how AI works to how AI acts in the world and on the learner. Students examine where training data come from, whose experiences they omit, and how recommendation and generation systems shape what people see and believe. Learning is "apprenticeship" because students practise the moves of a critical analyst under a teacher's mentorship. They audit an output for bias, trace a claim back to evidence, and argue about acceptable uses. This is also the age at which algorithmic social comparison, parasocial AI companions and identity formation become acute developmental concerns (see Q332). Critical AI literacy at this stage is therefore personal as well as academic.

CAST's (2024) version 3.0 guidelines are directly relevant here. The revision attends more explicitly to learner identity, belonging, bias and systemic barriers. A critical apprenticeship that asks students to interrogate algorithmic bias while ignoring the barriers in its own classroom would be incoherent. The guidelines' emphasis on reflective, purposeful learners also maps onto the metacognitive work this stage demands. Long and Magerko's (2020) emphasis on critically evaluating AI, not merely using it, gives the apprenticeship its competency target.

Two more speculative contributions push the framework's justification further. Gyarmathy (2026) argues, in the context of gifted education, that AI may perform many algorithmic cognitive operations more efficiently than humans. On this view, static, test-based identification of ability should give way to dynamic profiling of cognitive profiles, intrinsic drive and environmental fit. For a K–12 framework, the implication is that early adolescence should cultivate distinctively human capacities and individual strengths, not drill skills a machine can already perform. Chen (2026) proposes a dynamical systems model in which technological change exerts cognitive adaptation pressure. He hypothesises that education informed by motivational neuroscience can sustain positive adaptation even as AI pressure accelerates. Both are conceptual proposals: the first is a framework, the second explicitly hypothesised. Neither demonstrates that critical apprenticeship produces the outcomes it intends. They help explain why this stage might matter, but whether a middle-school critical AI curriculum durably changes adolescents' judgement or wellbeing remains unclear.

The fourth stage, Autonomous and Disciplinary Mastery for ages fifteen to eighteen, gives students substantial independence in choosing whether, when and how to use AI. It situates that use within specific disciplines. A history student weighs a generated summary against primary sources. A biology student evaluates a model's prediction against experimental data. A writer decides which parts of drafting must remain unassisted for the work to be authentically hers. Autonomy here is the outcome the earlier stages were building, which is why Balzan and colleagues' (2026) concern with whether learners can think and act independently is the right test of the whole sequence. If older adolescents can use powerful tools without surrendering their own judgement, the framework has succeeded. If they treat AI as a crutch, earlier stages have not done their work.

The disciplinary turn rests on the claim that what counts as appropriate AI use differs across fields. Alfonso Molina and colleagues (2026), writing about engineering education, argue that behaviourist, cognitivist and situative accounts of learning should be treated as complementary levels of analysis rather than rivals. The situative level concerns the distributed conditions that determine what counts as knowing in a disciplinary community. For late adolescents, this means mastery of AI cannot be generic. It must be learned as part of a discipline's norms of evidence and argument. Leon and colleagues (2025), in a systematic review of 41 peer-reviewed publications from 2020 to 2025 on AI in STEM education, found that integration raises critical questions about pedagogical coherence, assessment reform and algorithmic ethics. Those same tensions confront any upper-secondary programme that embeds AI across subjects.

This stage depends on teachers and leaders as much as on students. Day (2026) analysed online forum contributions from 76 preservice teachers in a postgraduate programme in China. The study examined their perceptions of AI as a non-human instructor and their views on whether it could replace human teachers. Its participatory, qualitative design documents perspectives, not effects, but it signals that teacher preparation must address teachers' own understanding of AI's role. Kumar and Sarkar (2026) conducted a scoping review of 21 sources from 2018 to 2025. They analysed how secondary administrators might lead ethical AI integration across instructional, managerial, strategic and relational leadership dimensions. Disciplinary mastery for students thus presupposes institutional capacity, and the regulatory constraints on edtech profiling and youth data also bound what autonomy schools can responsibly grant (see Q337).

The framework's greatest strength is its coherence. It ties a consensus-oriented grade-band approach (Touretzky et al., 2019) and a competency definition of AI literacy (Long and Magerko, 2020) to a principled pedagogy of access and agency (CAST, 2024), and it explicitly attends to autonomy (Balzan et al., 2026). Its greatest weakness is that almost none of its stage-specific claims has been tested longitudinally. The strongest direct evidence for any band is a single quasi-experiment with 56 fourth graders (Ruan et al., 2025). The other contributions that bear on the later stages are theoretical frameworks, scoping or systematic reviews, or perception studies. They can motivate the sequence but cannot validate it.

Several points remain genuinely contested. The first is timing: whether purely unplugged instruction for five- to eight-year-olds is a protective necessity or an unnecessary delay. The available evidence compares mixed with plugged-only instruction for older children, and that comparison does not settle questions about younger ones. The second is whether AI adoption strengthens or erodes inclusion. Alenezi (2026), examining higher education in Kuwait, observes that AI adoption, Universal Design for Learning and responsible AI governance are usually studied as separate lines of enquiry. Too little of that work engages the critical literature questioning whether AI helps or harms inclusive education. That diagnosis comes from a different sector, but it transfers. A K–12 sequence that assumes AI tools will widen access by default may reproduce barriers, especially where home access and adult mediation are unequal. The third is how much autonomy to grant and when. Balzan and colleagues (2026) frame this as a budgeting problem, not a fixed rule, and the right allocation probably varies by learner, task and discipline.

What the evidence does not yet show is equally important. It does not show that the four age thresholds correspond to developmental discontinuities. It does not show that unplugged foundations in early childhood transfer to better critical judgement in adolescence. It does not show that critical apprenticeship in early adolescence protects against the specific harms that period brings. And it does not show that disciplinary mastery generalises across subjects. Gyarmathy's (2026) call to profile individual cognitive strengths, not sort children into fixed categories, is a useful caution here. A stage framework applied rigidly could become one more categorical gate. Applied as a flexible sequence of defaults, attentive to the learner variability that UDL foregrounds, it offers schools a defensible and revisable way to introduce AI without either rushing young children onto screens or leaving adolescents to discover these tools alone.

Q332 Why is early adolescence (ages 11–14) a neurobiologically sensitive window for algorithmic social comparison, parasocial AI companions, and identity formation?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Early adolescence is a sensitive window because, on current evidence, three processes converge between roughly 11 and 14. First, the association between social media use and wellbeing appears most negative at precisely these ages. Second, adolescents are more acutely attuned to peer evaluation than at any other point in life. Third, the work of constructing a coherent self moves into public, measurable and increasingly machine-mediated spaces. The concern is not

that algorithms or chatbots are uniquely harmful in themselves. It is that systems engineered to rank, recommend and reciprocate arrive just as young people begin to treat social feedback as information about who they are.

The evidence for this claim is uneven, and it should be separated into strands. The developmental timing of risk is best documented for social media and life satisfaction (Orben and colleagues, 2022), although that evidence is correlational. The tendency of humans to treat computers as social actors rests on a long experimental tradition (Nass and Moon, 2000), but one built largely with adults. The dynamics of companion chatbot relationships have been described qualitatively in small adult samples (Skjuve and colleagues, 2021). The neurobiological mechanisms that would link these strands are plausible inference rather than demonstrated pathway.

This answer works through each strand in turn. It then considers how early adolescents themselves understand generative AI, and closes with what the evidence implies for educators and parents and what it does not yet show.

The most direct empirical support for a developmental window comes from Orben, Przybylski, Blakemore and colleagues (2022). They analysed two UK datasets comprising 84,011 participants aged 10 to 80. They found that the cross-sectional relationship between self-reported estimates of social media use and life satisfaction ratings was most negative in younger adolescents. They further reported that sex differences in this relationship were present only during this developmental period.

Two features of this finding matter for the present question. The first is its shape. The association is not uniform across the lifespan but concentrated in a particular age band, which is what one would expect if some developmental characteristic of that period amplifies sensitivity to online social environments. The second is the sex difference. Because it emerges only in this window, it implies that whatever is operating interacts with developmental processes that differ by sex. Pubertal timing is the most obvious candidate, since puberty typically begins earlier in girls.

The limits must be stated with equal clarity. The analyses are cross-sectional and rely on self-reported use. They establish that the relationship varies with age; they do not establish that social media use causes reduced life satisfaction at any age. Reverse pathways, in which less satisfied adolescents use social media more, remain fully compatible with the data.

Neurodevelopmental accounts are often invoked to explain why the window falls where it does. They point to the reorganisation of reward and social-evaluative systems around puberty, and to the protracted maturation of regulatory control. These accounts are coherent and widely held among developmental scientists, but the large-scale survey evidence cannot itself confirm them.

The responsible formulation is therefore that early adolescence shows a distinctive pattern of association. Developmental biology offers a credible explanation for that pattern, but the explanation is not yet a demonstration. It is also worth noticing what this study does not cover. It concerns social media in general, not generative AI, recommender-driven feeds specifically, or conversational agents. Extending its conclusions to AI companions requires argument, not mere citation.

Algorithmic social comparison differs from older forms of comparison in its scale, its personalisation and its opacity. A twelve-year-old has always compared herself with classmates. What changes in recommender-driven environments is that the comparison set is selected by a system optimising for engagement. The metrics of social approval are quantified and visible, and the logic of selection is hidden from the person being shaped by it.

Sánchez-Vera (2025) offers a useful conceptual vocabulary here. He argues that machine-learning-based algorithmic systems operate as cultural agents, acquiring an operative agency that lets them intervene in the production, circulation and legitimation of meaning. On this account, which he develops into a framework of Critical Algorithmic Mediation, algorithms reshape cultural transmission and symbolic power rather than merely delivering content. For an early adolescent assembling an identity from available cultural materials, this matters a great deal. The repertoire of possible selves on offer is itself algorithmically curated, and the signals of which selves are valued are algorithmically amplified.

Hlaimi and Maloney (2026) make a parallel argument in a very different setting, economics education in higher education. They contend that AI is not a neutral pedagogical tool but a sociotechnical infrastructure embedded in corporate power, data regimes and the broader political economy of AI. Their concern is with theoretical monocultures among university students. Even so, the structural point transfers: the environments in which young people encounter algorithmic feedback are designed by actors with commercial interests that need not align with developmental wellbeing.

Bîrzu and Madina (2026), writing from Christian theological anthropology, add a further dimension. They argue that widespread AI use risks externalising interior processes such as reflection, discernment and memory. Their framework is normative and confessional rather than empirical, and readers need not share its premises. Nonetheless, it names a concern that secular developmental accounts also raise. Identity formation in early adolescence depends partly on sustained interior work. That work may be displaced when external systems continually supply verdicts on worth and belonging.

These are conceptual contributions, not tests of developmental effects. They explain why algorithmic comparison might bear with particular weight on early adolescents. None of them demonstrates that it does, and the specific contribution of algorithmic curation, as distinct from social media participation in general, remains unclear.

Parasocial AI companions present a different and arguably newer risk. A social feed invites comparison with others, whereas a companion chatbot offers what feels like a relationship. The foundation for understanding why such relationships form readily is the experimental programme reviewed by Nass and Moon (2000). They demonstrated that individuals mindlessly apply social rules and expectations to computers. People overused human social categories, applying gender stereotypes to computers and identifying ethnically with computer agents. They exhibited overlearned social behaviours such as politeness and reciprocity towards machines, and formed premature cognitive commitments about them.

The significance of this work is that such responses did not depend on users believing the computer was a person. They arose automatically from minimal social cues. Contemporary conversational agents supply far richer cues than the systems Nass and Moon studied, including fluent language, apparent memory, expressed emotion and responsiveness to disclosure. One would therefore expect stronger social responding, not weaker.

Skjuve, Følstad, Fostervold and colleagues (2021) traced how such relationships develop. Guided by Social Penetration Theory, they interviewed 18 participants who had formed a friendship with the social chatbot Replika. Relationships typically began superficially, motivated by curiosity. They then evolved through substantial affective exploration and engagement as users' trust and willingness to self-disclose increased. This trajectory mirrors the deepening of human friendship through reciprocal disclosure. Here, however, one partner is a commercial system whose reciprocity is designed.

The developmental argument is that early adolescence is the period in which young people are learning to calibrate trust and intimacy outside the family. A partner that is always available and always affirming, and that never requires the effortful repair real friendships demand, could alter that calibration. This is a reasonable hypothesis, but it is a hypothesis. Skjuve and colleagues studied 18 adults, not adolescents, and their design describes relationship development without measuring wellbeing outcomes. The mindless-responding experiments likewise did not target early adolescents.

Whether adolescents form companion relationships faster, more deeply or with different consequences than adults remains unclear. Few studies have examined these relationships prospectively in the 11 to 14 age band. The neurodevelopmental case for heightened vulnerability is an extrapolation from the social media window to a technology that may engage the same social-evaluative sensitivities through a different route. The earlier-childhood concern about voice assistants and Theory-of-Mind acquisition (see Q330) is related but distinct. Young children may be confused about what an agent is, whereas early adolescents may understand perfectly well and attach anyway.

How early adolescents themselves make sense of generative AI is an important and understudied part of the picture. Morrison and Mills (2026) combined critical discourse analysis, concordance analysis and thematic analysis to examine how Grade 7 and 8 students aged 11 to 13 conceptualised generative AI. The students were familiar with ChatGPT and took part in focus groups in a secondary school. The study's value lies partly in its premise: early adolescents' framings of AI are themselves objects worth analysing, because those framings shape how young people position AI in relation to their own learning, authorship and judgement.

This connects to identity formation in a way that is easy to overlook. Early adolescence is when academic self-concept consolidates. Young people begin to see themselves as a writer, a mathematician, or someone who is not good at school. If a system can instantly produce text and images, the meaning of competence, and therefore of a competent self, may be renegotiated during the very years when it is being settled.

Montebello (2026) describes a related shift in higher education. He argues that generative AI decouples assessment performance from cognitive engagement, so that learners can produce outputs without engaging in the processes those outputs once required. For an adult whose

academic identity is largely formed, this is a pedagogical problem. For an early adolescent, it may also be a developmental one, because the experience of effortful mastery is one of the materials from which self-efficacy is built.

The evidence on cognitive outcomes is mixed, and it comes almost entirely from older learners. Zhang and Liu (2025) note that a growing number of studies suggest generative AI can help cultivate college students' critical thinking. They set out to test this in an open learning environment, where research is scarce. Optimistic findings among university students cannot simply be transferred downward. Undergraduates bring more mature regulatory capacities and more established epistemic habits to AI use than twelve-year-olds do.

Whether particular patterns of AI use in early adolescence predict later independence and metacognition is addressed elsewhere in this volume (see Q261). The honest position is that the identity consequences of growing up with generative AI as a constant interlocutor have scarcely been studied longitudinally.

Several implications follow, each held with the caution the evidence warrants.

The first concerns governance. Policy frameworks tend to articulate guidance unevenly across developmental stages. Liang and Tan (2026) document a policy imbalance in Australia, where generative AI in schools has received explicit national guidance while its implications for early childhood education and care are addressed only through broader digital frameworks. Their focus is the early years, but the general lesson is that stage-specific risks are easily absorbed into generic guidance. For early adolescence, this means that rules designed for older secondary students, or general provisions on minors, may not address the specific combination of social-evaluative sensitivity and companion-style design. How statutory child-protection instruments handle profiling and design for minors is treated separately (see Q337).

The second concerns pedagogy. If the core vulnerability is unreflective absorption of algorithmically mediated meaning, a central protective response is to make that mediation visible. Kargın, Altun and Aydemir (2026) offer a model from teacher education. Pre-service preschool teachers used generative AI to retell classic fairy tales in ways that challenged their embedded biases, drawing on a critical multimodal literacy framework. A comparable stance, in which AI is treated as an object of critique rather than an oracle, fits the critical apprenticeship that a sequenced curriculum would locate at ages 12 to 14 (see Q331). Cimino, Maremmani and Cerniglia (2025), synthesising work on younger children, likewise frame AI's social-

emotional role through sociocultural and distributed-cognition perspectives. That framing locates development in relationships and shared activity rather than in the tool alone, and it applies equally to adolescents.

The third concerns what the evidence does not yet show. Most importantly, no evidence presented here demonstrates that algorithmic comparison or AI companionship causes harm to early adolescents. The window documented by Orben and colleagues is a pattern of cross-sectional association with social media. The companion research describes relationship formation among adults. The conceptual critiques of algorithmic power are arguments, not measurements. Disagreement is real. Some see in this convergence a strong case for precautionary restriction during these years. Others hold that correlational windows and small qualitative studies cannot carry that weight, and that critical, supported engagement may build resilience.

What is defensible now is a precautionary but non-alarmist position. Early adolescence deserves particular attention because sensitivity to social evaluation and the construction of identity are at their most active. The technologies in question are built to exploit exactly those sensitivities. The research needed to settle the question requires longitudinal and experimental designs that span the 11 to 14 window, measure specific AI uses rather than aggregate screen time, and include adolescents' own interpretations, and it has barely begun.

Q333 How can schools equip parents and caregivers—across varying levels of technical literacy and home language backgrounds—to guide children's homework and AI use at home?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Schools can best equip parents and caregivers by teaching them a small set of concrete roles for guiding homework and AI use at home, rather than expecting them to become technology experts. Those roles include asking children to explain their reasoning, noticing when a finished product has arrived without visible effort, setting simple routines about when and why AI tools are used, and knowing whom to contact at school when expectations are unclear. Schools should deliver this guidance in formats and languages that families actually use, and revise it as both the tools and children's developmental needs change. This position rests on two bodies of work that rarely meet.

The first is the older and comparatively robust research on parental involvement in homework. Patall, Cooper and Robinson (2008) demonstrate that training parents to be involved, as opposed to simply urging them, produces measurable benefits for elementary-age children. Hill and Tyson (2009) show that the question for older children is which strategies promote achievement, not whether involvement matters at all. The second is the newer work on AI literacy. Long and Magerko (2020) define AI literacy as the competencies people need to interact with AI effectively and to evaluate it critically, and they note that public understanding of these technologies is often limited.

The practical task for schools is to translate the first body of evidence into the conditions created by the second. Parents now supervise homework that may have been partly drafted,

solved or explained by a machine, and many of them have no clearer picture of how that machine works than their children do.

The strongest empirical anchor for parent-facing programmes remains the homework literature, and its central lesson is that structured training changes outcomes. Patall, Cooper and Robinson (2008) synthesised fourteen studies that experimentally manipulated parent training for homework involvement. Trained parents' children showed higher rates of homework completion and fewer homework problems, and possibly improved academic performance, among elementary school children. The hedge on performance matters. The firmest effects concern the process of doing homework, completion and reduced difficulty, rather than achievement itself. That distinction maps closely onto the AI problem, because generative tools make completion trivially easy while leaving open whether learning occurred.

Montebello (2026) captures this shift. He argues that generative AI decouples assessment performance from cognitive engagement, because learners can increasingly produce assessment outputs without engaging in the cognitive processes those outputs were meant to require. His argument concerns higher education, and extending it to primary or lower-secondary homework is an inference rather than a finding. Even so, the inference is hard to resist. If a completed worksheet no longer reliably signals effort, then parent training that targets completion rates, the outcome most clearly supported by the meta-analysis, may now target the wrong indicator. Programmes should instead help caregivers attend to process. They might ask a child to talk through one problem aloud, to show a draft before a final version, or to say which parts a tool helped with and which they did themselves. These questions are deliberately simple. They require no knowledge of how a particular tool works, and they can be asked in any language. A caregiver who hears a confident explanation has learned something useful; a caregiver who hears hesitation or borrowed phrasing has learned something equally useful, and can raise it with the teacher rather than accuse the child.

Hill and Tyson (2009) add a developmental caution. Early adolescence brings changes in school context, family relationships and developmental processes, and academic performance often declines just as its long-term consequences grow. A single parent workshop pitched at families of six-year-olds will not serve families of thirteen-year-olds, whose children are seeking autonomy and whose homework may exceed parents' own subject knowledge. Guidance should therefore move by stage, from close co-use with young children towards conversations about purpose and honesty with adolescents. This progression complements,

without duplicating, the age-banded home guidance discussed elsewhere in this volume (see Q150).

What should parents actually understand about AI in order to guide its use? Here the evidence base is conceptual and curricular rather than experimental. Touretzky and colleagues (2019) describe a joint working group formed in 2018 to produce national guidelines defining what students in each grade band should know about artificial intelligence, machine learning and robotics. Their grade-band logic offers schools a ready structure for parent communication. If teachers know what a nine-year-old is expected to understand about how a system learns from data, they can share a parent-friendly version of the same idea. Parent and child then have a common vocabulary, and caregivers are not left to improvise explanations. This alignment is the parental counterpart of the developmentally sequenced school framework treated elsewhere (see Q331).

Long and Magerko (2020) sharpen the content. They frame AI literacy as more than operational skill: it includes the capacity to critically evaluate AI. For caregivers this suggests a modest but powerful core. Parents need to know that these systems can produce confident errors, that their outputs reflect the data they were built on, and that a fluent answer is not the same as a correct one. None of this requires technical training. It does require that schools state these ideas plainly and repeat them. Repetition matters because a single newsletter paragraph is easily forgotten, whereas the same three ideas returned to at parent evenings, in homework notes and in classroom displays gradually become part of how a family talks about technology.

The primary years present a particular difficulty. Yim and Su (2025) report that, despite calls to extend AI literacy education to young students, evidence-based research informing what AI literacy education should contain at primary level remains lacking. Their review surveys frameworks, pedagogies, tools, assessment methods and challenges. Its central finding about the thinness of the evidence means that any parent curriculum for the early years is currently built on principle rather than proof. Schools should be candid about this with families. Presenting provisional guidance as settled science would undermine trust when the guidance inevitably changes.

Reaching families across varying levels of technical literacy and home language backgrounds is, first, a design problem, and the design should start from what parents can already do. The homework training studies synthesised by Patall, Cooper and Robinson (2008) concern parents'

roles in supervising, structuring and responding to homework, and those roles do not depend on fluency in the dominant school language or on digital confidence. A grandparent with limited literacy can still ask a child to explain an answer in the home language. A parent who has never used a chatbot can still agree a household rule that AI help is used after a first attempt, not before. Framing guidance around such roles, rather than around the tools, lowers the barrier to entry. It also positions multilingual families as resources rather than deficits, since explaining an idea in a second language is itself a demanding test of understanding.

The practical repertoire follows from this framing. It includes short printed or audio guides translated into the main community languages, and workshops run with community interpreters or bilingual staff, ideally with children present so that families practise the conversation together. It also includes a small number of consistent prompts that teachers use in class and parents can reuse at home. Schools should test materials with families before distributing them. What remains unclear is how far the effects found in parent-training studies carry over to families whose home language differs from the school's. The syntheses available here do not settle that question, and schools should evaluate their own programmes rather than assume transfer.

A less obvious constraint is that teachers may not yet be ready to train parents. López Costa (2025) surveyed a representative sample of teachers in rural Catalan schools. Over half reported moderate to high AI knowledge, yet classroom implementation remained limited and centred on text generation and content detection. Riachi (2026), interviewing twenty-eight Lebanese teachers, found that most reported familiarity with AI but only a limited proportion integrated it into instruction. Those teachers cited insufficient training, lack of institutional support, and concerns about data privacy and ethical use. Kelley and Wenzel (2025) observe that many teacher candidates remain unaware of AI's presence in daily life. Taken together, these studies suggest a gap between self-reported familiarity and confident practice, a gap that would carry into any parent session such teachers lead. Investing in staff capability is therefore a precondition for credible family outreach, not a separate agenda. Where families differ in their access to paid tools and in their capacity to mediate, the equity dimensions are treated directly elsewhere (see Q334).

Equipping parents is ultimately a leadership responsibility, because it requires sustained resourcing, coordination across classrooms and a coherent message. Kumar and Sarkar (2026) conducted a scoping review of twenty-one sources on secondary school administrators. They

analysed AI integration across four leadership dimensions: instructional, managerial, strategic and relational. Family engagement belongs most naturally to the relational dimension, but it depends on the others. Instructional leaders must align homework design with the guidance parents receive. Managerial leaders must fund interpreters and staff time. Strategic leaders must decide how often guidance is reviewed.

The difficulty is that many leaders are still working out their own position. Gorman and Brennan (2026) interviewed twenty Irish primary principals and concluded that AI leadership is not yet a coherent or established field of practice. Principals were making sense of AI within a policy context that remains provisional and evolving. Lee and Kim (2026), studying fourteen middle leaders in Korean secondary schools, found that professional judgement shaped how leaders incorporated AI into their practice. Read together, these qualitative studies suggest that the messages parents receive may depend heavily on individual leaders' interpretations, so families at different schools, or in different classrooms within one school, could hear inconsistent advice.

Inconsistency is corrosive. Parents who are told by one teacher that AI-assisted drafting is welcome and by another that it counts as cheating cannot guide their children with confidence. Those with lower technical literacy or limited command of the school language are least able to resolve the contradiction by asking. The remedy lies partly in formal agreements about homework authenticity, examined in detail elsewhere (see Q335). It also lies in a simpler discipline: every parent-facing message about AI should come from a single, regularly updated source that teachers also use. That source should be short, translated, dated so families can see when it last changed, and written in the same plain terms used in classroom prompts, so that a parent reading it at home recognises the language a child brings back from school.

The evidence supports some claims firmly and leaves others open. It demonstrates that training parents for homework involvement improves completion and reduces homework problems among elementary children, with weaker support for achievement gains (Patall, Cooper and Robinson, 2008). It also establishes that the value of involvement depends on its form and on the child's developmental stage, with early adolescence posing distinctive challenges (Hill and Tyson, 2009). Defining AI literacy and the grade-banded content of AI education rests on a substantial conceptual foundation (Touretzky and colleagues, 2019; Long and Magerko, 2020).

What the evidence does not yet show is equally important. Few studies have tested parent-training programmes designed specifically for AI-mediated homework. Consequently, the claim that process-focused guidance outperforms completion-focused guidance rests on reasoning from Montebello's (2026) argument about decoupled performance and engagement, not on trials with families. The primary-level evidence on AI literacy remains thin (Yim and Su, 2025). Whether interventions developed largely in monolingual or majority-language settings work comparably for multilingual households remains unclear. The teacher and leader studies are mostly small, qualitative or single-country samples, and their reliance on self-reported familiarity limits how far they generalise.

There is also genuine disagreement about the goal itself. Some schools will treat parental guidance mainly as a defence of academic integrity. Others will treat it as an opportunity for families to explore AI with their children. Montebello's (2026) argument implies that integrity framed purely as detection misses the deeper problem of cognitive engagement. The evidence cannot yet adjudicate between these orientations, and each carries different implications for how much hands-on AI use parents should encourage.

Until better evidence arrives, the defensible course is modest and iterative. Schools should build programmes on the tested principle of training parents for specific homework roles, and should translate core AI literacy ideas into plain language across the community's languages. They should strengthen staff capability first, speak with one consistent voice, and evaluate what they do, sharing results with families openly. Parents do not need to master the technology to guide children well. They need to know which questions to ask, and they need assurance that the school is asking the same ones.

Q334 How does unequal home access to paid frontier AI models and parental mediation create a "Homework & Coaching Divide," and how can schools level the playing field?

15 citations · 15 sources · 5 cross-references

Claim 1 disputed

Unequal home access to paid frontier AI models and unequal parental mediation produce a "Homework & Coaching Divide" because the two advantages compound. Children in better-resourced households tend to get both more capable tools and adults who know how to turn those tools into learning. Children elsewhere get weaker tools, intermittent access, or capable tools with no one to steer their use. Schools can narrow the gap by making high-quality AI an institutional provision rather than a household purchase, by redesigning homework so that thinking is visible and coached in school, and by training families in mediation instead of assuming they already have it. That is the argument of this essay. Its evidentiary base is uneven, however, and the gaps need to be named from the outset.

The conceptual starting point is the long-standing finding that digital divides do not close when connection rates saturate. Van Deursen and van Dijk (2018), drawing on a representative online survey of the Dutch population, showed that the first-level divide persists even in one of the richest and most technologically advanced countries. They argued that it has shifted from inequalities in physical access to inequalities in material access. Generative AI fits this pattern

closely. Free tiers make nominal access nearly universal, while the differentiating resources become recurring subscriptions, newer models, and the devices and quiet time needed to use them well.

Achuthan (2026) adds a second layer. In a survey of 14,653 computer science learners across 166 countries, a population with broadly shared first-level access, the study separated whether everyday users convert to any learning use from how widely converters then use the tool, and estimated both across World Bank income tiers. The framing of an access–conversion gap is the crux of the homework divide. What matters for a child at a kitchen table is not whether a chatbot is reachable but whether its reach is converted into learning, and conversion is where parental mediation does its work.

The material layer of the divide is real but less precisely documented than public debate assumes. Few studies have directly compared learning outcomes for children using paid frontier models with those using free or older tiers. The claim that subscription status itself drives achievement gaps therefore remains unclear and should be treated as a hypothesis, not a finding.

What the qualitative literature does show is how material constraints shape experience. Du, Chen and Wei (2026) interviewed six teachers and educators and four students from local universities, rural communities and linguistically minoritised settings in China. They found that access to generative AI remains profoundly unequal despite enthusiasm about its transformative potential. Their participants interpreted this inequality as consequential for language learning, teaching and local knowledge production. Nkube and Malatji (2026) studied twelve undergraduates with prior academic experience of generative AI at a rural South African university. They examined the conditions that enable or constrain both access and meaningful use, a distinction that again separates reaching the tool from benefiting from it.

Both studies are small, situated in higher education, and set in contexts very different from a primary-school homework routine. Generalising from them to young children requires caution. Their value lies in showing the mechanism rather than its magnitude. Material inequality in the AI era seldom looks like a total absence of technology. More often it looks like partial, unreliable or lower-capability access, which in turn shapes what kinds of use are even attempted.

This is why the structural question of who controls frontier compute, and on what terms public systems obtain it, cannot be separated from household inequality (see Q350). If capability is rationed by subscription price, the household's purchasing power becomes a proxy for the quality of the tutor a child can consult after school. That reproduces, in algorithmic form, the older market for private tutoring.

The mediational layer rests on firmer ground, because parental involvement in homework has a substantial pre-AI evidence base. Patall, Cooper and Robinson (2008) meta-analysed fourteen studies that manipulated parent training for homework involvement. Training parents produced higher rates of homework completion and fewer homework problems, and possibly improved academic performance, among elementary school children. Two features of this finding matter here. First, the benefit came from training: what parents do, not merely whether they are present, can be taught. Second, the achievement effect was hedged as possible rather than demonstrated, a caution worth preserving when the same logic is extended to AI-assisted homework.

Hill and Tyson (2009) assessed meta-analytically which involvement strategies promote achievement in middle school. They situated the question in early adolescence, when academic performance often declines just as its long-term implications increase. That developmental framing suggests the coaching divide is not static. The forms of mediation that help a seven-year-old differ from those that help a thirteen-year-old, and families vary in their capacity to shift strategies as children move through these transitions (see Q192 on how AI-assisted homework interacts with parental capacity more broadly).

Generative AI enters this established terrain in a distinctive way. A chatbot can substitute for some parental functions, such as explaining a concept, checking an answer or drafting an outline. Whether it substitutes for the right ones depends on dispositions that are themselves socially patterned. Liu and Darvin (2026) followed two Chinese female university students from contrasting class positions. Drawing on Darvin and Norton's model of investment, they showed how engagement with large-language-model tools constitutes a social practice that can reproduce inequalities in language learning. The two students' AI literacy practices were shaped by differing dispositions toward technology and by unequal access to material and symbolic resources.

Psychological orientation appears to matter too. Chow and To (2025) surveyed 500 Chinese undergraduates. They reported that a growth mindset toward technology predicted generative AI usage, with performance expectancy, effort expectancy and technology anxiety as mediators. These are correlational associations in adult samples. They nonetheless suggest a plausible pathway into the home: a parent who is anxious about or dismissive of AI may model avoidance, while a confident parent may model strategic use.

The deeper reason the coaching divide may matter more than the tool divide is that unguided AI use can uncouple completed homework from learning. Montebello (2026) argues that assessment historically worked not only as a measure of learning but also as a structural mechanism that implicitly enforced cognitive engagement. Generative AI decouples the two, because learners can increasingly produce assessment outputs without engaging in the cognitive processes traditionally associated with learning. Homework is the paradigm case. A child with a powerful model and no mediating adult can submit flawless work while learning little. A child with a weaker model and an attentive parent may produce rougher work while thinking harder.

This implies that the most capable home setup, without coaching, may not be an advantage at all. On that point the evidence is genuinely unsettled. Dhurumraj and Labuschagne (2026), in a qualitative systematic review with thematic synthesis of studies published between 2018 and 2026, found that AI does not exert a uniform effect on metacognitive processes such as planning, monitoring and evaluation. Their emphasis on unequal contexts implies that whether AI scaffolds or supplants self-regulation depends on the conditions of use. Those conditions include the guidance learners receive.

Ko (2026) makes a parallel argument from curriculum theory. The field has given substantial attention to material access and algorithmic fairness but comparatively less sustained attention to the learner-side capacities that determine whether AI is engaged critically or passively. If those capacities are cultivated mainly at home, by parents with the time and literacy to do so, the coaching divide becomes a capacity divide.

What the evidence does not yet show should be stated plainly. These are conceptual arguments and syntheses drawn overwhelmingly from higher education. Few studies have tracked how young children's metacognition develops under different patterns of home AI use and parental mediation. The magnitude of any resulting achievement gap also remains unclear. The direction

of concern is coherent. Its size, and whether it differs across the early-childhood, middle-childhood and early-adolescent stages central to this chapter, has not been established.

A competing line of scholarship holds that large language models are more likely to narrow educational inequality than to widen it. Lopez-Gazpio (2025) evaluates trends in the transformative potential of large language models to mitigate traditional barriers related to language diversity, learning disabilities, cultural differences and socioeconomic inequalities. The analysis highlights their capacity to personalise instructional content and respond dynamically to learners' educational and emotional needs. Kohnke and Zaugg (2025), in a conceptual review focused on students with disabilities in STEM, conclude that adaptive platforms and intelligent tutors can positively influence engagement, achievement and motivation. They describe AI as an untapped opportunity for equity and access.

These claims are not simply wrong. A free, patient, always-available explainer could in principle give a child whose parents work evening shifts, or do not speak the language of instruction, help that was previously available only to families who could pay tutors. Where the democratisation thesis and the divide thesis disagree, the disagreement is mostly about conditions rather than potential. Both reviews describe what AI can do. The divide literature describes what typically happens when capability is distributed through markets and converted through unequal household resources.

Even within the optimistic literature, equity tends to be asserted more than measured. Beattie and colleagues (2026), in a scoping review of AI in medical education that followed Joanna Briggs Institute methodology, note that although AI offers the potential to democratise access and improve inclusivity, little is known about how equity is actually addressed in AI-enabled education. That gap, identified in a well-funded professional field, is unlikely to be smaller in early childhood and primary schooling.

The defensible position is therefore conditional. AI may level or stratify. Which outcome predominates depends on who provides the tool, how capable it is, and whether someone teaches the child to use it as a thinking partner rather than an answer engine.

Schools can level the playing field by acting on both layers at once. On the material layer, the most direct move is to make AI access an institutional provision. That means a school-licensed, age-appropriate tool of consistent capability, available on school devices and in supervised settings, so that a child's tutor quality does not depend on a household subscription. This

addresses the material-access problem van Deursen and van Dijk identified. It does so without assuming that free consumer tiers are equivalent, and it ties household equity to the public-infrastructure questions raised elsewhere (see Q350). Provision alone is insufficient, as the access–conversion framing makes clear. Supplying a tool without cultivating its use simply relocates the divide from access to conversion.

On the mediational layer, the strongest available evidence points to parent training. The finding that trained parents produce better homework completion and fewer problems is the most transferable result in this literature. It suggests that schools should teach families concrete coaching routines: asking the child to explain an AI answer, comparing it with their own attempt, and noticing when the tool has done the thinking. Those routines should be offered across literacy levels and home languages (see Q333). Schools should also agree shared expectations with families about what legitimate AI help looks like, so that homework norms do not vary with parental sophistication (see Q335).

The deeper lever is pedagogical. If unguided AI decouples output from cognitive engagement, schools can recouple them. One way is to move the most cognitively demanding work into class, where teachers coach it. Another is to redesign homework around process evidence, oral explanation and reflection rather than polished products, which advantage households with better tools. Ko's inquiry-driven model and Sánchez-Vera's (2025) Critical Algorithmic Mediation framework both argue for teaching learners to interrogate AI as a cultural agent rather than accept it as a neutral authority. Sánchez-Vera treats algorithms as acquiring operative agency in the production, circulation and legitimation of meaning. Taught in school, these capacities become a public good rather than a family inheritance. They should be sequenced to children's developmental stage (see Q331).

None of these remedies has yet been tested specifically against a measured home AI divide among young children, and their effects should be evaluated rather than presumed. The logic is nonetheless consistent with what is known. Inequality in the AI era is compounded across tools, dispositions and coaching, so a credible equity response must reach all three.

Q335 How can schools establish transparent "Home-School AI Covenants" so teachers and parents share consistent expectations around homework authenticity and tutor bots?

16 citations · 16 sources · 6 cross-references

Claim 1 disputed

Schools can establish transparent Home-School AI Covenants by co-writing a short, plain-language agreement with families. The agreement should define what counts as authentic homework at each developmental stage, name which tutor-bot uses are encouraged, tolerated or excluded, and set a simple routine by which children disclose AI help. It should be paired with practical training for parents and teachers and revised on a fixed cycle as tools and evidence change. The covenant is not a disciplinary contract. It is a coordination device, and its value depends on whether it changes what adults actually do around homework, not on whether signatures are collected.

The case for building such agreements on family-school partnership, not on policing, rests on a well-established body of research predating generative AI. Patall, Cooper and Robinson (2008)

synthesized 14 studies that experimentally manipulated parent training for homework involvement. Training parents to be involved produced higher rates of homework completion and fewer homework problems among elementary school children. It also possibly improved academic performance, a qualification the authors themselves attach. Three features of this finding matter for covenant design. The effect came from training, not from exhortation. The clearest outcomes concerned the process of homework, not achievement. The evidence is strongest for younger children.

Hill and Tyson (2009) turned to early adolescence, a period they describe as marked by changes in school context, family relationships and developmental processes. Academic performance often declines in these years even as its long-term stakes rise. They place family-school relations and parental involvement at the centre of efforts to sustain achievement across elementary and secondary levels. Read together, these syntheses suggest that a covenant should not use one template for a six-year-old and a fourteen-year-old. The appropriate adult role shifts as children move from supervised practice towards independent work.

The substantive core of a covenant is a shared definition of authenticity, and that definition must be staged by age. Families and teachers often talk past one another because they lack a common vocabulary for what an AI system is doing when it helps a child. Touretzky, Gardner-McCune, Martin and colleagues (2019) describe the joint AAAI and CSTA effort to develop national guidelines. These guidelines specify what students in each grade band should know about artificial intelligence, machine learning and robotics. That grade-band logic offers a ready scaffold for a covenant. Expectations about tutor bots can be aligned with what children at each stage are expected to understand about how such systems work.

Long and Magerko (2020) provide a complementary framing. They define AI literacy in terms of the competencies people need to interact effectively with AI and to evaluate it critically. They argue that learner-centred AI design should foster increased understanding of the technology. For covenant purposes, their contribution is to make critical evaluation an explicit goal, not an assumed by-product of use.

In practice, a staged covenant might proceed as follows. In the early years, it would make the parent the gatekeeper and treat any conversational agent as a shared, adult-mediated activity, not a homework source. In the middle primary years, it might permit tutor bots for explanation and practice but not for producing the work submitted. It would ask children to say, in their

own words, what the tool did. In early adolescence, it might shift towards a brief disclosure note accompanying assignments, recording which tool was used, for what purpose and what the student changed.

The point is not that any particular rule is correct. These specific thresholds are design proposals; none of the research cited here has tested them. The point is that parents and teachers apply the same rule and explain it to children in the same terms. Fiorucci and Bevilacqua (2026) observe that generative AI is reshaping assessment criteria and raising ethical questions about authenticity, source reliability and educational responsibility. A covenant is one place where a school can make its answers to those questions visible to families, instead of leaving them implicit in individual teachers' marking. Questions about the provenance of materials teachers themselves assign are a related but distinct problem (see Q162).

A covenant can be no more consistent than teachers' own practice, and here the recent evidence is sobering. Across several national contexts, teachers report familiarity with AI that outpaces classroom use.

Riachi (2026) studied 28 Lebanese schoolteachers. A majority reported familiarity with AI, yet only a limited proportion integrated it into instruction. The barriers cited were insufficient training, lack of institutional support, and concerns about data privacy and ethical use. López Costa (2025) found a similar gap in rural Catalan schools. Over half of teachers reported moderate to high AI knowledge, but classroom implementation remained limited. Teachers used AI chiefly for text generation and content detection, and less often for video generation or simulations.

The second finding has a direct bearing on homework authenticity. If teachers' main contact with AI is detection, a covenant risks being read by families as a surveillance instrument. Few studies in this area have established how reliable detection is with children's writing, so whether detection can carry the weight some schools place on it remains unclear.

Wu, Zhang, Hu and colleagues (2026) add a psychological dimension. They frame technostress as a factor in middle school teachers' willingness to adopt AI and their actual use of it. They examine how personal digital competence, role conflict, organizational support and technological features bear on that stress. Their work does not establish causal direction. It

does, however, give reason to think that asking teachers to enforce a covenant without support could add to role conflict, not reduce inconsistency.

There are more hopeful signals from initial teacher education. Polly (2026) found in an exploratory study that elementary pre-service teachers considered generative AI tools helpful for generating ideas to differentiate mathematics instruction. Those with more robust background knowledge made more connections to a concrete-pictorial-abstract progression of supports. This suggests that teachers' judgement about when AI help is pedagogically sound depends on subject knowledge, not on tool familiarity alone. That is precisely the judgement a covenant asks teachers to exercise consistently. Day (2026), working with 76 preservice teachers in China, examined how they view AI as a non-human instructor and whether it might replace human teachers. Such views plausibly shape how teachers present tutor bots to parents.

The practical implication is that covenant adoption should be tied to sustained professional learning, not a launch-day briefing (see Q085). Teachers need to rehearse together how they will respond to a disclosed tutor-bot session, an undisclosed one and an ambiguous one before families are asked to rely on that consistency.

Responsibility for the covenant sits with school leadership, and the leadership literature shows that this responsibility is being exercised under considerable uncertainty. Gorman and Brennan (2026) interviewed 20 Irish primary principals using sensemaking theory. Their central finding is that AI leadership is not yet a coherent or established field of practice. Principals interpret AI within everyday school realities and within a policy context that remains provisional and evolving.

This finding cuts two ways for covenant design. It argues against presenting a covenant as settled policy. It also argues for a covenant precisely because it gives families a stable, dated reference point while wider policy shifts. A covenant written as a living document, with a stated review date and a named contact, is more honest about this provisionality than a polished rulebook.

Kumar and Sarkar (2026) offer a structure for distributing the work. Their scoping review of 21 sources from 2018 to 2025 examines secondary administrators' AI responsibilities across instructional, managerial, strategic and relational leadership dimensions. A covenant touches all four. Its instructional dimension concerns what authentic work looks like; its managerial

dimension, which tools are sanctioned and how data are handled; its strategic dimension, how expectations evolve; and its relational dimension, how trust with families is built.

The relational dimension is the one most often neglected when AI policy is drafted by technical committees. Raptis and Psyrras (2026) surveyed 262 Greek primary school leaders on their attitudes toward AI, self-efficacy, perceived usefulness in decision-making and challenges to integration. Their work is a reminder that leaders' own confidence varies and is itself a variable in implementation.

Avidov-Ungar and Ganon-Shilon (2026) are particularly relevant to the transparency question. They studied how 16 elementary and high school principals communicated leadership practices to spread adoption of an AI-in-education policy during the persuasion stage of innovation diffusion. A covenant is, in effect, a persuasion-stage instrument. It succeeds only if teachers and parents come to see its expectations as reasonable, not merely imposed.

The question of who should hold formal decision rights over AI adoption is treated elsewhere (see Q235). So are general strategies for communicating with communities (see Q086). The covenant adds something narrower: a specific, reciprocal statement of what the school will do, what families are asked to do and what children are expected to disclose.

Transparency also means being candid about what tutor bots may do to children beyond homework. A covenant that addresses only academic integrity will miss concerns that matter to many parents.

Singh, Boruah and Rajkhowa (2026) note that adaptive systems and chatbots offer opportunities for personalised learning and early identification of student needs. They also note that the implications for adolescent wellbeing remain under-explored, particularly in the Indian context they examine. A responsible covenant can acknowledge this uncertainty openly. It can invite parents to report patterns that worry them, such as a child preferring the bot to asking a teacher, or late-night use. This turns parents into partners in monitoring, not enforcers of a rule.

Privacy belongs in the covenant for the same reason. Riachi (2026) found data privacy and ethical use among the barriers teachers themselves cited. Families deserve to know which sanctioned tools collect what information. The statutory framework governing children's data is addressed separately (see Q337), but the covenant is where a school translates those obligations into language parents can act on.

Equity requires that the covenant be usable by every family, not only those already fluent in the technology. Patall and colleagues' (2008) evidence concerns trained parents. A covenant distributed without training therefore risks widening the gap between families who can interpret it and those who cannot. Approaches for supporting caregivers across technical literacy and home languages are developed in a companion discussion (see Q333). Here it suffices to say that a covenant should be accompanied by the kind of concrete, rehearsed guidance that the homework-training studies tested.

Children with special educational needs warrant explicit provision. Abu Mukh, Abd-Rabo and Tarteer (2024) investigated the computing competencies pre-service teachers consider necessary for integrating AI in special education schools. Their work signals that AI use in these settings calls for distinct preparation. Assistive uses of AI that are legitimate for one child may look like unauthorised help in another child's work. A covenant should state that individual plans take precedence over general rules, so that parents of these children are not placed in an impossible position.

The evidence supporting Home-School AI Covenants is indirect, and honesty about that is part of what makes a covenant transparent. The strongest foundation is the established finding that structured parent training improves homework completion and reduces homework problems for elementary children (Patall et al., 2008). Alongside it stands the broad recognition that family-school relations matter across schooling (Hill and Tyson, 2009). Neither synthesis concerns AI, and generalising from parental homework help to adult mediation of tutor bots is an inference, not a demonstrated result.

The AI-specific studies are recent, largely cross-sectional or qualitative, and drawn from teachers and leaders, not from families or children. Their samples are modest: 28 teachers in Lebanon, 20 principals in Ireland, 16 principals in another national programme. Researchers have measured attitudes, readiness and stress, but these studies do not report whether any particular home-school agreement changes children's learning, honesty or wellbeing.

Several points are genuinely contested. One is whether covenants should emphasise disclosure and learning or detection and sanction. Teachers' reported reliance on content detection (López Costa, 2025) pulls towards the latter. The partnership evidence pulls towards the former. A second is how far tutor bots should be permitted for young children at all. The grade-band approach of Touretzky and colleagues (2019) supports differentiated expectations but does not

settle where boundaries lie. A third is whether schools should attempt such agreements before leadership practice has stabilised, given Gorman and Brennan's (2026) finding that AI leadership is not yet coherent.

What would strengthen the case is evaluation of actual covenants. Such evaluations should compare schools that co-design and train against those that simply distribute rules. They should measure outcomes for parents and children, not only teachers. Until such evidence exists, the defensible position is modest. Covenants are a reasonable way to align adult expectations, provided they are co-authored, staged by development, supported by training and openly revisable.

Q336 What urgent safety education and victim-support protocols must schools and families implement regarding non-consensual synthetic intimate imagery

(deepfake bullying) and voice-cloning scams targeting youth?

13 citations · 13 sources · 5 cross-references

Claim 1 disputed

Schools and families need two linked sets of protocols, and they need them before an incident occurs. The first is preventive safety education. It should treat non-consensual synthetic intimate imagery as a form of sexual abuse rather than a prank, and it should replace reliance on spotting fakes with verification routines, such as agreed family code words and call-back checks, that blunt voice-cloning scams. The second is a victim-first response protocol. Under it, the young person is believed. Evidence is preserved without being recirculated. Removal from platforms is pursued quickly. The victim is never required to prove that an image is fake before receiving support, and is never disciplined for having been targeted. Wellbeing follow-up is coordinated by trained adults. Perpetrators, who are often peers, are held accountable in ways that are proportionate and educative. None of these elements rests on a mature evaluation literature. They are inferences from what is now known about how synthetic abuse is produced and experienced, and from what schools are and are not equipped to do.

The case for urgency starts with the nature of the technology. Kietzmann and colleagues (2020) note that manipulating visual and auditory media is as old as the media themselves. They also argue that deepfakes mark a turning point, because AI and machine learning now automate the creation of fake pictures, video and audio that are increasingly hard for human observers to detect. Two features matter most for children: automation and difficulty of detection. Automation means that creating abusive content no longer requires skill, so the pool of potential perpetrators includes ordinary classmates. Difficulty of detection means that neither the victim nor the adults around them can rely on visual inspection to settle what is real.

The most directly relevant empirical work is the cross-country study by Flynn, Powell, Scott and colleagues (2021). Using multiple methods across the United Kingdom, New Zealand and Australia, they examined the creation, distribution and threatened distribution of deepfake and digitally altered nude and sexual imagery. They characterise this as a serious and harmful emerging form of image-based sexual abuse. Three of their findings bear directly on school protocols.

First, the abuse involves poly-victimisation and poly-perpetration. People who are targeted this way are often targeted in other ways too, and people who perpetrate it often engage in multiple forms. A school that handles a deepfake incident as an isolated event may therefore miss a wider pattern of harassment, coercion or threat.

Second, the abuse is disproportionately experienced and engaged in by people with mobility or communication assistance needs, members of the LGB+ community, males and young people. This profile complicates a common assumption that synthetic sexual imagery is almost exclusively a problem affecting girls. Safety education built only around that assumption risks leaving boys, sexual-minority students and disabled students without language for what has happened to them. It also risks signalling to them that their victimisation is less real.

Third, racial minorities were disproportionately represented in perpetration only. This finding calls for care. Without further analysis it should not be translated into suspicion of particular groups, and the abstract does not explain the pattern.

The study also highlights the threat to distribute as distinct from distribution itself. Protocols should therefore treat sextortion-style threats involving fabricated images as reportable abuse even when no image has yet circulated.

Work on political deepfakes adds a sobering corollary. In an experiment with a large representative UK sample, Vaccari and Chadwick (2020) found that people were more likely to feel uncertain than to be misled by deepfakes, and that this uncertainty in turn reduced trust in news on social media. Their study concerned political video, not intimate imagery, and adults, not children, so any extension is analogical. Still, it suggests something important for victim support. Saying that an image is fake does not restore the victim's standing among peers. Uncertainty itself corrodes trust, and a fabricated image can retain social force after it has been exposed as fabricated. Support therefore cannot end with establishing falsity.

Preventive education should be developmentally sequenced rather than delivered as a single assembly after a crisis. In the early years, the relevant foundations are not technical. Children learn bodily autonomy, learn that pictures of people belong to those people, and learn that they should tell a trusted adult when something online feels wrong. These sit within the play-based, relational approach to early childhood argued elsewhere in this volume (see Q331). In early adolescence, peer status, image-sharing and online identity become intensely salient (see Q332). Explicit instruction then becomes essential: on consent as it applies to synthetic images,

on the fact that creating or forwarding such material is abuse regardless of whether it is 'real', and on bystander action, which means refusing to forward, reporting and supporting the target.

The detection evidence should change what teachers emphasise. If, as Kietzmann and colleagues (2020) argue, synthetic content is becoming harder for human observers to detect, curricula that train students mainly to spot visual artefacts may build false confidence. They may also implicitly place the burden on victims to prove manipulation. A more robust approach teaches provenance and verification habits. Students learn who shared an item, through what channel, and how a claim can be checked independently.

The same logic applies to voice-cloning scams. The abstract by Kietzmann and colleagues (2020) explicitly includes manipulated audio among the products of deepfake techniques, and audio carries the emotional immediacy of a familiar voice. A family protocol might include a private code word, a rule that urgent requests for money, passwords or secrecy are always verified by calling back on a known number, and permission for children to hang up and check without fear of being rude. These routines do not depend on anyone hearing the difference between a real and a cloned voice. That is their advantage. Schools can model and distribute such protocols, but families with different levels of technical confidence and different home languages will need adapted materials (see Q333).

Evidence that awareness interventions work is thin and indirect. Leahy, Ozer and Cummins (2025) report a multicentre, teacher-led intervention that aimed partly to promote awareness of the strengths and limitations of generative AI tools. Haroud and Saqri (2025) examined teacher and student perspectives on generative AI and digital literacy in Moroccan higher education. Both studies concern university settings and general AI literacy rather than abuse prevention with minors. They indicate that structured digital-literacy work is feasible, but whether such work reduces victimisation or perpetration among children remains unclear.

When an incident occurs, the response sequence matters as much as the content of the curriculum.

A defensible protocol names a designated lead with safeguarding training. It sets a rule that staff do not view, copy or forward the imagery beyond what statutory reporting requires. It records the fact and context of the material without reproducing it. It notifies parents or carers in a way that respects the young person's safety, including where the home itself may be a source of risk. It pursues platform removal and any legally required reports. Finally, it plans a

return to normal school life that does not place the victim in the same spaces as the perpetrator without safeguards. Legal duties differ by jurisdiction and are addressed elsewhere in this volume (see Q337). The pastoral elements, however, do not need to wait for legal clarity.

Wellbeing follow-up should be clinically informed but human-led. Singh, Boruah and Rajkhowa (2026), writing an applied practice paper on Indian schools, describe AI tools such as chatbots and adaptive systems as offering early identification of student needs. They also stress that the implications of these tools for adolescent wellbeing remain under-explored. Zhou and Geng (2026) make a related point about adolescent depression and anxiety. Young people may present with sleep disturbance, irritability, somatic complaints, school refusal or social withdrawal before meeting diagnostic thresholds. AI is best framed as decision support rather than automated diagnosis, and predictive accuracy alone does not establish clinical value. For victims of synthetic abuse, this argues that staff should be trained to notice these early, non-specific signs after an incident. Any digital screening should be treated as an aid to professional judgement, never as a substitute for a counsellor's conversation.

A further consideration is where young people turn when adults feel unsafe. In a qualitative study of sixteen lonely UK university students, Li and Ritchie (2026) explored how participants used conversational AI for emotional and relational support and how they positioned it alongside other coping strategies. Their participants were older than school pupils and the study was exploratory. It nonetheless suggests that some young people may confide first in a chatbot. Protocols should anticipate this. They should not shame such use, and they should ensure that human routes to help are visible, quick and non-punitive. Given the disproportionate victimisation of young people with communication assistance needs that Flynn and colleagues (2021) report, reporting channels must also be accessible to students who cannot easily give a spoken or written account.

The main obstacle to implementation is institutional readiness rather than a lack of ideas.

Gorman and Brennan (2026) interviewed twenty Irish primary principals and concluded that AI leadership is not yet a coherent or established field of practice. Leaders were interpreting AI within a policy context they described as provisional and evolving. Kumar and Sarkar (2026) offer a structure. Their scoping review of twenty-one sources maps administrators' responsibilities for ethical AI integration across instructional, managerial, strategic and

relational dimensions. Synthetic-abuse protocols touch all four: curriculum content, incident procedures, policy and partnerships, and trust with families and students.

The teacher evidence points to a gap between familiarity and preparedness. López Costa (2025) found that more than half of teachers in rural Catalan schools reported moderate to high AI knowledge, yet classroom implementation was limited and centred on text generation and content detection. Riachi (2026), studying twenty-eight Lebanese teachers, reported similar familiarity alongside limited integration. Barriers included insufficient training, lack of institutional support, and concerns about data privacy and ethical use. Neither study examined abuse response. Together, however, they suggest that schools cannot assume staff understand image and audio synthesis well enough to respond calmly to a disclosure.

Lee and Kim (2026) found that professional judgement shaped how Korean middle leaders adapted AI to their practice. Middle leaders such as heads of year and pastoral coordinators are likely to be the first responders in practice, and they need explicit authority and training to act.

The practical implication is that schools should not wait for comprehensive national guidance. They should adopt an interim protocol, rehearse it as they would a fire drill, and review it after each use. Home-school agreements that already set out shared expectations about AI can carry a short section on synthetic abuse and scam verification (see Q335).

Several things remain genuinely unsettled. The first is how to treat child and adolescent perpetrators. Flynn and colleagues (2021) document perpetration among young people, but the abstract does not say whether punitive, restorative or educational responses reduce reoffending. Schools therefore face a real tension between protecting victims and avoiding the criminalisation of minors. The second is the balance between detection skills and verification habits in curricula. The argument here favours verification, but the evidence comparing the two approaches is not yet available in work focused on children.

The third concerns voice-cloning scams aimed specifically at youth. The general capability is well described, as Kietzmann and colleagues (2020) show, but little prevalence or outcome evidence exists on children as targets. The protocols proposed here are reasoned precautions rather than tested interventions. Similarly, the finding of Vaccari and Chadwick (2020) that deepfakes breed uncertainty more than outright deception comes from adults viewing political content. Whether the same dynamic governs peer responses to fabricated intimate images in schools remains unclear.

What the evidence does support is narrower but sufficient to act on. Synthetic intimate imagery is a recognised form of image-based sexual abuse. It is entangled with other forms of victimisation and disproportionately affects young people and several marginalised groups. Detection by eye is unreliable, and the mere uncertainty that fakes create can damage trust. Schools, for their part, are entering this terrain with provisional policy and uneven staff preparation.

Those facts justify immediate, modest and revisable protocols: education that names the harm, verification routines that do not depend on detection, responses that start from belief, and human-led wellbeing support. Reliable evidence about which elements work best will come only if schools document what they do and researchers evaluate it.

Q337 How do updated child-protection statutes (such as COPPA 2.0, the UK Age Appropriate Design Code, and EU AI Act protections for minors) regulate smart toys, edtech profiling, and youth data harvesting?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Updated child-protection regimes regulate smart toys, edtech profiling and youth data harvesting through three different legal techniques. The United Kingdom works through design obligations: a statutory code tells services how they must be built and configured when children are likely to use them. The European Union works through risk-based product regulation, prohibiting certain AI functions outright in educational settings. The United States has historically relied on parental notice and consent, which proposals labelled COPPA 2.0 seek to update. These approaches are not interchangeable. They assign responsibility to different actors, they are triggered by different facts, and they protect children at different points in the data lifecycle.

The most fully specified instrument is the Age Appropriate Design Code, a statutory code of practice issued by the Information Commissioner's Office (2020) under the Data Protection Act 2018. It sets out 15 standards. These apply to online services likely to be accessed by children under 18, and the code expressly includes connected toys and devices and educational technology. The European instrument, Regulation (EU) 2024/1689, the Artificial Intelligence Act (European Parliament and Council of the European Union, 2024), takes a different route. Its risk-based architecture includes, in Article 5(1)(f), a prohibition on placing on the market or using AI systems to infer the emotions of a natural person in workplaces and education institutions, except where the system is intended for medical or safety reasons.

The American position is harder to characterise with precision. Successive proposals to update the Children's Online Privacy Protection Act have circulated under the COPPA 2.0 label, and their legislative form has been in flux. For that reason this essay treats COPPA 2.0 comparatively and does not attribute specific operative provisions to it. That restraint matters for practitioners: a school procuring a smart speaker or an adaptive reading platform cannot assume that obligations familiar from one jurisdiction travel to another. Across all three regimes, the deeper conceptual frame is the one Livingstone and Third (2017) articulate. Rights-based approaches must balance children's need for protection with their capacity to

benefit from connectivity, and the child functions as a limit case that exposes the adult assumptions built into both rights discourse and digital design.

For smart toys and edtech, the UK code is the most operationally demanding of the three regimes. It does not simply require a consent box at the point of sale. It requires that the best interests of the child be a primary consideration, and that services carry out data protection impact assessments before processing children's data (Information Commissioner's Office, 2020). Its default rules bite directly on the business models of connected play and learning. Privacy settings must be high by default, and only the minimum personal data needed may be collected and retained. Geolocation and profiling must be switched off by default. Services must avoid nudge techniques that lead children to weaken their own privacy protections, and transparency must be age-appropriate rather than buried in adult-oriented terms.

Applied to a talking doll or a voice-enabled learning companion, these standards reorganise the product. Continuous audio capture, persistent behavioural logs and inferred profiles of a child's interests or abilities are no longer neutral engineering choices. Each must be justified against minimisation and best-interests tests. The prohibition on nudging matters for products designed to sustain engagement, because prompts that encourage a child to share more, unlock features or turn on location are exactly the techniques the code targets. The developmental case against such devices in the earliest years, particularly during language and Theory-of-Mind acquisition, is treated elsewhere in this volume (see Q330). The legal point here is narrower: the code converts some of those developmental concerns into enforceable configuration duties.

The code also reaches products marketed as protective. Tan and Mo (2024) design an Artificial Intelligence Internet of Things safety protection system for preschool education, motivated by the persistence of accidental injury among young children, especially in developing countries, and by the hours children spend at school. Systems of this kind illustrate a recurring regulatory tension. A service justified by child safety may still involve extensive sensing and data collection. Under a best-interests and minimisation framework, the safety rationale does not exempt the system from impact assessment. It requires that the sensing be proportionate to the stated purpose and that retention be limited. Whether particular preschool monitoring architectures satisfy those tests is a matter for case-by-case assessment rather than something the design literature itself establishes.

Profiling in edtech is where the EU AI Act and data protection law most clearly intersect. The Article 5(1)(f) prohibition on emotion inference in education institutions removes one of the most contested forms of learner analytics from the European market: systems that claim to read engagement, frustration or attention from faces, voices or behaviour (European Parliament and Council of the European Union, 2024). For young learners this is significant. Affective computing has often been pitched to schools as a means of personalising instruction, and the prohibition treats that inference as unacceptable in the educational setting regardless of claimed pedagogical benefit.

The exception for medical or safety reasons will need careful interpretation, because many child-facing products describe themselves in safety terms. The scope of the prohibition is also bounded. It concerns emotion inference in workplaces and education institutions. It does not, on its own terms, address every form of behavioural profiling of children, nor does it reach a toy used at home. Other profiling remains governed largely by data protection law and by the Act's other risk tiers.

The friction between machine learning and data protection is not specific to children, but it is sharpened by them. Ruschemeier (2025) identifies an often overlooked conflict between generative AI and data protection law. Debate has concentrated on copyright and on regulatory strategy under the AI Act, while the unresolved tension between fundamental protection rights and the vast scale of data processing required for machine learning has received less attention. That analysis bears directly on youth data harvesting. Children's conversations with tutoring bots or companion toys can become training material, and principles such as minimisation sit uneasily with systems that improve by accumulating data.

Voloch and Hirschprung (2026) offer a useful corrective to purely restrictive framings. Their review of 94 research papers categorises the AI-privacy relationship as running in both directions: AI as a source of privacy violation and AI as a tool for privacy protection. For regulators of edtech, this suggests that privacy-preserving techniques could help providers meet minimisation and default-protection duties. How far such techniques are deployed in products used by young children, and how effective they are in practice, remains unclear.

Generative AI has changed the object of regulation faster than statutes have adapted. Earlier smart toys mostly collected data through scripted interactions. Generative systems invite open-ended disclosure: a child can tell a chatbot or AI-enabled toy almost anything, and the system

responds fluently. Kanders and colleagues (2024) note that scholarship in developmental psychology and early childhood education on generative AI for babies and young children is limited. Drawing on stakeholder discussion and desk research, they set out potential use cases, opportunities and risks for the application of AI in early childhood. Their contribution is explicitly a perspectives piece rather than an empirical evaluation, which signals how thin the evidential base remains.

Nikolopoulou (2025) argues that early childhood education deserves special attention as a uniquely sensitive and formative stage of human development. On that view, integrating generative AI raises interlocking questions of developmental appropriateness, ethics and equity that require critical safeguards. Tao (2025) proposes a developmentally aligned, five-tiered framework spanning ages 3 to 18 for responsible use in K-12 education. The framework seeks to move beyond a polarised choice between prohibition and unrestricted adoption, weighing opportunities such as personalised learning and creative scaffolding against risks including cognitive offloading, misinformation exposure and the erosion of critical thinking. Age-tiered frameworks of this kind are pedagogical rather than legal, and their detailed sequencing is discussed elsewhere (see Q331; see also Q150 on age-appropriate home use). They nonetheless converge with the regulatory logic of the UK code: obligations should scale with the child's developmental capacities rather than switch on at a single age threshold.

The technology research community has not, by and large, organised its work around these protective questions. Luo, Tang and Sun (2026) screened 1032 papers from four premier technology-oriented education conferences published between 2023 and 2025 and retained 189 empirical studies. Their thematic synthesis focuses on pedagogical roles, application domains and technical enablement strategies. That focus is understandable for a technology-perspective review, but it suggests a gap between the pace of system development and the attention given to children's data rights within that development pipeline. The gap is consequential because the duties to conduct impact assessments and to design for minimisation fall on precisely the developers whose research agendas centre on capability.

A further weakness lies below the school years, in early childhood education and care. Liang and Tan (2026) describe a policy imbalance in Australia. Generative AI use in schools has received explicit national guidance, while its implications for early childhood education and care are addressed only through broader digital frameworks. Their interviews with Australian educational experts explore whether and how such systems should be incorporated into policy

for this sector. The finding is specific to one country, and expert interview evidence cannot establish how widespread the pattern is. Even so, it points to a plausible structural problem elsewhere. Statutes framed around online services, schools or AI systems in general may leave the settings that serve the youngest children governed by default rather than design.

That gap matters because it is in these settings that smart toys, monitoring devices and tablet-based apps are often introduced with the least specialist oversight. The UK code formally covers services likely to be accessed by children of any age under 18 (Information Commissioner's Office, 2020). Formal coverage, however, is not the same as practical capacity. Settings serving very young children may lack the procurement expertise to interrogate default settings or impact assessments. The burden then shifts to providers, and to whatever enforcement attention regulators direct at products aimed at the youngest users.

Children's own participation complicates any simple protective account. Silva, Matthews and Danby (2026) adopted a children's rights approach with children aged four to eight using a generative image tool. The children suggested prompts, reflected on the outputs and refined them iteratively until they achieved their desired result. This work does not address data governance directly. It does show that young children can be active, reflective users of generative systems, which is consistent with the dual emphasis on protection and opportunity in Livingstone and Third (2017). Regulation that treats children only as objects of data extraction risks neglecting the participation and provision rights a rights-based framework also demands. Regulation that treats them only as capable users risks underestimating asymmetries of power and comprehension. The statutes reviewed here lean towards protection, with the UK code's insistence on age-appropriate transparency the clearest bridge to participation.

Several questions remain open, and the scholarly record does not yet resolve them. First, evidence on outcomes is lacking. The UK code specifies what services must do, but the material available here does not show whether its high-privacy defaults, profiling-off settings and anti-nudging standards have measurably reduced data collection from children by smart toys or edtech platforms. Compliance and effect are different questions, and the second is largely unanswered.

Second, the boundaries of the AI Act's emotion-inference prohibition are uncertain. Its exception for medical or safety purposes may prove broad or narrow in practice. Its limitation to education institutions and workplaces leaves home-based companion toys outside its express

terms. How enforcement authorities will classify hybrid products, such as a learning app used both in class and at home, remains unclear.

Third, the American trajectory is unsettled. Without a settled statutory text, claims that COPPA 2.0 extends protections to teenagers, restricts targeted advertising or alters consent mechanisms should be treated as claims about proposals rather than about enacted law.

Fourth, there is genuine disagreement about whether regulation should primarily restrict or enable. Ruschemeier (2025) emphasises an unresolved tension between data protection rights and the scale of data processing machine learning requires. Voloch and Hirschprung (2026), by contrast, show that AI can also serve privacy protection. Tao (2025) and Nikolopoulou (2025) both resist prohibition-versus-adoption binaries but differ in emphasis on how far early learners should engage. These positions are not strictly contradictory. They do imply different regulatory priorities: firm limits on collection on one view, mandated privacy-enhancing design on the other.

For educators and families, the practical implication is that statutory protection is partial and jurisdiction-specific. A school should ask any provider for evidence of a data protection impact assessment, for confirmation that profiling and geolocation are off by default, and for assurance that no emotion inference is performed. Such questions translate the strongest available legal standards into procurement practice. They complement, rather than replace, the home-school agreements and parent-facing guidance discussed elsewhere (see Q335). Above all, the field needs longitudinal and comparative studies of how these instruments change actual product design and children's data exposure. Until such studies exist, assessments of their effectiveness should be framed as expectations rather than findings.

Chapter 27: Technical Mechanics of Educational AI Systems

14 questions · 188 citations · 167 unique sources · 63 cross-references

Q011 Who is responsible when an AI teaches something false, biased, or harmful to a student?

21 citations · 21 sources · 5 cross-references

Claim 1 disputed

Responsibility for an AI system that teaches a student something false, biased, or harmful is currently shared in principle among several parties and firmly assigned to none of them in practice. The question looks simple but becomes tangled once one tries to answer it. At least four parties are implicated: the technology developers who build and train the models, the schools and universities that procure and deploy them, the classroom teachers who recommend or permit their use, and the students who act on what the systems tell them. The law does not yet offer a clean way to allocate duty among them.

The systematic reviews that frame this chapter treat accountability as one of the central unresolved problems of generative AI in education, alongside bias, opacity, and data protection. Writing across sectors that include education, Agarwal (2025) points to the lack of global regulation and the difficulty of building truly transparent systems as structural obstacles. He argues that ethical safeguards must be designed in from the start rather than treated as an afterthought. That argument is normative rather than empirical, but it sets the terms of the discussion that follows. If ethics are bolted on after deployment, responsibility for harm is likely to be dispersed after the fact as well, among actors who each had only partial control over what the student eventually saw.

The harms in question are not hypothetical. AI models frequently "hallucinate," producing false information that students may accept as true because of the authoritative way the systems present their responses. Collins (2024), writing from the sociology of knowledge, offers an explanation of why this happens. He argues that large language models such as ChatGPT have "no moral compass" and answer queries with fabrications as fluently as they provide facts. In

his account, learning from the internet is not the same as socialisation. These systems lack the primary socialisation that grounds human moral understanding and are instead "retrospectively socialised" by human intervention meant to align them with accepted ethics. This is a theoretical argument rather than a measured finding. Its relevance to responsibility is direct, however, because it locates the source of fluent falsehood in how the systems are built and corrected, not in any isolated malfunction.

Educational researchers reach compatible conclusions from a more practical angle. Lye and Lim (2024) note that generative models trained on internet data can produce biased and discriminatory outputs, and that hallucination yields made-up and untruthful content. Bobula's (2024) review of the higher-education literature lists the propagation of misinformation and biases inherent in the models among the principal challenges of large language models. That hallucination occurs is effectively established. How often it misleads students in practice, and with what lasting effect on learning, remains unclear.

Bias is the second category of harm. Despite improvements in content filtering, bias remains a concern. The MinorBench work on content risks for children reports that chatbots can reinforce stereotypes and can mislead young users into believing AI-generated content is accurate. As generative AI spreads through education, reviews have documented multiple cases in which algorithms reproduced and amplified existing inequalities, with effects on academic assessments, course recommendations, and even the allocation of learning opportunities. Zuiderveen Borgesius (2025), in a study prepared for the Council of Europe's Anti-discrimination Department, describes the capacity of AI to embed and perpetuate discrimination as one of the most pressing challenges of its growing use.

The most precise evidence of educational bias concerns assessment rather than instruction. Yvan, Charles and Lucy (2026) systematically reviewed 27 studies of generative AI in medical, nursing, pharmacy and dental assessment. Six experimental studies found that AI detectors falsely labelled the writing of non-native English speakers as AI-generated in 50.2% to 61.3% of cases, compared with under 5% for native writers. Four automated scoring studies showed a systematic downward bias of 0.5 to 1.2 standard deviations against non-native speakers. These findings complicate the responsibility question in a revealing way. The harm here comes from tools an institution chose to deploy against students, not from a chatbot a student consulted. The cultural and linguistic dimensions of such bias are taken up separately (see Q019).

For younger students the risks compound. The MinorBench authors observe that children tend to anthropomorphise chatbots and seek emotional support from systems that lack true understanding. This can cause distress when responses are inappropriate or unhelpful, a pattern that shades into questions of dependency (see Q246).

Existing law was not built for this situation. As the review of accuracy and regulatory concerns in educational AI observes, legal and ethical frameworks assume a human-in-the-loop model in which accountability rests with the user, because AI tools are not recognised as legal persons or responsible agents. That assumption breaks down in schools. A child using a tutoring chatbot has no meaningful ability to audit its outputs, and the human supposedly "in the loop" may be the least equipped party in the chain.

Traditional product liability theories, such as design defect and failure to warn, are being tested and redefined in the AI context. Commentators on emerging tort law note a basic difficulty with applying them. Because AI decision-making can be opaque even to its creators, it is hard to assess liability, assign responsibility, and anticipate the full range of potential harms. A design-defect claim presupposes that one can identify what a reasonable alternative design would have been. That is difficult when the behaviour in question emerges from training rather than from any explicit specification.

Early court cases have set limited and cautious precedents. In a 2025 ruling against a plaintiff who sued OpenAI for defamation, the court recognised OpenAI's efforts to reduce inaccuracies and provide user warnings, and concluded that the legal threshold for defamation had not been met. Legal commentators read the decision as suggesting that disclaimers and responsible design practices may protect developers from liability, even though the broader question of AI accountability remains unsettled.

For education, the implication is uncomfortable. The defence that worked in that case relies on a warned, competent adult reader. Whether a comparable defence should succeed when the reader is a twelve-year-old completing homework has not been tested. Credible commentators disagree about whether warnings can ever discharge a developer's duty toward minors.

In practical terms, responsibility is being distributed, unevenly, across three layers, and the developer layer is where normative arguments are most insistent. Researchers increasingly argue that bias mitigation must be addressed across the whole AI lifecycle, from data collection and training to inference and system updates. The systematic review in Humanities and Social

Sciences Communications identifies mitigation strategies at each of these stages. The Frontiers review of ethical and regulatory challenges adds that developers should conduct human rights impact assessments to identify risks before deployment. The broader review of AI ethics in education concludes that developers must ultimately be held accountable for ensuring that educational AI fosters ethical, inclusive, and pedagogically meaningful innovation.

Work outside the education literature points the same way. Figueiras and colleagues (2026), setting out European research and innovation agendas for AI, data and robotics, stress the need for robust frameworks addressing bias, fairness, and accountability, alongside explainable and adaptive AI. Collins's (2024) argument adds a sharper point. If models acquire their ethical alignment through retrospective human correction, then those who perform that correction are making substantive choices about what students will be told. He urges vigilance about "who is socialising them" and warns that the models may end up socialising users to align with them rather than the reverse. On that view, the developer's responsibility goes beyond technical quality control and covers the epistemic and moral content of the system.

These arguments have broad support among ethicists. Their translation into enforceable obligations specific to education remains thin, and the mechanisms that might supply it are considered elsewhere (see Q259).

At the institutional level, schools and universities are being pushed to take responsibility for what they deploy. The analysis of ethical challenges in university education published in the Journal of Academic Ethics argues that institutional accountability requires clear standards and monitoring mechanisms for the ethical and responsible use of these tools. Practitioner guidance for schools using AI tutors makes the contractual side concrete. Schools need clear agreements with vendors that set out liability, and they need to monitor AI's impact regularly so that it supports rather than disrupts learning goals.

Evidence on what institutions actually do suggests that guidance has grown faster than accountability. McDonald and colleagues (2025) analysed policy documents from 116 US R1 universities. A majority (63%) encouraged the use of generative AI, 41% offered detailed classroom guidance, 56% provided sample syllabi, and 50% provided sample curricula and activities. More than half addressed ethics across a range of topics. The emphasis falls on enabling use rather than on allocating responsibility when use goes wrong. The gap is felt by students. In Mujtaba's (2024) survey of 126 South Florida undergraduates, most regarded AI

use as ethical and legal, but some remained uncertain because professors and institutions had not provided clear guidelines. Lye and Lim (2024) argue that policing AI through an "arms race" may not address fundamental problems, and propose an Against, Avoid and Adopt principle for redesigning assessment. That stance implicitly places on institutions a duty to design around known failure modes rather than simply prohibit tools. The detector findings of Yvan and colleagues (2026) show what is at stake when institutions adopt tools without scrutiny.

Legislatures are beginning to act as well. During the 2026 legislative session alone, FutureEd is tracking 71 bills across 27 states that address artificial intelligence in classroom instruction. Bill counts measure legislative activity, not settled duties, and how many of these bills will allocate liability remains unclear.

Teachers occupy a third position, one the law has barely begun to define. Reviews of AI ethics in education note growing concerns about transparency and accountability as AI becomes more embedded in decision-making. An educator who recommends, or simply permits, a particular AI tool may carry an implicit duty of care that has no established legal precedent. Whether teachers can reasonably discharge such a duty depends on their preparation. MacDowell and colleagues (2024) report a self-study of a course in which 35 preservice and in-service teachers developed AI literacy through experiential activities and co-authored an open textbook. From this work they derived the Student Artificial Intelligence Literacy (SAIL) framework, which combines cognitive, socio-emotional, and instructor-guided interactions. This is a single illustrative case, not evidence of effectiveness at scale. It does suggest that a teacher's duty of care is only as meaningful as the training institutions provide.

What remains open is whether any single party can or should bear primary responsibility. The lack of transparency and accountability in algorithmic processes fundamentally complicates ethical oversight, as the systematic review in Humanities and Social Sciences Communications emphasises. The Journal of Academic Ethics analysis adds that personal data can be exploited unnoticed when users lack awareness and no one is accountable. The opacity of so-called black-box algorithms compounds both problems.

Students complete the four-party picture, and their position is the most ambiguous. Some evidence suggests that older students already reason about their own stake. Nelson and colleagues (2025) surveyed 56 Ecuadorian undergraduates writing in English as a foreign

language. The students worried more about hindering the development of their own writing skills than about being caught. They regarded submitting chatbot-generated text as dishonest, though fewer saw submitting machine-translated work that way. That study concerns integrity rather than exposure to falsehood, and its sample is small. It does suggest that university students can exercise some critical agency. The same cannot be assumed of children, who may anthropomorphise the systems they use. Any account that places significant responsibility on the learner must therefore scale it to age and capacity.

The practical consequence is a diffusion of responsibility that benefits no one, least of all the student who simply trusted the machine. Developers point to disclaimers, institutions point to vendor contracts, teachers point to institutional policy, and the law points back to the user. For now, accountability is shared in principle and enforced by almost no one in particular. That condition reflects how quickly the technology arrived more than any considered social judgment about where the duty of care should lie.

Q095 How are multimodal and voice-based AI changing learning beyond text — in languages, arts, sciences, and physical skills?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

Multimodal and voice-based AI are extending AI-supported learning from the typed page into speech, image, sound and movement. Conversational systems now give language learners spoken practice and pronunciation feedback. Vision-capable tutors can read handwritten and

drawn work. Generative tools let arts students move across media they have not mastered. Early systems are beginning to observe physical technique. The evidence base thins sharply, however, as one moves from language toward the body.

The first generation of AI in education was text-centric: chatbots, essay feedback and text-based tutoring. The second generation is multimodal. These systems process and generate across voice, vision, video and text, and they are changing what AI can do in domains where text was never the medium of learning. Language, the arts, the sciences and physical skills each offer different affordances, and each is being changed in different ways and at different speeds.

Language acquisition is fundamentally an oral skill, and it is the domain where voice-enabled AI has moved furthest. Learners can now practise target languages through real-time conversation with AI systems that give immediate feedback on pronunciation, fluency and comprehension. Until recently such practice was available only through human conversation partners, which most learners lacked. The 2026 overview of voice, vision and interaction in Computer Assisted Language Learning places this shift within a broader move from text-only exercises toward integrated multimodal interaction.

The technology also extends beyond simple dialogue. The 2026 review of intelligent avatar-based systems in Frontiers in Computer Science describes architectures that combine linguistic, paralinguistic and affective components. These include gesture generation, facial expressions and prosodic control, which together aim to make instruction engaging and culturally relevant. For learners of less-commonly-taught languages this is a genuine expansion of opportunity, because the supply of human teachers and conversation partners is thin.

The central pedagogical question remains open. It is unclear whether AI conversation partners can develop the pragmatic and cultural competence that human interaction develops. Meanwhile the practice itself is already widespread and has run ahead of the evidence on these deeper outcomes.

Vision-enabled AI has changed what a tutor can see. Text-only systems could respond only to typed input. Multimodal systems can interpret handwritten mathematical equations, code diagrams, lab notebook entries and student drawings, and can give feedback on work that was previously invisible to the machine. The language-learning overview in Computer Assisted Language Learning treats vision as a complement to voice in the same interactional loop. A practitioner overview of multimodal learning published by Everything-PR describes similar

capabilities for mathematics and science. That source is a commentary rather than research evidence, but it usefully catalogues the infrastructure such capabilities assume.

This matters pedagogically because much of learning in science and mathematics is carried by representations: equations, graphs, diagrams and experimental records. A system that can see and respond to those representations comes much closer to what a human tutor does when looking over a student's shoulder. It also opens new assessment possibilities. Systems that observe a student's process, and not just the final answer, can in principle diagnose where reasoning goes wrong rather than simply marking the result incorrect. How such laboratory and coding tools should be designed and evaluated is a question in its own right (see Q226).

Voice is also entering science and STEAM classrooms as a way of monitoring learners, not only as an interface. Wu and Peng (2025) built an AI system that combines speech recognition, natural language processing, keyword analysis and text sentiment analysis. Its purpose is to estimate the emotional, cognitive and behavioural engagement of university students working through a computational thinking curriculum, with participation experiences collected through dedicated study sheets.

The study is best read as a demonstration of design feasibility. Its abstract does not report validation statistics, so whether such systems measure engagement accurately remains unclear. The study nonetheless shows the direction of travel: multimodal pipelines that turn students' spoken and written reflections into inferred affective states. That direction carries privacy and interpretive questions the field has barely begun to address.

In the arts, generative AI works as what one Springer chapter calls a "voicing agent" for transdisciplinary exploration. Cross-modal generation means producing music from paintings, images from musical scores, or movement from text. It lets students explore relationships between artistic domains that were previously hard to bridge. Students can compose, critique and iterate in media they have not mastered, and can experience the creative process from several sensory perspectives at once.

The ethical questions are substantial, and they are not settled. The study of multimodal composition with AI in the CITE Journal gathered student and educator perspectives. It records concerns about bias and representation in generative models, about authorship and the value of human creation, and about students "cheating themselves" out of the creative struggle. Educators are responding in two ways. They are shifting the pedagogical emphasis from

generation to critical editing and evaluation, teaching students to judge algorithmic output rather than merely produce it. They are also developing critical AI literacy as a core arts competency.

Whether this pivot actually builds judgement is an empirical question that is only beginning to be tested. Zhang and Liu (2025) note that a growing number of studies report generative AI as conducive to college students' critical thinking. They also observe that research on its effect in open learning environments, where students use the tools without close structuring, remains scarce, and they set out to investigate exactly that case. The distinction matters for arts education. Critical evaluation that works under a teacher's scaffolding may not carry over to students' independent studio practice, and the existing evidence does not yet show that it does.

A more philosophical strand argues that the AI era requires rethinking what aesthetic knowledge is. Jiang (2026) proposes Christopher Alexander's theory of "living structure" as a foundation for liberal arts and whole-person education. On this view, the perception of wholeness is a distinctly human capacity, while the structural order underlying it can be computed through fifteen geometric properties and a small set of laws and principles. The argument is conceptual rather than empirical. It does offer one way of framing the division of labour that arts educators are improvising: machines handle computable structure, and students take responsibility for perceiving and judging whether a work is alive. How these debates are reshaping assessment and authorship in creative arts programmes is taken up more fully elsewhere (see Q227).

Physical skills are the domain where text-based AI was most obviously inadequate, and multimodal AI is beginning to address them. Systems that observe movement, posture and gesture can give feedback on technique in sports, dance, instrument playing and manual trades. They can also support rehabilitation and motor learning. The practitioner overview from Everything-PR treats this as a frontier application.

This is the least mature of the four domains and the evidence base is thin. The direction is clear all the same: AI is moving from the symbolic domain of language to the embodied domain of action. The infrastructure demands are significant, including cameras, microphones, and privacy governance for continuous audiovisual data. The ethical stakes are also higher, because recordings of bodies are more sensitive than text.

The human side of this transition is uneven, as one recent study shows. Varga and Fügedi (2026) surveyed 416 pre-service physical education teachers across seven Hungarian universities during the autumn semester of 2025/2026, using the MIATT 2024_rev questionnaire. They analysed attitudes, knowledge, usage habits and intentions to apply AI through principal component analysis, with a sampling-adequacy statistic (KMO) of 0.741. Their framing is telling. AI diffusion in higher education is reshaping practice, yet its integration into practice-oriented teacher education remains uneven, and institutional constraints sit alongside individual digital readiness.

The finding is cross-sectional and specific to one national system. It should therefore be read as describing readiness rather than effects on motor learning. It does suggest that the bottleneck in physical skills may lie as much in teacher preparation and institutional conditions as in the sophistication of motion-capture models. A fuller treatment of AI in physical education and sports science pedagogy appears elsewhere in this volume (see Q232).

Multimodal AI carries a distinctive equity risk. Text-based AI could reach students through devices they already owned. Multimodal AI needs cameras, microphones and bandwidth that many classrooms and homes lack, and students without them will be excluded from the most advanced capabilities. The same technology that lets a vision-enabled tutor see a student's handwritten work also requires the infrastructure to capture that work, a dependency the Everything-PR overview treats as a precondition rather than an afterthought.

Institutions should therefore treat multimodal deployment as an equity decision. That means deciding which students get access, under what conditions, and with what alternatives for those who do not. The gap is not only one of hardware. Where teachers themselves have uneven AI readiness, as in the Hungarian physical education sample described above, access to advanced tools may concentrate in institutions and programmes that are already better resourced.

There is also an accessibility opportunity. Multimodal interfaces can serve learners who struggle with text, including young children, students with reading disabilities and learners from oral cultures. Gyarmathy (2026) proposes a Neurodiversity-Based Developmental Profiling Framework for gifted education. It would replace static, norm-referenced identification with dynamic mapping of cognitive profiles, intrinsic drive and environmental fit, on the argument that AI is changing what human potential means and how it is developed.

The framework is conceptual and untested. Its logic still bears directly on multimodal design: learners whose strengths are visual, spatial, oral or kinaesthetic may be better served by systems that do not route everything through written text. Whether multimodal tools actually widen participation for such learners, or simply add new channels that advantaged students exploit first, remains unclear. Their design should be evaluated against that question. The practical translation of these possibilities into special education and individualised support plans is examined separately (see Q098).

The same challenges recur across all four domains. The first is privacy. Multimodal systems collect voice and video data, which are more sensitive than text and require stricter governance under FERPA and comparable frameworks. Engagement-inference systems of the kind Wu and Peng (2025) describe sharpen the point, because they derive affective judgements from students' speech as well as storing it.

The second is infrastructure. Multimodal AI needs hardware that text-based systems did not, including cameras, microphones and bandwidth, and this raises equity questions about which students get access.

The third is evaluation. The field needs model cards and evaluation frameworks that assess multimodal systems on pedagogical quality, not just technical capability. At present, prototype studies that report system design without validation figures are common, and practitioner commentaries often stand in for evidence.

The fourth is pedagogy. The evidence so far suggests that multimodal AI is most effective as scaffolding for complex tasks, with students moving from generating content to critically evaluating algorithmic output, as the CITE Journal study's educators describe. How much human structure that scaffolding requires is itself under investigation. González-Rico and Lluch Sintes (2024) studied 182 university students in two groups. One group built an academic topic autonomously using only ChatGPT, while the other combined the tool with one-to-one tutoring, and the study examined how the two arrangements affect the development of soft skills. Read alongside Zhang and Liu's (2025) concern with open, unstructured environments, this line of work frames a live disagreement. One position holds that AI tools can independently cultivate higher-order and interpersonal capacities. The other holds that those gains depend on human mentoring wrapped around the tools. Neither position yet rests on replicated evidence across modalities.

The picture that emerges is therefore uneven. Voice-based language practice is widespread, though its effect on pragmatic competence is unproven. Vision-based tutoring in science and mathematics is plausible and promising but thinly evaluated. Cross-modal generation in the arts is pedagogically generative and ethically contested. Feedback on physical skills remains largely prospective and is constrained by teacher readiness and institutional conditions.

Institutions that engage with these technologies early will help define the pedagogical practices. Those that wait may find the practices defined for them by platform developers. Early engagement should mean careful piloting under clear governance, not uncritical adoption. Readers can follow two threads further: how generative AI is reshaping pedagogy, authorship and assessment in the creative arts is examined in Q227, and the evidence on AI-supported second-language acquisition in Q228.

Q101 Should teachers be required to disclose their own classroom use of AI, as the EU AI Act requires of AI systems, even when disclosure weakens the exercise?

12 citations · 12 sources · 5 cross-references

Claim 1 disputed

Teachers should be held to a transparency standard modelled on the EU AI Act, but not a blanket one. Students should know when they are interacting with an AI system and when the material in front of them is AI-generated. The decision not to disclose AI assistance in designing a particular exercise should rest with the teacher's professional judgment, coupled with a duty to justify that choice afterwards to students and parents. The rest of this answer sets out the reasons.

The benchmark is Article 50 of the Artificial Intelligence Act, Regulation (EU) 2024/1689. Article 50 imposes transparency obligations that apply to AI systems in specified situations, regardless of how those systems are classified for risk. Systems intended to interact directly with natural persons must be designed so that people know they are dealing with AI, unless this is obvious from the context. Providers of generative AI must ensure that outputs are marked in a machine-readable format and are detectable as artificially generated. Deployers who use AI to create deepfakes, or to publish AI-generated text informing the public on matters of public interest, must disclose that the content is artificial.

These obligations become applicable in August 2026. The European Commission has published guidelines and a voluntary Code of Practice on AI-generated content to support compliance, and practitioner commentary such as Orrick's analysis has begun mapping how providers and deployers will implement them. The question here is whether this standard should extend to a teacher's own use of AI in the classroom, including cases where disclosure might undermine the pedagogical value of an exercise. Answering it requires three steps: distinguishing the separate transparency obligations, examining the special character of the classroom, and weighing the values transparency is meant to serve.

The AI Act's transparency regime is not a single rule but a set of differentiated obligations, each with its own scope, exceptions and rationale.

The first is the interaction obligation, which requires that a person be informed they are interacting with an AI. It applies to systems intended to interact directly with natural persons. It is subject to an exception where the AI's involvement is "obvious from the point of view of a natural person who is reasonably well-informed, observant and circumspect."

The second is the content obligation, which requires AI-generated output to be marked. It applies to synthetic content, with exceptions for systems that perform assistive functions such as standard editing, for example grammar correction, or that do not substantially alter the input data.

The third is the deepfake obligation, which requires disclosure of artificially generated or manipulated content. It falls on deployers. It is reduced, not removed, for evidently artistic, creative, satirical or fictional works, where disclosure need not hamper display or enjoyment of the work. The parallel duty for AI-generated public-interest text lapses where the content has undergone human review or editorial control and a person holds editorial responsibility. That

exception matters for teachers, who routinely exercise exactly this kind of control over materials before students see them.

Each obligation protects something different. The interaction obligation protects the autonomy of the person in the exchange. The content obligation protects the integrity of the information environment. The deepfake obligation protects against deception.

The obligations also attach to different actors. Machine-readable marking binds providers of generative systems, not the teacher who uses them. A teacher is, at most, a deployer. Extending the content rationale to classroom practice is therefore partly an argument by analogy rather than a direct reading of the legal text. Applying the regime to the classroom means asking which of the three rationales a given use actually engages, rather than treating "AI use" as a single category.

A teacher's use of AI in the classroom is not the paradigmatic case the AI Act was designed for. Its transparency obligations protect individuals against deception and manipulation by AI systems acting on them: chatbots that impersonate humans, synthetic content that masquerades as real, deepfakes that deceive.

The classroom relationship differs in kind. The teacher is a professional with a duty of care toward students. The interaction is pedagogical rather than commercial. In schools, the students are often minors whose educational interests are the very purpose of the interaction.

None of this removes the transparency obligation. The Act applies to deployers in education as elsewhere, and the Commission's overview of the regulatory framework treats certain educational uses as high-risk, such as systems that determine access to education or score examinations. The classroom's character changes how the Article 50 obligations should be interpreted and applied, not whether they apply.

The practical scope of the question is wide. Cincioğlu, Mutlu Bayraktar and Altan (2026), in a systematic review of teachers' generative AI use in K–12 education, find AI supporting lesson planning, assessment, feedback generation, content creation and classroom support.

They also note that the research is scattered across contexts, methods and theoretical frameworks. A single disclosure rule would therefore have to cover activities that touch

students very differently. A lesson plan a student never sees engages none of Article 50's rationales. AI-generated feedback on a student's essay engages several.

How students and teachers understand AI's role in the room also matters. Day (2026) studied 76 preservice teachers on a postgraduate programme in China, using thematic analysis of forum posts. The study explored their views of AI as a "non-human instructor" and whether it could replace human teachers. This confirms that the boundary between AI as interlocutor and AI as tool is something participants themselves actively negotiate, not a settled fact. Jia (2025) surveyed 373 Chinese undergraduates and modelled how the history and frequency of AI use relate to their cultural values and their interactions with teachers. The abstract does not report the direction or size of the effects, so whether AI use reshapes the student–teacher relationship in ways that bear on disclosure remains unclear.

There are four strong arguments for extending the transparency standard fully to the classroom.

The first concerns autonomy and trust. Students and parents have a claim to know when AI is involved in their education, and undisclosed use erodes the trust on which the teacher–student relationship depends.

The second concerns informed consent. The data protection analysis of educational AI presupposes that families know which systems are in use. That analysis rests on the GDPR and on the school-consent models discussed elsewhere in this volume.

The third concerns modelling. If students are to develop AI literacy, they must be able to recognise AI in their environment. A classroom where AI is invisible teaches the wrong lesson.

The fourth is the Act's own logic. The transparency obligation exists because AI interaction can be consequential, and classroom AI is consequential for the students involved.

On this view, the pedagogical value of an exercise cannot justify concealment. The harm of concealment outweighs the benefit: harm to trust, to autonomy, and to students' ability to evaluate their own learning.

Recent evidence on student disclosure sharpens the modelling argument. Qu and Wang (2026) studied 409 undergraduates at a Singaporean university who used generative AI for academic work. Their mixed-methods design was guided by Bandura's social cognitive theory. They report that students frequently conceal their AI use despite institutional disclosure mandates,

reflecting ethical uncertainty and relational risk. They also find that willingness to disclose is shaped jointly by cognitive, social and emotional factors, including peer influence.

If disclosure is a socially learned norm, the conduct of the most visible adult in the room plausibly matters. A teacher who requires students to document their AI use while concealing their own undermines the norm being taught (see Q083).

The study's limits should be stated plainly. It sampled a single university, relied on self-report and concerned students rather than teachers. Whether teacher modelling actually changes student disclosure behaviour has not been tested and remains unclear. The reciprocity argument is therefore a reasonable inference, not a demonstrated effect.

The counterargument is that the classroom is precisely where the "obvious from the context" exception and the pedagogical purpose should be read generously. Three examples show why. Consider a teacher who uses AI to generate a Socratic dialogue for a philosophy lesson, a teacher who creates a writing prompt designed to elicit a student's unassisted response, and a teacher who simulates a conversation partner for language practice.

In each case, disclosure at the moment of use could alter the pedagogical effect. Students who know a dialogue is AI-generated may engage with it differently, and the exercise's value may depend on that engagement.

The deeper point is that a teacher's use of AI is not the same as an AI system acting on a student. The teacher remains the accountable agent, and the AI is a tool in the teacher's hands, like a textbook or a film. The obligation that protects against deception by systems is less clearly engaged when the system is not the interlocutor. Here it is the instrument of a human professional who is present, accountable and known to the student. This reading echoes the Act's own exception for content under human editorial responsibility, although that exception is framed for public-interest publication rather than teaching.

The argument rests heavily on professional judgment, and the evidence on that judgment cuts both ways.

Letina, Tomaš and Škugor (2026) surveyed 322 primary and secondary teachers in Croatia. They examined how professional awareness of AI and conceptual beliefs about its educational role contribute to explaining teachers' preferred pedagogical approaches. Teachers, on this

account, do not approach AI uniformly; their choices vary with what they know and believe. Polly's (2026) exploratory study of elementary pre-service teachers points the same way. Participants using generative AI to plan differentiated mathematics instruction found it helpful. Those with more robust background knowledge made more connections to research-based differentiation strategies.

Taken together, these studies suggest that the quality of AI-assisted pedagogy depends on the expertise of the person using it. That supports trusting expert judgment, but it also warns that judgment is uneven. Neither study measured outcomes for students, and neither addressed disclosure directly.

Credible positions therefore disagree. One side holds that professional discretion is the proper safeguard. The other holds that discretion is too variable to replace a rule.

The defensible resolution is a graduated standard that tracks the obligations the AI Act actually imposes.

The interaction obligation should apply. Students should know, at the level of the classroom and the lesson, when they are interacting with an AI system rather than with the teacher. That obligation protects the student's autonomy in the interaction itself. A language-practice chatbot can preserve its value if students are told at the outset of the unit that practice partners will be simulated, without interrupting each exchange. This is how the "obvious from the context" exception is meant to work.

The content obligation should apply, by analogy, to AI-generated materials that students consume as content. Students should be able to tell what is AI-generated, because the integrity of the information environment matters in education as much as anywhere.

Deepfake-style disclosure of every AI-assisted pedagogical act is a different matter. Requiring a label on every AI-generated prompt or every AI-drafted exercise is neither demanded by the Act's rationale nor necessary for its purposes. Here a teacher's professional judgment about when disclosure serves the learning objective should be respected. Where an exercise depends on delayed disclosure, as with the Socratic dialogue, the honest course is to disclose afterwards. The reveal can then become part of the lesson rather than being withheld altogether.

The standard, then, has three parts: transparency about the system, transparency about the content, and professional judgment about the pedagogy. The burden falls on the teacher to be able to justify, to students and parents, why a particular exercise was conducted without disclosure. That burden answers the concern raised by the uneven expertise documented by Letina and colleagues and by Polly. Discretion is permitted, but it is accountable rather than unreviewable.

Two complementary safeguards would give the standard practical force. The first is a professional code of practice for teachers' AI use (see Q217), which would articulate the justifications schools accept. This could parallel how the Commission's voluntary Code of Practice operationalises Article 50 for providers.

The second is attention to how disclosure practices shape classroom authority and trust once students encounter competing AI explanations of their own (see Q260).

This approach preserves the values the AI Act protects: autonomy, trust and the integrity of information. It also recognises that the classroom is a pedagogical space, not a marketplace, and that the teacher's professional judgment is itself part of what students are learning to trust.

What changed in this edition: This answer is unchanged in Edition 122. Its most recent revision, in Edition 117: Expanded to six sections. Added recent evidence on student concealment, teacher judgment and the range of teacher AI uses. Clarified that provider-side marking duties and the editorial-responsibility exception apply. Added post-hoc disclosure and cross-references. Converted the two bulleted lists into running prose. (1,061 → 2,092 words · 6 new sources)

Q266 What is the full cost of adopting, operating, maintaining, and eventually replacing or leaving an AI system in an educational institution?

14 citations · 14 sources · 4 cross-references

Claim 1 emerging

The full cost of an educational AI system is everything an institution must spend, and every hour its people must give, from the first evaluation of a product to the day its data has been retrieved and the service switched off. The licence fee is the most visible part of that sum and often not the largest. On current evidence the answer has two halves. The categories of cost are well understood and set out in established total-cost-of-ownership (TCO) frameworks. The proportions, meaning how much of the total each category represents in a typical school or university, are not reliably established, and several widely repeated percentages cannot be traced to published primary research. An institution can know with confidence what to count, but it must measure its own figures rather than borrow someone else's.

Here "AI system" means any externally supplied or institutionally built tool that relies on machine-learning models. Total cost of ownership is the full lifecycle cost of a technology rather than its purchase price. The Consortium for School Networking (CoSN), the US association of school technology leaders, groups it into five areas: hardware and software, infrastructure, support and maintenance, training, and indirect labour, defined as "staff time spent troubleshooting and managing disruptions" [SRC-446]. The examples below come mainly from the United States, where most published procurement figures originate. Funding rules, labour costs, and data-protection obligations differ elsewhere, and the figures should not be transferred to other jurisdictions without adjustment.

A full cost account separates five things that budget presentations routinely merge. First, initial expenditure (evaluation, procurement, legal review, integration, set-up, launch training) differs from recurring cost (subscriptions, usage charges, support, renewal, refresher training). Second, direct cost, meaning what appears on an invoice, differs from indirect cost, chiefly staff time that is real but not separately budgeted. Third, cost borne by the institution differs from cost shifted to teachers who learn a tool in their own time, to students and families who pay for what the institution does not supply (see Q270 and Q271), and to neighbouring budgets such as networking or devices. Fourth, expected cost differs from contingent cost: price rises at renewal, emergency fixes, or the expense of leaving a vendor. Fifth, the cost of a licence differs from the cost of use. A price quoted per licensed user says little about the price per person who actually uses the tool.

Before any student or teacher uses an AI system, an institution has already spent money and time. Products must be evaluated against an educational purpose and against alternatives. Contracts must be reviewed for data protection, ownership of inputs and outputs, model-

training rights, security obligations, and exit terms. Systems must be connected to identity management, learning platforms, and student information systems, and staff must be trained before launch. These costs are largely staff time, so they rarely appear as a line item.

In the United States, the Department of Education's July 2025 guidance confirms that federal formula and discretionary grant funds may be used for AI-powered instructional materials, tutoring, and advising, including training for educators. It also reminds grantees that such uses must comply with federal privacy law, including the Family Educational Rights and Privacy Act [SRC-1673]. Compliance of this kind is not free: it requires review of vendors' data practices and, often, negotiated contract terms. The guidance makes certain spending lawful; it does not pay for the work needed to make a particular product compliant.

Evaluation is partly a question of fit, and fit has a cost. Abdekhoda and Dehnad (2024) surveyed 163 faculty members at Tabriz University of Medical Sciences about their intention to adopt AI-driven technology in medical education, using a task-technology fit model, which treats adoption as dependent on how well a tool matches the work it is meant to support. The study is a single-institution survey of intentions, not of spending. Still, it reflects a practical point: judging whether a product suits the tasks staff actually perform takes deliberate work before purchase, and skipping that work moves the cost to later, when poor fit shows up as low use.

Institutions that build rather than buy face a different initial profile. Twabu and Nakene-Mginqi (2024) describe developing an AI-driven auto-marking and feedback system at an online distance e-learning institution in South Africa, aimed at reducing lecturer workload, through a design-thinking framework of empathy, problem definition, ideation, prototyping, testing, and iterative improvement. The abstract reports the design process, not its cost or measured workload savings. The iterative approach nonetheless implies sustained staff and developer time that a subscription price would otherwise conceal or transfer to a vendor.

Once in service, an AI system carries recurring charges. Most institutional products are sold per user per year. Some charge by usage, so costs rise with adoption. Many bundle AI features into existing platforms, which makes the AI share of a larger renewal hard to isolate.

Underneath the subscription sits infrastructure the institution must already maintain or must now upgrade. A practitioner guide to the cost of student devices sets out five cost areas districts should include: acquisition; software and management; deployment and operations, including

staff labour; repair and downtime, including the value of lost instructional time; and retirement, including data sanitisation and disposal [SRC-1674]. The guide concerns devices rather than AI. But AI tools run on those devices and networks, and an AI programme that assumes one capable device per student inherits the full lifecycle cost of that assumption. The book's earlier analysis of system-level cost reaches the same conclusion (see Q122): institutions that do not count infrastructure systematically understate what AI costs them. Infrastructure is not fixed, however. Alcaraz-Valencia and colleagues (2025) built a gamified expert system for teaching AI concepts on a low-cost Raspberry Pi Pico W microcontroller that stores gameplay data locally and uploads it remotely only as an option. The example is a narrow engineering teaching tool, but it shows that design choices about hardware and where data lives can shape both running costs and later data obligations.

AI systems change more often than conventional software. Models are updated, features appear and disappear, and usage policies shift. Each change creates work: help-desk support, revised guidance, refresher training, checks that safeguards still behave as intended, and responses to incidents such as inaccurate outputs or inappropriate content. CoSN's inclusion of indirect labour [SRC-446] matters especially here. The largest maintenance cost is usually teacher and support-staff time, spread across many people in small amounts and almost never measured. An institution that records only invoices will see a stable cost while its staff absorb a growing one (see Q269).

Staff time can also be a benefit, which is why it must be measured rather than assumed. Chang and colleagues (2024) randomly assigned forty third-year dental students to mount full-mouth radiograph series with or without an AI-assisted interface, to evaluate efficiency and accuracy. Studies of this design are the kind of evidence needed to set time saved against time spent, though a single small trial of one clinical task cannot indicate how such savings would generalise across an institution.

The most detailed public example of institutional AI pricing shows how quickly the headline number can move. In early 2025, the California State University Chancellor's Office signed an 18-month contract (February 2025 to July 2026) providing up to 500,000 ChatGPT Edu licences to students and employees [SRC-1675]. The cost was reported as about $17 million [SRC-1676]. In May 2026 the system renewed for three years at $13 million a year, $39 million in total, with an annual option to cancel on advance notice [SRC-1677]. CSU states that the renewal costs $1.60 per user, that the next-closest bid was $8.00 per user per month, and that

coverage will expand from 500,000 to 675,000 users, including graduates for a year after graduation [SRC-1675]. Dividing $13 million by 675,000 users and twelve months gives roughly $1.60. This suggests the figure is per user per month at full projected enrolment, but that is an inference from the published numbers, not a disclosed contract term.

On that basis the first contract cost about $11.3 million a year, or about $1.89 per licence per month ($22.70 a year), while the renewal works out at about $1.60 per month ($19.26 a year). The unit price fell by roughly a sixth while the annual commitment rose by more than a tenth. Together the two contracts commit about $56 million in licence fees over four and a half years, before any staff time, training, integration, or exit cost is counted. For comparison, the next-closest bid of $8.00 per user per month, applied to the same 675,000 users, implies about $64.8 million a year.

Three lessons follow. First, per-user price and total commitment can move in opposite directions. Second, the price per licensed user is not the price per active user. CSU's figures describe eligible users. This research cycle found no disclosed figures on how many use the tool regularly, so the cost per person actually served cannot be calculated. If half the eligible users never log in, the effective price per user doubles. Spreading the renewal's annual sum across regular users only, the cost would be about $32 per regular user a year if three in five eligible users used the tool regularly, about $58 if one in three did, and about $193 if one in ten did. These are scenarios built on the book's own arithmetic, not reported uptake. This is why a systemwide purchase can be good value per licence and still poor value per person served. The decisive variable is the share of licence holders who actually use the tool, and that share is precisely the figure institutions most rarely publish. Third, contract structure is itself a cost-control instrument. A multi-year agreement with an annual cancellation option limits exposure if prices, products, or priorities change.

The renewal was also contested. EdSource reported faculty opposition, with critics arguing that the money should be weighed against jobs and other needs on campuses facing budget pressure [SRC-1676]. The debate is a reminder that the full cost includes opportunity cost: what the same money would otherwise have bought (see Q267).

Every AI system will eventually be replaced, renegotiated, or abandoned, and the cost of leaving is set largely when the contract is signed. Exit costs include retrieving and converting institutional data, confirming deletion of student data held by the vendor, rebuilding

integrations, retraining staff on a successor product, rewriting course materials, assessments, and guidance that assumed the old tool, and running two systems in parallel during transition. Where a vendor has used institutional data to configure or tune its service, the configuration may not be portable at all. Contracts that specify data-return formats, deletion timelines, transition assistance, and notice periods reduce these costs; contracts that are silent on them transfer the risk to the institution. The book's procurement question (Q073) sets out the relevant contract terms. This answer adds that exit should be priced at the outset, as a contingent liability, rather than discovered at renewal. The retirement category in the device guide, with its emphasis on data sanitisation [SRC-1674], is the closest published analogue.

Precise-sounding proportions are often repeated in commentary on AI costs: that licence fees represent only 40–50 per cent of total cost of ownership, that institutions underestimate the total by 40–60 per cent, and that AI subscription prices rise by around 12 per cent a year. One source presenting these figures is a vendor blog post on the economics of AI in education, rated low credibility in this book [SRC-1678]. This research cycle could not trace any of them to published primary research, meaning a multi-institution study with a stated method and sample. They may be broadly right; they may not be. Either way, they cannot bear the weight of a budget decision. The direction they point in is supported by the frameworks above, which consistently show that recurring, indirect, and contingent costs are substantial [SRC-446] [SRC-1674]. Their specific magnitudes remain unclear.

The cost structure differs by sector. School districts typically buy for children, which raises the bar for data protection and parental consent. They also depend heavily on grant and categorical funding whose rules shape what can be bought and for how long [SRC-1673]. Universities more often buy for adults at very large scale, as the CSU case shows [SRC-1675]. They face distinctive costs in research data governance, academic-integrity processes, and support for graduates and staff.

The academic-integrity cost is not hypothetical. Bissessar (2025) interviewed nine Guyanese Master's students completing theses about their use of content-generating AI tools, framing plagiarism and academic integrity as the main threats associated with such tools in the scholarly literature. The study is a small qualitative case, but it indicates why integrity policy, guidance, and case handling belong in a university's cost account. Training costs, too, extend beyond tool operation. Vázquez-Parra and colleagues (2024) note that educational institutions

feel responsible for ensuring students develop competences for the appropriate use of AI. That responsibility implies curricular and staff-development spending which no licence covers.

In both sectors the largest uncertainties are the same: actual uptake, staff time, and the price at renewal. Comparison with other sectors underlines how partial uptake can be. Baten (2024), analysing 2022 American Hospital Association data, found that 18.70 per cent of US hospitals (1,107) had adopted some form of AI. The figure describes institutional adoption in health care, not individual use in education, but it is a reminder that broad availability and actual use are different quantities.

An institution deciding whether to adopt, renew, or replace an AI system can apply seven criteria. It should estimate cost over the whole expected life of the system, including exit, not over the first contract year. It should report cost per active user alongside cost per licence, and collect the usage data needed to do so. It should record staff time for implementation, support, and training, even approximately, rather than treating it as free. It should identify costs shifted to students, families, and staff. It should compare the system against at least one non-AI alternative and against doing nothing, using the kinds of evidence discussed in Q268. It should treat unsourced industry percentages as hypotheses to test against local data, not as planning assumptions. And it should write down and publish its assumptions, so the analysis can be checked and revisited.

The full cost of AI is knowable in structure. What institutions lack is the habit of counting all of it.

Q338 Why do standard autoregressive language models default to giving direct answers rather than Socratic guidance, and how do system-prompt engineering, Chain-of-Thought hiding, and pedagogical RLHF enforce instructional restraint?

11 citations · 11 sources · 4 cross-references

Claim 1 disputed

Standard autoregressive language models default to direct answers because every stage of their construction rewards completing the user's request as fully as possible. Socratic restraint asks for the opposite: withholding a completion the model can readily produce. A pretrained model is optimised to predict the next token from patterns in vast text collections. In most of that text, a question is followed by its answer and a worked problem by its solution. When a learner types "How do I solve 3x + 5 = 20?", the most probable continuation is the solution, not a counter-question about which operation would isolate x. Nothing in the pretraining objective distinguishes a learner who wants to understand from one who wants a result; both receive the continuation that text statistics make most likely. Pedagogical intent, if it is to shape the output at all, must therefore be introduced by later stages of training or by the deployment context.

Instruction tuning and reinforcement learning from human feedback sharpen this tendency rather than correct it. Ouyang and colleagues (2022) framed alignment as bringing models into line with "user intent." Their method collected labeler demonstrations of desired behaviour, fine-tuned GPT-3 on them with supervised learning, and then further optimised against human preferences. In a tutoring exchange, the user's surface intent is usually to obtain the answer. A model that faithfully serves that intent is therefore, almost by definition, a poor Socratic tutor.

The LearnLM Team (2024) state the consequence plainly. Today's generative AI systems, they write, are "tuned to present information by default, rather than engage users in service of learning as a human tutor would." The default is not a bug in any single model. It is the predictable product of an objective that measures success by how satisfied the asker is with the immediate response.

A second mechanism compounds the first. Human preference data does not simply reward helpfulness; it rewards agreeableness. Sharma and colleagues (2023) showed that five state-of-the-art AI assistants consistently exhibited sycophancy across four varied free-form generation tasks. Sycophancy here means producing responses that match the user's beliefs rather than truthful ones. The authors then analysed existing human preference data to ask whether such judgments drive the behaviour. The full causal account is more qualified than a headline can convey. Still, their framing places the source of sycophancy partly in the feedback signal itself rather than in any peculiarity of a single model.

For education the implication is direct. A learner who pushes back ("just tell me the answer") is expressing a preference. A model shaped by preference optimisation has learned that yielding to such pressure tends to be rated favourably. Productive struggle, which many pedagogical traditions treat as the engine of learning, looks like friction from the point of view of a preference model.

Perez and colleagues (2022) add a methodological point that matters here. As models scale they develop many novel behaviours, good and bad, and these are often discovered only through systematic evaluation. The authors generated such evaluations automatically with language models, and crowdworkers agreed with 90 to 100 percent of the resulting labels. Answer-giving under social pressure is precisely the kind of behaviour that general capability benchmarks are not designed to detect. This is one reason, explored elsewhere in this volume, why strong benchmark performance says little about teaching quality (see Q346).

The evidence that sycophancy specifically erodes instructional restraint in tutoring dialogues remains largely inferential. The sycophancy findings concern truthfulness and belief-matching, not pedagogy. Extending them to the capitulating tutor is plausible but not yet directly measured at scale.

System-prompt engineering is the cheapest and most widely deployed countermeasure. A developer prepends instructions the user does not see, for example: do not reveal final answers;

ask one guiding question at a time; diagnose the learner's misconception before offering hints.

The LearnLM Team (2024) gave this practice a more principled formulation. They reframe the problem of injecting pedagogical behaviour as one of "pedagogical instruction following." In this framing, training and evaluation examples include system-level instructions describing the pedagogy attributes present or desired in subsequent model turns. The design choice is deliberate. It avoids committing the model to any single definition of pedagogy, and instead allows teachers or developers to specify the behaviour they want. Treating restraint as something to be specified rather than hard-coded accommodates genuine pedagogical disagreement. A mathematics teacher seeking strict Socratic questioning and a language teacher seeking corrective recasts can both be served by the same underlying model. It also shifts responsibility: the quality of restraint then depends on how carefully the instruction is written, and a vague directive such as "be Socratic" leaves much of the interpretation to the model's defaults.

The weakness of prompting alone follows from the analysis above. A system prompt conditions the model's next-token distribution, but it does not change the weights that encode the answer-giving prior or the preference for agreeableness. Over a long dialogue, user turns accumulate in the context. Persistent requests, reframings ("my teacher said it's fine"), and emotional appeals all exert pressure in the very direction that preference training has made the model receptive to (Sharma et al., 2023).

Practitioners widely report that prompted restraint erodes as conversations lengthen, though this remains anecdotal rather than systematically quantified. LearnLM's contribution is to train the model to follow such instructions more reliably, rather than relying on a base model's general instruction-following. That framing implicitly concedes that prompting an untrained model is insufficient. How robust trained instruction-following is to sustained adversarial pressure from determined students remains unclear.

Hiding the chain of thought addresses a subtler tension. Good tutoring requires the tutor to know the answer and the solution path, yet not to say them. Wei and colleagues (2022) demonstrated that generating a chain of thought, a series of intermediate reasoning steps, significantly improves large language models' performance on arithmetic, commonsense, and symbolic reasoning. They showed that this ability emerges naturally in sufficiently large models when a few worked demonstrations are provided as exemplars.

In an unmodified assistant, this reasoning appears in the output, and the visible chain of thought is itself a complete worked solution. The pedagogical problem is therefore not only that models give final answers. Their best reasoning mode is also a mode of full disclosure.

The architectural response is to separate reasoning from response. The model first generates a private scratchpad that the learner never sees. There it solves the problem, locates the learner's error, and selects a move. Only a constrained, scaffolded turn is then released. Wang and colleagues (2024) offer the clearest pedagogical grounding for this design. Their Bridge method uses cognitive task analysis to translate an expert's latent thought process into a decision-making model for remediating math mistakes. Before generating a response, the expert identifies (a) the student's error, (b) a remediation strategy, and (c) their intention. The work is motivated by the observation that novice tutors struggle to address student mistakes and thus miss prime learning opportunities.

Read technically, Bridge structures the hidden reasoning around pedagogical decisions rather than mathematical ones. The scratchpad becomes a place for diagnosis and intention, not merely calculation. Where arithmetic reliability within that hidden reasoning is the concern, delegating computation to external tools is a complementary strategy (see Q347).

Two cautions apply. First, hiding reasoning is an interface decision, not a guarantee. Information in the scratchpad can leak into the visible turn, and a model under pressure may simply copy its private solution into the reply. Second, concealment reduces transparency for teachers and researchers who might want to audit why a tutor chose a particular hint. The reported value of making decision steps explicit lies precisely in their inspectability. Whether hidden-reasoning tutors outperform visible-but-scaffolded ones on learner outcomes has, to my knowledge, received little direct comparative study. A comparative trial would need to measure not only immediate task success but also retention and transfer, since a tutor that withholds effectively may look worse on the first measure and better on the others.

Pedagogical RLHF is the most ambitious approach because it attempts to change the model's priors rather than constrain them at inference time. The template is the pipeline Ouyang and colleagues (2022) described. Collect demonstrations of desired behaviour, fine-tune on them, then optimise against human comparisons. Substituting pedagogical judgments for generic helpfulness judgments is conceptually simple. A tutor turn that elicits the learner's next step should be ranked above one that supplies it.

The LearnLM framing extends this by attaching system-level pedagogical instructions to the training examples themselves (LearnLM Team, 2024). The model then learns not only to behave pedagogically but to behave in the specific way an instruction requests. That matters because restraint is not uniformly good. Sometimes a direct explanation is the right move, and a model trained only to withhold would serve learners poorly.

The central difficulty is whose preferences are encoded. If learners themselves supply comparisons, the sycophancy mechanism documented by Sharma and colleagues (2023) predicts drift back toward answer-giving, since learners in the moment often prefer the answer. If expert teachers supply the comparisons, cost rises sharply. Disagreement among experts about what counts as a good pedagogical move also becomes part of the reward signal.

The expert-modelling approach of Wang and colleagues (2024) suggests one way through. Make the expert's reasoning explicit so that it can be taught and evaluated, rather than inferred from coarse preferences. Whether such structured supervision transfers into durable model dispositions is not yet established.

Parameter-efficient methods have lowered the barrier to this kind of specialisation. Hu and colleagues (2021) introduced LoRA, which freezes pretrained weights and injects trainable rank-decomposition matrices into each Transformer layer. This greatly reduces the number of trainable parameters, motivated by the prohibitive cost of maintaining fully fine-tuned copies of models as large as GPT-3 175B. Dettmers and colleagues (2023) went further with QLoRA. It backpropagates through a frozen 4-bit quantized model into low-rank adapters, enabling a 65B-parameter model to be fine-tuned on a single 48GB GPU while preserving full 16-bit fine-tuning task performance. Their Guanaco models reached 99.3 percent of ChatGPT's performance level on the Vicuna benchmark after 24 hours of fine-tuning on a single GPU.

These results concern general task performance, not pedagogy. But they make it plausible for universities, districts, or researchers to train restraint into smaller local models rather than depending on a vendor's alignment choices. The privacy and equity dimensions of such local deployment are treated separately (see Q344). What parameter-efficient methods do not resolve is the reward-design problem. Cheap fine-tuning on a poorly specified pedagogical signal simply produces a cheaply misaligned tutor.

The educational stakes of getting this right are frequently asserted and less frequently measured. Lopez-Gazpio (2025) argues that LLMs can personalise instructional content,

respond dynamically to learners' educational and emotional needs, and reduce barriers related to language diversity, learning disabilities, cultural difference, and socioeconomic inequality. Claman and Sezgin (2024) describe both opportunities and challenges for LLMs and multimodal foundation models in dental education. Both are largely synthetic and prospective accounts. They describe potential rather than demonstrating that any particular restraint mechanism produces learning.

Zhang and Liu (2025) note that although a growing number of studies suggest generative AI can support college students' critical thinking, research on its effects in open learning environments remains scarce. Open environments are exactly the settings in which learners can bypass a restrained tutor by opening a different chatbot. Controlled settings, where alternative tools are unavailable or discouraged, may therefore overstate how much a restrained tutor shapes learner behaviour.

That last point exposes a limit no model-side technique can overcome. Instructional restraint enforced inside one system is only as strong as the learner's willingness to stay inside it. A Socratic tutor competing with freely available answer engines faces an incentive problem that is institutional and motivational, not merely technical. The philosophical shift this represents, from answers discovered to answers generated, is addressed elsewhere (see Q005).

There is also a genuine pedagogical argument against overcorrection. A model trained to withhold may frustrate learners who need a worked example to proceed. It may disadvantage those whose language proficiency or disability makes extended questioning burdensome, the very learners whose inclusion Lopez-Gazpio emphasises. LearnLM's decision to keep pedagogy configurable rather than fixed is one response to this tension (LearnLM Team, 2024).

Taken together, the mechanisms form a layered defence of increasing depth and cost. System prompts specify restraint. Hidden reasoning lets the model know the answer while choosing a pedagogical move. Pedagogical fine-tuning and preference optimisation attempt to make restraint a disposition rather than an instruction. The evidence that each layer reshapes model behaviour is reasonably developed. The evidence that the resulting behaviour improves learning, durably and across diverse learners, is much thinner. That second question, rather than further refinements of the first, is where the field's attention most needs to turn.

Q339 How does Retrieval-Augmented Generation (RAG) ground an educational AI in a teacher's specific syllabus and textbook—and what are its five primary failure modes (chunking fractures, retrieval misses, context-window dilution, unfaithful synthesis, and poisoned sources)?

16 citations · 16 sources · 4 cross-references

Claim 1 disputed

Retrieval-Augmented Generation grounds an educational AI in a teacher's materials in four steps. It divides the syllabus, textbook and handouts into passages, indexes them, retrieves the passages most relevant to each student query at the moment of answering, and instructs a language model to compose its response from that retrieved text rather than from whatever it absorbed during pre-training. The grounding is only as reliable as five weak joints in the pipeline: how the text was cut, whether the right pieces are found, whether the model attends to

them amid competing material, whether it reports them faithfully, and whether the store itself can be trusted.

The architecture originates in the proposal by Lewis and colleagues (2020) to pair a pre-trained generator with a differentiable access mechanism to explicit non-parametric memory. Their motivation was that knowledge stored in model parameters is hard to access precisely, hard to update, and offers no provenance. Karpukhin and colleagues (2020) supplied a key enabling component. They showed that passage retrieval, long dominated by sparse methods such as TF-IDF and BM25, could be implemented with dense embeddings alone, learned through a simple dual-encoder from a small number of questions and passages. Gao and colleagues (2023), surveying the field, frame RAG as a remedy for hallucination, outdated knowledge and untraceable reasoning. They emphasise that it permits continuous knowledge updates and the integration of domain-specific information.

For a teacher, those properties map onto classroom needs. A general model knows a chemistry curriculum. A retrieval layer can make it answer from this department's scheme of work, this edition's notation and this term's assessment criteria, and cite the page it drew on. The appeal is also practical. Updating the system when a syllabus changes means re-indexing documents rather than retraining a model, and the provenance trail gives a teacher a way to audit what the tutor said and where it came from.

Applied work is accumulating. Rugemalila and colleagues (2026) argue that general LLMs lack curriculum grounding and perform unreliably in low-resource languages, and they build a curriculum-aware RAG tutor for Swahili–English secondary schooling in Tanzania. Liu and colleagues (2025) combine RAG with prompt engineering in LPITutor to adapt responses to learner skill levels and question complexity. Zheng and colleagues (2025) use knowledge enhancement to meet the structural, logical and accuracy demands of lesson-plan generation. Ramesh (2025) describes question-paper generation from uploaded textbooks, question banks, lecture notes and past examinations.

Kasneci and colleagues (2023) had earlier set out both the content-creation and personalisation promise of large language models in education and its attendant challenges. Where RAG sits relative to prompting and fine-tuning is treated separately (see Q340); the concern here is how the mechanism breaks.

The first two failure modes occur before the language model writes anything. Barnett and colleagues (2024), reporting from the engineering of RAG systems, identify seven failure points. They trace them to two sources: limitations inherent to information retrieval, and reliance on LLMs.

Chunking fractures belong to the first source. Retrieval operates on units, and a textbook is not naturally made of units of the right size. A fixed-length splitter may separate a worked example from the problem statement it solves, detach a definition from the exception stated in the next paragraph, sever a table from its caption, or strip the chapter heading that tells the model a passage concerns a special case rather than the general rule.

Each fragment may then be retrieved in isolation. The model receives text that is locally accurate but pedagogically incomplete. Mathematics and science textbooks, whose meaning depends on figures, equations and sequenced derivations, are especially exposed. The problem compounds when scanned documents lose their layout during text extraction. Overlapping windows and structure-aware splitting that respects headings and example boundaries are common responses, but each involves trade-offs: overlap duplicates text and inflates the index, while structure-aware splitting depends on clean document markup that many school resources lack.

Retrieval misses occur when the relevant passage exists but is not returned. Dense retrievers of the kind Karpukhin and colleagues (2020) introduced match meaning rather than surface strings, which helps when a student paraphrases. But students rarely phrase questions in the textbook's vocabulary. A learner asking why a rolling ball slows down may not retrieve the section titled frictional forces. Teachers can add glossaries of student phrasings to the store, though that shifts curation work back onto them. Conversely, a query naming a specific term, page or exercise number may be better served by sparse lexical matching than by embeddings, which is a rationale for combining both. Evidence comparing such hybrid configurations specifically in classroom deployments is thin.

Rugemalila and colleagues (2026) point to a further layer. In low-resource languages and code-switched queries, curriculum grounding is harder to achieve, and retrieval quality cannot be assumed to transfer from English-language settings.

A retrieval miss is pernicious because it is silent. The model, finding nothing useful, may fall back on parametric knowledge and answer fluently from a different curriculum, edition or

national convention. Nothing in the output signals that the syllabus was never consulted.

The third failure mode, context-window dilution, arises when retrieval succeeds but too much else arrives with it. Long context windows tempt designers to pass many chunks, or entire chapters, to the model on the theory that more grounding is better.

Liu and colleagues (2024) demonstrate otherwise. On multi-document question answering and key-value retrieval, performance degraded significantly when the position of the relevant information within the input changed. They conclude that current models do not robustly use long contexts. Their title's phrase, lost in the middle, has become shorthand for the risk that a crucial textbook passage placed among a dozen others will be under-weighted.

Shi and colleagues (2023) add a complementary finding from grade-school mathematics. They built a benchmark of arithmetic problems seeded with irrelevant information and showed that a model's problem-solving accuracy can be swayed by irrelevant context. For an educational system the implication is direct. A tutor that retrieves the correct worked example alongside three superficially similar exercises from adjacent sections may blend them, apply the wrong constraint, or answer the neighbouring question.

Asai and colleagues (2023) name the design pattern behind much dilution. Retrieving and incorporating a fixed number of passages indiscriminately, regardless of whether retrieval is needed or the passages are relevant, can diminish a model's versatility and lead to unhelpful responses. Their Self-RAG approach trains a model to decide when to retrieve and to critique retrieved material through self-reflection.

Whether such adaptive retrieval resolves dilution in curriculum-scale stores remains unclear. Within a single subject's materials, many passages are legitimately similar, and few studies have tested retrieval critique under that kind of dense overlap. Model capability also moves quickly. The positional sensitivity documented in 2024 may diminish in later architectures, so it should be measured per deployment rather than assumed as a fixed property. Dilution also has a cost dimension: every additional chunk lengthens the prompt, slows the response and, in metered deployments, raises the per-query price, so the instinct to pass whole chapters is rarely free.

The fourth failure mode, unfaithful synthesis, is the one RAG was meant to cure and does not fully cure. Ji and colleagues (2023) document that neural generation is prone to hallucinate

unintended text across tasks including abstractive summarisation and dialogue. Composing an answer from retrieved passages is, structurally, a form of abstractive summarisation. Huang and colleagues (2025), in a taxonomy oriented to information-retrieval settings, describe hallucination as plausible yet nonfactual content. They stress that the open-ended, general-purpose character of LLMs makes it distinct from the errors of earlier task-specific systems.

In a grounded tutor, unfaithfulness takes recognisable shapes. The model may retrieve the right page but overstate its claim, merge two passages into a statement neither makes, attach a correct citation to an incorrect paraphrase, or let parametric knowledge override the textbook where the two conflict.

The last case is subtle. A teacher's materials may deliberately use a simplified model suited to the year group, and the system may correct it toward a more advanced convention the class has not met. The output may be factually defensible yet curricularly wrong. A history teacher's source pack illustrates the risk differently: a model summarising two primary documents may smooth over the very disagreement between them that the lesson was designed to expose.

Citations amplify the hazard. Barnett and colleagues (2024) list linking sources to responses among RAG's aims, and a visible reference reassures students and teachers that an answer has been checked. Yet a reference proves only that a passage was retrieved, not that the answer follows from it.

Remedies remain partial. Asai and colleagues (2023) frame self-critique as one response, with models trained to assess whether their outputs are supported. In quantitative domains, a sturdier remedy removes calculation from the generator altogether (see Q347).

For prose explanation, no mechanism yet guarantees faithfulness. The relative effectiveness of self-critique, external verification and constrained quotation for educational content remains unclear. Kasneci and colleagues (2023) count such reliability concerns among the challenges of educational LLMs. Because a learner consulting a tutor is by definition not yet expert, the burden of verification must fall on design rather than on the student.

The fifth failure mode, poisoned sources, turns RAG's chief virtue into an attack surface: its knowledge can be updated simply by adding documents. Zou and colleagues (2024) observe that RAG research had concentrated on accuracy and efficiency, leaving security largely unexplored. They introduce knowledge corruption attacks, in which text planted in the

knowledge database steers generated answers. Greshake and colleagues (2023) show more generally that LLM-integrated applications blur the line between data and instructions. Adversaries can therefore exploit such applications remotely by injecting prompts into content likely to be retrieved at inference time. Retrieved text is not merely evidence; the model may treat it as a command.

Educational deployments have distinctive exposures. Knowledge stores are often assembled from shared drives, learning-management systems and teacher uploads; some designs let students add their own notes; and some retrieve from the open web to supplement the textbook.

Each widens the set of people who can write into what the tutor treats as authoritative. A student could embed hidden instructions in a submitted document that a feedback assistant later retrieves. Detection is difficult in practice, because injected instructions can be phrased in innocuous language, hidden in white text or metadata, and triggered only by particular queries, so a teacher skimming the store would see nothing amiss.

Poisoning can also be accidental. A mislabelled answer key, an outdated edition or an erroneous worksheet can corrupt answers without any malice at all. This category deserves more attention than it receives, because curricular materials are constantly revised, superseded and duplicated. A store holding two versions of a specification will retrieve whichever sits closer to the query in embedding space.

The obvious mitigations are provenance controls, write permissions, versioning, and separating instructional from evidential text. How well they hold against the attacks these studies describe has not been established in school settings. Where data governance favours locally hosted models, the same questions of corpus integrity persist (see Q344).

Taken together, the five failure modes suggest that RAG relocates rather than removes the reliability problem. Grounding a tutor in the teacher's materials transfers trust from the model's parameters to a pipeline of chunking, indexing, ranking, prompt assembly and source curation, each of which can fail silently.

The applied educational studies establish feasibility and design intent more firmly than learning effects. They show that curriculum-aware, personalised and lesson-planning systems can be built. Few report component-level failure analysis of the kind Barnett and colleagues (2024)

encourage, and fewer still link retrieval quality to what students learn. Measuring that link is a separate problem (see Q346).

Disagreement persists over how far the failures are transient. One reading treats longer contexts and self-reflective retrieval as steadily eroding dilution and unfaithfulness. The security research suggests instead that poisoning and injection will co-evolve with defences.

The evidence does not yet show how often each failure occurs in real classroom traffic, which subjects, languages and age groups are most exposed, or whether students learn to calibrate their trust in cited answers.

Until it does, the prudent course is to evaluate each deployment against the teacher's own materials. Evaluators should probe whether known passages are retrieved, whether answers stay within them, and whether the store's contents are controlled. Teachers themselves are part of the evaluation: a small bank of questions whose answers they know sit on specific pages can serve as a standing test set, rerun whenever materials or models change. A citation should be treated as an invitation to check rather than as proof.

and textbook, and analyses five failure modes from chunking fractures to poisoned sources, with classroom implications. (0 → 2,103 words · 16 new sources)

Q340 What is the technical and pedagogical hierarchy between In-Context Prompt Engineering, RAG, Parameter-Efficient Fine-Tuning (LoRA/QLoRA), and Reinforcement Learning from Pedagogical Feedback (RLPF), and when should an institution use each?

15 citations · 15 sources · 4 cross-references

Claim 1 disputed

The four techniques form a hierarchy of intervention depth rather than a ladder of quality. In-context prompt engineering changes only what the model is told at inference time. Retrieval-augmented generation (RAG) changes what the model can see by attaching external documents. Parameter-efficient fine-tuning such as LoRA and QLoRA changes a small set of trainable weights. Reinforcement learning from pedagogical feedback (RLPF) reshapes the model's default behaviour toward learner-centred objectives. An institution should therefore climb only as far as its problem requires. Prompting comes first for almost everything. RAG is the tool when the deficit is missing or local knowledge. Parameter-efficient fine-tuning is warranted when a stable behavioural or stylistic pattern cannot be reliably elicited by instruction. Preference-based training is realistically the province of model developers and well-resourced consortia.

A strict ranking would mislead, because the techniques act on two different axes. One axis is knowledge: what facts, syllabi and texts the system has access to. The other is behaviour: how it questions, scaffolds, withholds answers and responds to error. Lewis and colleagues (2020) framed retrieval as a non-parametric memory that addresses limits on accessing knowledge, updating it and showing provenance. These are knowledge problems, and changing weights solves them poorly. Hu and colleagues (2021) and Ouyang and colleagues (2022) addressed a different problem: adapting or aligning the model's behaviour itself. The LearnLM Team (2024) states the educational version of that problem directly. Generative systems are tuned to present information by default rather than to engage users as a tutor would.

The practical consequence is that a school whose tutor gives away answers will not fix that by adding more textbook chunks. A school whose tutor misstates the local syllabus will not fix that by tuning the model on Socratic dialogue. Diagnosing which axis is failing is the first institutional decision. Choosing a technique is the second.

Prompt engineering sits at the base of the hierarchy because it is cheap, reversible and transparent to teachers. It requires no training data and no infrastructure beyond the model itself. Its educational value depends heavily on whether prompts encode pedagogical structure rather than merely request content.

Lu, Li and Cai (2026) illustrate this. Starting from the observation that simple prompts often yield incomplete and misaligned lesson plans, they built a three-step framework grounded in Bloom's taxonomy, ACT-R theory, Gagné's nine events and problem-chain theory. The framework decomposes planning into objective, unit and activity design. They generated 150 lesson plans across ten computer-networking topics with three DeepSeek models and five prompting strategies. Coverage and quality were assessed by an LLM judge with human validation. The design suggests that theory-driven decomposition is a legitimate engineering lever. It also shows that evaluating such prompts already requires a judging apparatus, which should not be mistaken for evidence of learning gains.

Wang and colleagues (2024) point in the same direction for tutoring. Their Bridge method uses cognitive task analysis to make an expert's latent reasoning explicit. The expert identifies the student's error, selects a remediation strategy and states an intention before a response is generated. Whatever the implementation, the lesson for practitioners is that structuring the decision sequence, not just the persona, is where much pedagogical gain appears to lie. Comparisons of prompting against fine-tuning remain domain-specific. Nfaoui and Elfaik (2024) compared emotional-stimulus prompting, in-context learning and fine-tuning for Arabic emotion recognition. Results from such classification tasks cannot simply be transferred to open-ended tutoring.

Prompting has two firm limits. First, instructions are not binding: a model can drift from a carefully specified pedagogy over a long conversation. Second, longer is not better. Liu and colleagues (2024) found that performance can degrade significantly depending on where relevant information sits in a long input. Current models do not robustly use long contexts. Sprawling system prompts that try to encode an entire curriculum and pedagogy are therefore

fragile. Moving to retrieval or training is often motivated by this fragility rather than by ambition.

RAG is the second rung and the correct answer to most knowledge problems in education. Lewis and colleagues (2020) introduced it as pairing a pretrained generator with a differentiable access mechanism to explicit non-parametric memory. Their motivation was that language models store factual knowledge in their parameters but cannot access and precisely manipulate it well. They also noted that providing provenance and updating world knowledge remained open problems. Gao and colleagues (2023), surveying the field, describe RAG as a response to hallucination, outdated knowledge and untraceable reasoning. In their account it permits continuous knowledge updates and integration of domain-specific information.

For institutions, these properties map closely onto real needs. Syllabi change each term and examination specifications are revised. Teachers want answers traceable to the assigned text rather than to an opaque training corpus. Retrieval lets a school change what the system knows by editing a document store. This is an operation teachers and librarians can govern, whereas weight updates require machine-learning staff. Provenance also supports academic integrity norms, since a cited passage can be checked. A further advantage is separation of duties. Curriculum leads can decide which documents enter the store, while technical staff maintain the retrieval pipeline, and neither needs to understand the other's work in depth for the system to remain accountable. When a document is withdrawn, its influence disappears from subsequent answers, which is not true of material absorbed into weights.

RAG is not, however, a pedagogical intervention in itself. Retrieving the correct page of a textbook does not make the model withhold the answer, diagnose a misconception or pace a hint. It also inherits the context-use limits that Liu and colleagues (2024) documented. Retrieved passages compete for attention, and relevant material placed in the middle of a long context may be underused. The engineering details belong elsewhere, including chunking, retrieval misses, dilution, unfaithful synthesis and poisoned sources (see Q339). The point for the hierarchy is narrower: RAG should be adopted when the failure is knowledge-related, and combined with prompting for behaviour.

Institutions should not treat fine-tuning as a substitute for retrieval when the goal is currency. Knowledge baked into weights cannot be updated by editing a document. It also cannot point a student to its source in the way a retrieved passage can.

Parameter-efficient fine-tuning occupies the third rung. Its rationale is both technical and economic. Hu and colleagues (2021) observed that full fine-tuning becomes less feasible as models grow, giving the example that deploying independent 175B-parameter instances of GPT-3 is prohibitively expensive. LoRA freezes the pretrained weights and injects trainable rank-decomposition matrices into each Transformer layer. This greatly reduces the number of trainable parameters.

Dettmers and colleagues (2023) lowered the threshold further. QLoRA backpropagates through a frozen 4-bit quantized model into low-rank adapters. Memory use falls enough to fine-tune a 65B-parameter model on a single 48GB GPU while preserving full 16-bit fine-tuning task performance. Their Guanaco models reached 99.3% of ChatGPT's performance level on the Vicuna benchmark after 24 hours of fine-tuning on one GPU. That benchmark measures chat quality, not teaching quality.

The broader PEFT literature shows rapid methodological churn. A systematic review by Afrin, Haque and Mastropaolo (2026) documents the growing adoption of PEFT for code models in resource-constrained settings. Singh and colleagues (2026) frame PEFT as crucial for privacy-sensitive environments and propose a split-learning variant. Zhao and colleagues (2026) note that high-rank methods such as MoRA improve update expressiveness through compression, transformation and decompression, yet their bottleneck subspaces may still be used inefficiently; they propose structural regularisation in response. For an institution, such work signals that the adapter technique chosen today may be superseded quickly, which argues for keeping training data and evaluation suites portable rather than tied to one method. These developments matter to schools mainly because they make local adaptation of open models feasible. Local adaptation intersects with data-residency and cost questions treated separately (see Q344).

PEFT is warranted when an institution needs a durable behavioural pattern that prompting cannot sustain. Examples include a consistent feedback format aligned to a rubric, a register suited to young learners, competence in a minority language of instruction, or a house style of hinting. It is poorly suited to injecting changeable facts, which belong in retrieval. Its pedagogical costs are easily underestimated. Adapters learn whatever the training dialogues contain, so the institution needs a curated corpus of exemplary teacher–student exchanges. Assembling that corpus is itself a substantial pedagogical, ethical and consent undertaking. Few educational studies have yet shown that LoRA-tuned tutors outperform well-prompted base

models on learning outcomes. The technical efficiency of these methods is established. Their instructional payoff remains unclear.

At the top of the hierarchy sits training against feedback about desirable behaviour. Ouyang and colleagues (2022) supplied the template. They argued that making models bigger does not inherently make them better at following user intent, since large models can produce untruthful, toxic or unhelpful output. They showed that alignment could be improved by fine-tuning with human feedback. Their pipeline began with labeler-written and API-submitted prompts and a dataset of labeler demonstrations of desired behaviour, which were used for supervised fine-tuning of GPT-3.

"Reinforcement learning from pedagogical feedback" names the educational extension: feedback comes from teachers or learning scientists judging pedagogical quality rather than general helpfulness. The closest published large-scale effort is LearnLM (LearnLM Team, 2024). It reframes the injection of pedagogy as "pedagogical instruction following." Training and evaluation examples carry system-level instructions describing the pedagogical attributes desired in later turns. The authors note that this framing deliberately avoids committing to any single definition of pedagogy, so that teachers or developers can specify behaviour. This design choice signals that the field has not agreed on what a pedagogical reward should reward. Productive struggle, answer-withholding, affective support and efficient explanation can pull in different directions, and a single reward model would arbitrate among them invisibly.

Wang and colleagues (2024) suggest one route to principled feedback. Expert decision models, which make explicit the error, strategy and intention behind a response, can specify what good remediation looks like. Such specifications could in principle become annotation guidelines for preference data. Whether rewards derived this way generalise across subjects and age groups remains unclear. Measuring success also requires pedagogical benchmarks rather than static academic ones (see Q346).

The institutional implication is sobering. Preference-based training requires large volumes of expert judgements, careful annotation protocols, compute and evaluation infrastructure. Its errors are subtle, because a model tuned to please raters may learn to sound pedagogical rather than to teach. For nearly all schools and universities, RLPF is something to procure, scrutinise and demand evidence about, not something to build. Its main local use is shaping the specifications that vendors' instruction-following models are asked to honour.

A defensible institutional policy follows a principle of minimal sufficient intervention.

The first step is prompting, ideally with pedagogically structured templates co-designed with teachers. Prompt-level interventions have the lowest cost and the clearest accountability.

Retrieval should be added when the failure is knowledge-related: outdated content, misalignment with the local syllabus, or the need for citable sources. Retrieval is also the only tier whose content can be audited by non-specialists.

Parameter-efficient adapters are the next step when a well-specified behavioural requirement persists despite good prompts and retrieval. They are justified only when the institution can assemble consented, high-quality exemplar data and run local evaluation.

Preference-based pedagogical training is best left to developers. Institutions retain the role of informed purchasers who require evidence of learning, not of fluency.

Combinations are the norm rather than the exception. A typical mature deployment uses a pedagogically tuned model, a structured system prompt and a curriculum retrieval layer. Some institutions also distribute these functions across specialised agents, which multiplies both the affordances and the error pathways (see Q343).

The higher tiers also concentrate power and opacity. Adapters and reward models encode pedagogical choices in weights that teachers cannot read. Prompts and document stores remain legible. Reviews of AI in higher education bear on this. Adamakis and Rachiotis (2025) emphasise pedagogical integrity, AI literacy and policy integration. Espinoza-Celi and Vargas-Saritama (2026) synthesised evidence on technical and pedagogical limitations in undergraduate English-as-a-foreign-language instruction and examined how the two kinds of limitation co-occur across studies. That co-occurrence framing is a reminder that technical choices and pedagogical shortcomings are entangled. Escalating the technique does not by itself resolve the second kind.

The evidence does not yet show which tier yields the largest learning gains per unit of cost. The efficiency of LoRA and QLoRA is well documented. RAG's knowledge benefits are well motivated. Behavioural alignment through human feedback has been demonstrated for general helpfulness. Comparative trials measuring student learning across these tiers, in comparable

settings, are scarce. Until they exist, the hierarchy is best read as a guide to cost, control and governance, and not as a ranking of educational effectiveness.

Q341 How can neuro-symbolic architectures combine Bayesian or Deep Knowledge Tracing (BKT/DKT) and formal domain graphs with LLM natural-language interfaces to build verifiable Intelligent Tutoring Systems (ITS)?

15 citations · 15 sources · 4 cross-references

Claim 1 disputed

Neuro-symbolic architectures can produce verifiable intelligent tutoring systems by giving each component a bounded role. A formal domain graph encodes what is correct in the subject and which concepts depend on which. A knowledge-tracing model, Bayesian or deep, estimates

what a particular learner probably knows. A large language model translates between the learner's natural language and these structured representations, and every pedagogically consequential output it produces is checked against the symbolic layer before it reaches the student. Verifiability therefore does not reside in the language model, whose outputs remain probabilistic. It resides in an architecture in which the language model proposes and the symbolic components dispose. A hint, a mastery claim or a decision to advance is acceptable only when it can be traced to a node in the domain graph and to an inspectable state in the learner model.

The case for building on this inheritance rather than replacing it with conversational agents rests partly on what classical tutoring systems have achieved. Kulik and Fletcher's (2016) meta-analysis of 50 controlled evaluations found a median effect of 0.66 standard deviations over conventional instruction, equivalent to moving a student from the 50th to the 75th percentile. They also reported that the size of the improvement depended heavily on whether outcomes were measured with locally developed or standardized tests, which suggests that alignment between assessment and instructional objectives is a critical determinant of measured success. That caveat matters for hybrid designs, because a system that cannot state precisely which objectives it is teaching cannot be properly evaluated against them.

The broader rationale comes from neurosymbolic AI itself. Garcez and Lamb (2023) frame the field as a third wave that responds to concerns about trust, safety, interpretability and accountability by integrating well-founded knowledge representation and reasoning with deep learning. Bougzime and colleagues (2026) similarly argue that combining neural processing of unstructured data with symbolic reasoning can improve generalization, reasoning and transparency while addressing interpretability and data efficiency. Tutoring is an unusually clean fit for this argument. Student utterances are unstructured and suit neural interpretation, whereas curricula, prerequisite relations and correctness conditions are structured and suit symbolic reasoning.

The learner model is where the two traditions of knowledge tracing pull in opposite directions, and an honest architecture has to choose deliberately between them. Bayesian Knowledge Tracing represents each skill as a latent binary state updated from observed responses. Its parameters are few and readable, so a teacher or auditor can ask why the system believes a student has mastered a skill and receive an answer in terms of observed evidence. Piech and colleagues (2015) introduced Deep Knowledge Tracing by applying recurrent neural networks

to student interaction sequences. They emphasised that such models do not require explicit encoding of human domain knowledge and can capture more complex representations of student knowledge. For a verifiable tutor, both features cut both ways. Freedom from hand-coded structure reduces expert labour, but it severs the link between the model's internal state and the curriculum's named concepts. That link is precisely what a verification layer needs.

Recent work suggests the dichotomy can be softened rather than resolved. Salomons and Scassellati (2024) extended Bayesian tracing to settings where tasks lack a single correct answer and observations are ambiguous, modelling user skills over time rather than updating only upon task completion. This extension matters for language-model interfaces, because a free-text explanation or a partially correct multistep solution is exactly the kind of ambiguous observation that classical BKT handles poorly. Hooshyar, Azevedo and Yang (2024) approach the problem from the neural side. They identify three practical limits of artificial neural networks in education: the difficulty of incorporating symbolic educational knowledge such as causal relationships and practitioners' knowledge, a propensity to learn and reflect biases, and a lack of interpretability. Their response is to augment deep networks with symbolic educational knowledge. Feng, Si and Feng (2026) go further with a framework that embeds symbolic logic rules in the policy-gradient optimisation of a reinforcement-learning tutor, so that decision chains adhere to educational logic. A path-alignment mechanism links these logical paths to diffusion-modelled reconstructions of knowledge evolution.

These proposals indicate a design direction, not a settled consensus. Whether symbolic constraints preserve the predictive advantages that motivated deep tracing, or trade them for interpretability, remains unclear from the evidence available. Practitioners should treat claims of simultaneous gains in accuracy and transparency as hypotheses to test.

The formal domain graph is the component that makes verification possible at all, because it supplies the reference against which neural outputs are judged. In tutoring, the graph typically encodes concepts, prerequisite relations, misconceptions, worked procedures and the mapping from exercises to skills. Confalonieri and Guizzardi (2025) distinguish three roles that ontologies can play in producing intelligible explanations in neuro-symbolic systems. In reference modelling, the ontology fixes the meaning of terms. In common-sense reasoning, it licenses inferences that pure pattern-matching cannot guarantee. In knowledge refinement and complexity management, it organises and corrects what the system knows. Each role maps onto a tutoring function. Reference modelling ensures that "fraction equivalence" denotes the same

thing in the curriculum, the learner model and the language model's prompt. Reasoning over prerequisites allows the system to infer that repeated failure on a target skill may reflect an unmastered antecedent. Refinement allows teachers and designers to correct the graph when classroom evidence contradicts it.

Evidence that such graphs can be integrated with large language models in education is accumulating, though largely at the level of surveys and prototypes. Ben Chaabene and Hammami (2026) surveyed approaches integrating LLMs and knowledge graphs in education across Scopus, IEEE Xplore and SpringerLink for the period 2020 to 2024. Their dual focus was explainable reasoning and emotion-aware student support, and their aim was to assess how neuro-symbolic architectures and affective computing contribute to transparency and learner well-being. Their framing treats the knowledge graph as the explainability anchor, with the language model as the conversational surface.

Adjacent domains offer instructive analogues without being direct evidence. Viktor and Kiss (2026) reviewed 47 peer-reviewed studies, published between January 2018 and January 2026, on knowledge-graph reasoning in autonomous driving. There, graphs integrate heterogeneous sensor data, traffic regulations and domain knowledge into unified semantic frameworks. The structural parallel is close: regulations play the role that curricular standards play in education, as explicit constraints that a learned perception or language component must respect. The analogy also shows what education has not yet built. Few educational knowledge graphs are maintained with the formality and versioning that safety-critical domains demand, and an unverified graph offers little protection, since verification against it only confirms consistency with whatever errors it contains.

The language model's role in a verifiable tutor is best understood as two narrow translation functions, not as the tutor itself. On the input side, it parses a student's free-text answer, spoken explanation or partial derivation into a structured observation: which skill was exercised, whether the response was correct, and which misconception, if any, it exhibits. That observation then updates the knowledge-tracing model. On the output side, a symbolic policy selects the next instructional move, such as a hint, a prerequisite review or an advance to a new node, and the language model renders that move in accessible, context-sensitive language. Between these two functions sit the checks. Is the parsed skill a real node in the graph? Is the proposed hint consistent with the stored solution path? Does any claim about the learner's progress correspond to the tracer's current estimate?

De Boer and colleagues (2025) provide a vocabulary for such designs. They observe that neuro-symbolic systems employing LLMs can make explicit use of expert knowledge and can be inspected by humans, but that the growing variety of approaches makes it difficult to compare how they are designed, trained, fine-tuned and applied. They propose design patterns to address this. A tutoring architecture of the kind described here combines patterns in which the LLM acts as a parser feeding a symbolic reasoner with patterns in which the LLM generates from symbolic content. Bougzime and colleagues (2026) likewise work toward formalising neuro-symbolic architectures and evaluating them in relation to generative AI. That formalisation should eventually let tutoring designs be compared on shared terms, not described idiosyncratically.

The parser function is the weakest link, and it deserves more attention than it receives. If the language model misclassifies a student's reasoning, the error enters the learner model as apparently clean evidence and propagates into subsequent instructional decisions, with no symbolic check able to detect it, because the observation is well formed. Where correctness is formally decidable, as in arithmetic or algebraic manipulation, the parser can be backed by external solvers (see Q347). Where it is not, the architecture inherits the language model's interpretive uncertainty, and that uncertainty should be represented explicitly, for example as a probabilistic observation, not hidden. Grounding the output side in teacher-specific materials raises its own retrieval failures (see Q339). Splitting parsing, policy and rendering across separate agents can compound errors in ways a single verified pipeline avoids (see Q343). Sinha and colleagues (2026) also note that developers face a steep learning curve, a lack of user-friendly tools and libraries, and an absence of unifying frameworks, practical barriers that help explain why educational deployments remain rare.

"Verifiable" needs a precise meaning, because the term is easily inflated. In this architecture it can legitimately mean four things. Every instructional move corresponds to an explicit node and relation in an inspectable domain graph. Every mastery estimate can be traced to the sequence of observations that produced it. Generated text can be automatically checked for consistency with the symbolic content it was meant to express. Teachers can audit, contest and correct any of these layers. It does not mean that the system's pedagogy has been proven effective, that its parsing of student language is reliable, or that its domain graph is correct. Conflating these senses is the most common rhetorical failure in this area.

Work on explainability in neuro-symbolic AI clarifies what the architecture can offer human users. Mileo (2025) argues for a neuro-symbolic cycle oriented toward human-centred explainability, motivated by the difficulty experts face in understanding black-box deep models in high-stakes interpretation tasks such as medical imaging. Tutoring is lower-stakes per decision but high-stakes in aggregate, and the same logic applies. Teachers will not delegate placement or remediation to a system whose reasoning they cannot follow. Michel-Delétie and Sarker (2026), reviewing recent work at leading conferences, conclude that neuro-symbolic methods have shown considerable potential for some aspects of trustworthiness, particularly interpretability. Their wording is a useful corrective: the potential is partial and concentrated, not general. Wang and Qin (2026) illustrate the clinical analogue, proposing an explainable neuro-symbolic framework for interpreting corneal topography and assessing surgical eligibility, motivated by the limited interpretability of black-box ophthalmic models. A tutor that recommends holding a student back from advanced content makes a structurally similar eligibility judgement and owes a comparable explanation.

Garcez and Lamb (2023) tie the demand for sound explainability to accountability. In education, accountability flows to teachers, families and institutions, and the symbolic layer is what makes a tutor's behaviour answerable to them.

The evidence base for this hybrid design is uneven, and its gaps should shape both research and procurement. The effectiveness of classical intelligent tutoring is well documented, with Kulik and Fletcher's (2016) synthesis as the reference point, together with their warning that measured gains depend on alignment between tests and objectives. The interpretive power of language models and the explanatory value of symbolic structure are each supported by their own literatures. What remains unclear is whether adding a language-model interface to a graph-and-tracer core preserves the learning gains of classical systems, improves on them through richer dialogue, or erodes them through parsing errors and learner over-reliance on fluent text. The educational neuro-symbolic proposals examined here, from Hooshyar and colleagues (2024), Feng and colleagues (2026) and the systems surveyed by Ben Chaabene and Hammami (2026), are framed chiefly around interpretability, trustworthiness and transparency. They do not establish that hybrid tutors produce greater learning than their components alone. Static benchmark performance is a poor proxy for such gains (see Q346).

The deep-versus-Bayesian question also remains open. Piech and colleagues (2015) presented freedom from explicit domain encoding as an advantage, whereas the verification argument

treats explicit encoding as indispensable. The likely resolution is architectural rather than doctrinal. Deep models may serve as auxiliary predictors whose outputs are reconciled with, and constrained by, an interpretable tracer tied to the domain graph, along the lines that symbolic augmentation work suggests. Whether such reconciliation sacrifices predictive accuracy has not been settled. The tooling problems Sinha and colleagues (2026) identify mean that comparative evaluations remain expensive to run.

For the field, the defensible position is that neuro-symbolic architectures offer the most credible current route to tutoring systems whose behaviour can be inspected, contested and corrected. They achieve this by confining language models to translation and holding pedagogical authority in explicit graphs and learner models. That claim concerns accountability, not efficacy. Establishing efficacy will require controlled evaluations that report learning on both locally aligned and standardized measures, that isolate the contribution of the language-model interface, and that audit parsing accuracy as rigorously as knowledge-tracing accuracy has been audited.

Q342 How do native multimodal foundation models process handwritten math equations, student lab diagrams, spoken reading fluency, and classroom video—and what are their spatial-reasoning failure modes?

11 citations · 11 sources · 6 cross-references

Claim 1 emerging

Native multimodal foundation models process handwritten equations, lab diagrams, read-aloud audio and classroom video by converting each signal into sequences of learned embeddings. A transformer then attends over these embeddings alongside text. The model therefore 'reads' a student's work statistically rather than geometrically, and its most consequential failures arise wherever meaning depends on precise spatial relations: an exponent's height, an arrow's direction, the depth of a vector, or which of several speakers is pointing at which object.

Understanding why requires a brief account of the mechanics. In the dominant designs, an image is cut into small patches, and each patch is mapped by a vision encoder to a vector that is projected into the same representational space as word tokens. Audio is typically framed as short spectral windows and encoded in a parallel way. Video is usually reduced to a sample of frames, each treated as an image, sometimes with audio tokens interleaved. The language backbone then treats all of these as one long sequence. Positional information survives only as learned encodings attached to tokens, not as an explicit coordinate system.

Claman and Sezgin (2024) describe the defining appeal of this generation of systems as the capacity to combine multiple types of data, such as text, images and audio, within a single model. Tarhini, Dave and El Naqa (2025) characterise foundation models as general tools adaptable to many tasks from diverse inputs, trained on massive data. That versatility is precisely what makes them attractive to schools, which generate exactly this heterogeneous mix of evidence. It is also the root of the problem. A model optimised to produce plausible continuations across many modalities has no built-in guarantee of geometric fidelity in any one of them. The broader pedagogical promise of voice and vision across subjects is treated elsewhere (see Q095). The concern here is the machinery and where it breaks.

Handwritten mathematics is the clearest test of whether patch-based perception can recover two-dimensional symbolic structure. A typeset or handwritten equation is not a string. It is a layout in which vertical offset distinguishes a superscript from a coefficient, a horizontal bar governs which terms are numerator and denominator, and the extent of a radical sign determines scope. When a page is divided into patches, a small exponent or a decimal point may occupy a fraction of a single patch. If the student's handwriting is cramped, a stroke may fall across patch boundaries. The model must then infer structure from co-occurrence statistics learned in training, and it usually does so fluently. The errors are not random noise. They are confident, well-formed misreadings in which, for example, a squared term becomes a doubled term and the subsequent algebra proceeds impeccably from the wrong premise.

The benchmark evidence supports the general diagnosis, though not the specific mechanism. In introducing MathVista, Lu and colleagues (2023) assembled 6,141 examples drawn from 28 existing multimodal mathematics datasets and three newly created ones. They reported that the tasks require fine-grained, deep visual understanding and compositional reasoning, which all state-of-the-art foundation models found challenging. The pairing matters for education: perceptual precision and multi-step reasoning are not separable in mathematics, so a small perceptual slip propagates through every later step.

Applied work is beginning to exploit these capabilities while confronting their limits. Lim, Le and Chanoudam (2026) propose and evaluate a tool that uses large vision models to convert students' handwritten three-dimensional vector equations into interactive 3D graphical representations, aiming to bridge symbolic notation and geometric intuition. The design is instructive because it chains two spatial operations: reading a two-dimensional handwritten layout, then rendering a three-dimensional object. An error at the first stage becomes a vivid, persuasive, and wrong picture at the second. Cvengros and Kortemeyer (2026) took on a harder setting. They uploaded handwritten general chemistry exam pages and rubrics as images to cover reaction equations, symbolic derivations, numerical answers, and pencil drawing and sketching. They then compared AI-assigned scores with human grading across question types.

The value of such studies lies less in a headline agreement figure than in disaggregation by item type. Freehand sketches and structured symbolic answers stress perception very differently. A practical corollary is architectural. Once an expression has been transcribed, its evaluation should be delegated to symbolic tools rather than left to the model (see Q347). Delegation, however, cannot repair a transcription that was wrong in the first place.

Student lab diagrams and scientific figures pose a related but distinct difficulty. Here meaning is carried by topology and relative position: which component connects to which, whether an arrow points into or out of a system, how a graph's axes are scaled, and where a label sits relative to the feature it names. Yue and colleagues (2023) built MMMU from 11.5K questions taken from college exams, quizzes and textbooks across 30 subjects and 183 subfields. The questions span 30 highly heterogeneous image types, including charts, diagrams, maps, tables, music sheets and chemical structures, and are designed to demand deliberate reasoning grounded in subject knowledge.

The heterogeneity is the point. A model that handles bar charts well may handle circuit schematics or chemical structures poorly, because each image type encodes spatial meaning by different conventions. Aggregate scores conceal this variation, which is why the gap between benchmark success and classroom usefulness deserves separate scrutiny (see Q346).

Such variation is visible in evaluation work from professional education, where image-dependent items are routine. Al-Haj Ali (2026) compared Claude-3.5-Sonnet, Gemini-1.5-Pro and GPT-4o with a retrospective cohort of 48 students on 80 practical examination questions. These were divided evenly between visually supported multiple-choice and fill-in-the-blank formats, and the study explicitly examined how question characteristics shape performance. A companion study by Al-Haj Ali and Farah (2026) went further. It argued that accuracy alone cannot characterise how models engage with assessment tasks, and it profiled self-rated workload from ten multimodal models across three providers against twenty students on 70 items. Those items spanned plain multiple-choice, visual short-answer, visual multiple-choice and visual true/false formats.

Both designs treat the visual component and the response format as variables rather than background. That is the right methodological instinct for diagrams. A multiple-choice option list can let a model recover from imperfect perception by elimination, whereas an open response exposes it. The workload approach is more speculative. Whether a model's self-reported 'effort' corresponds to anything in its internal processing remains unclear, and such ratings should not be read as introspective evidence of difficulty. Still, the shift away from single accuracy figures reflects a growing recognition that visual items fail in item-specific ways.

Spoken reading fluency exposes a different failure surface, and here the evidence base is markedly thinner than for images. Fluency assessment depends on accuracy, rate and prosody: how many words a child reads correctly, how quickly, and with what phrasing and expression. A native multimodal model ingesting raw audio can, in principle, attend to all three. A cascaded system that first transcribes speech and then passes text to a language model typically discards timing, hesitation and intonation before any judgement is made.

The tendency of speech recognisers to normalise disfluencies is a particular hazard. A self-correction, a sounded-out word or a long pause is exactly the evidence a teacher needs, and it is exactly what a system trained toward clean transcripts tends to erase. Claman and Sezgin (2024) list audio among the data types foundation models now combine. Capability claims of this kind, however, are not validation of fluency measurement.

The major multimodal reasoning benchmarks discussed above, MMMU and MathVista, are image-and-text instruments. They offer no evidence about whether models score oral reading reliably across ages, dialects, accents or speech differences. Whether native audio models outperform cascaded pipelines on prosodic judgement in children's read-aloud speech therefore remains unclear. So does the question of whether any such advantage holds for multilingual learners and children with speech-sound disorders. The risk is not symmetrical. A system that systematically under-scores a dialect group would misclassify children as struggling readers, with consequences for placement and intervention. Responsibility for such errors is a question the book addresses directly (see Q011).

Audio is not spatial in the visual sense, but fluency assessment shares the structural weakness identified for equations: meaning resides in fine-grained relational detail, here temporal rather than geometric, that tokenisation can blur. Borazjani and colleagues (2025) observe that deploying multimodal, multi-task foundation models in education is hindered by privacy regulation, data silos and limited domain-specific data. Recordings of children reading aloud are an acute instance of all three, which helps explain why validation evidence is scarce.

Classroom video compounds every difficulty above and adds one of its own: time. To analyse a lesson, a model must track multiple people across frames, link speech to speakers, and interpret gestures toward boards, apparatus or peers' work. It must also recognise events that may last only seconds. Because most systems sample a limited number of frames, brief but pedagogically decisive moments can fall between samples entirely, such as a student's hand

going up, a demonstration going wrong, or a glance at a neighbour's paper. Spatial reasoning in video is therefore spatio-temporal reasoning. Errors include misattributing an utterance to the wrong student, confusing left and right from a moving camera, and inferring engagement from posture in ways that encode cultural assumptions about what attention looks like.

Direct evaluations of foundation models on authentic classroom footage are scarce in the work reviewed here. The closest technical analogue comes from clinical informatics, where Tang, Tang and Wu (2025) note that traditional systems struggle to capture complex temporal and semantic relationships in clinical data. They respond with symbolic representations, temporally evolving graphs and ontology-guided refinement to make latent spaces interpretable. The transfer to classrooms is only by analogy. Still, the design lesson is plausible: explicit structured representations of who did what, when and where may be needed to compensate for the weak temporal grounding of end-to-end models.

Video also raises governance problems out of proportion to its analytic yield. Footage captures minors, bystanders and identifiable faces and voices. Borazjani and colleagues (2025) propose federated training of multimodal, multi-task models across institutions so that raw data need not be pooled. This is a privacy-preserving paradigm whose educational effectiveness has yet to be demonstrated at scale. Local processing on school hardware offers a complementary route (see Q344), though smaller models typically sacrifice exactly the visual resolution on which spatial accuracy depends.

Finally, multimodal artefacts increasingly originate with students themselves. Jiang and Lai (2025) compared 14 generative-AI-assisted and 10 non-assisted digital multimodal composing groups across four English classrooms. Systems that analyse classroom media may thus encounter material partly produced by other models, a feedback loop whose effects on interpretation have barely been considered.

Drawing these strands together, the spatial-reasoning failure modes of native multimodal models in education fall into four recurring patterns.

The first is resolution loss. Small but decisive marks such as exponents, subscripts, decimal points, charge signs and arrowheads are degraded by patching and downsampling, especially in photographed handwriting. The second is relational misbinding. The model perceives the right elements but attaches them wrongly: a label to the wrong feature, a term to the wrong side of a fraction bar, a speaker to the wrong face. The third is dimensional collapse. Depth, orientation

and three-dimensional relations are inferred from flat images without an internal geometric model, which is why tools that render vectors in 3D, such as the one evaluated by Lim, Le and Chanoudam (2026), are both promising and exposed. The fourth is temporal sparsity. In audio and video, sampling and normalisation erase the pauses, corrections and brief events that carry instructional meaning.

Across all four, the defining danger for education is fluency. The models rarely signal uncertainty in proportion to perceptual difficulty, so a misread diagram yields an articulate, internally consistent, wrong explanation.

The evidence supports some of these claims more firmly than others. That fine-grained visual understanding combined with compositional reasoning remains challenging is reasonably well established by MathVista (Lu et al., 2023). The heterogeneity of image types in MMMU (Yue et al., 2023) gives good grounds to expect uneven performance across diagram genres. That performance depends on item format and visual load is suggested by examination studies (Al-Haj Ali, 2026; Al-Haj Ali and Farah, 2026), though their settings are specialised and their generalisability to school science is untested. Whether AI grading of handwritten work can match human reliability across item types is under active investigation (Cvengros and Kortemeyer, 2026). The answer will likely differ for sketches and for symbolic derivations. For reading fluency and classroom video, the evidence is thin enough that strong claims in either direction are unwarranted.

Several practical implications follow for designers and institutions. Perception and reasoning should be separated wherever possible: have the model produce an explicit transcription or structured description of the student's work, show it to the student or teacher, and only then reason over it, so that perceptual errors become visible and correctable. Validation should be disaggregated by modality, item type and student population rather than reported as a single agreement figure. The same calibration discipline applied to automated rubric scoring is needed here (see Q345). High-stakes decisions about reading placement, exam grades or behavioural judgements from video should not rest on unverified model perception.

What the field most lacks is evaluation on authentic classroom inputs rather than curated benchmark images. Such inputs include messy photographs of exercise books, children's read-aloud recordings in many accents, and lesson footage with occluded views, gathered under governance arrangements that communities can trust.

Q343 What are the pedagogical affordances and compounding-error risks of multi-agent educational workflows (e.g., orchestrating a Socratic Tutor Agent, a Peer-Simulator Agent, a Rubric-Critic Agent, and a Safety-Monitor Agent)?

14 citations · 14 sources · 6 cross-references

Claim 1 disputed

Multi-agent educational workflows offer one real affordance: they can split pedagogical functions that a single model handles poorly at the same time. Withholding answers, simulating a fallible peer, applying a rubric and screening for harm are different jobs, and separate agents can each be given one of them. The same architecture creates a distinctive risk. Errors made by one agent become inputs to the next, so they can be ratified, amplified or hidden as they pass

along the chain, and the evidence that orchestration improves outcomes is weaker than the enthusiasm for it. Cemri and colleagues (2025) open their study of multi-agent large language model systems by observing that performance gains on popular benchmarks are often minimal. They respond by building MAST-Data, a dataset of more than 1,600 annotated execution traces collected across seven popular frameworks, together with the first taxonomy of multi-agent system failures. Their starting premise is that these systems fail in patterned, classifiable ways. Designers of educational systems should take that premise seriously before assembling a Socratic Tutor Agent, a Peer-Simulator Agent, a Rubric-Critic Agent and a Safety-Monitor Agent into one pipeline.

The technical basis for such pipelines is now widely available. Wu and colleagues (2023) describe AutoGen, an open-source framework in which customizable, conversable agents combine language models, human inputs and tools. Developers define interaction patterns in either natural language or code, and the framework is presented as generic infrastructure for applications of varying complexity. That generality cuts both ways for education. Nothing in the framework knows what a Socratic move is, when a simulated peer should err, or which rubric criterion governs a given task. Pedagogy has to be supplied entirely by the designer, through role prompts, conversation topology and the conditions under which control passes from one agent to another. The weakest link is therefore usually the orchestration specification rather than the underlying model.

The pedagogical case for role separation rests on a tension that single-agent tutors handle badly. A model tuned to be helpful tends to resolve a learner's difficulty, whereas Socratic tutoring requires deliberately leaving the difficulty productively unresolved. The broader question of which pedagogical models AI makes feasible at scale is treated elsewhere (see Q023). Here the point is architectural. If questioning is assigned to a dedicated agent whose instructions forbid answer disclosure, and answer-checking to a separate critic, each set of instructions can stay simpler and harder to erode over a long dialogue than one prompt asked to do both. A Peer-Simulator Agent adds something tutors rarely provide: a partner whose reasoning the learner is invited to evaluate rather than accept. Such a partner might voice a plausible misconception, propose an alternative strategy or ask for clarification.

Recent reviews give this ambition some context, though not direct confirmation. Abedin, Hayajneh and Raahemi (2026) synthesized 30 peer-reviewed studies from 2019 to 2025. Among the opportunities they identify are tailored and adaptive education, the deliberate

fostering of critical thinking, and collaborative methods that treat AI as a co-teacher. Jansone and Cīrule (2026) reviewed 46 publications from 2020 to 2025 under PRISMA 2020. They frame AI-driven pedagogical agents as a response to the lack of personalization and immediate feedback in traditional e-learning, and as providing adaptive, data-driven experiences beyond rule-based systems. Both reviews concern AI agents in general, not orchestrated ensembles. Neither shows that splitting functions across several agents outperforms a well-designed single agent.

Classroom-facing work on human facilitation points the same way while widening the frame. Lee, Cheng and Chan (2026) refine the CRAFT framework (Content–Response–AI&peers–Fusion–reflecT) in a qualitative study of secondary classrooms. The framework places AI alongside human peers inside a teacher-facilitated scaffold for self-directed learning, with learner agency as an explicit aim. Hung and Chuang (2026) use a quasi-experimental design to test whether a human–AI co-teaching model within a 5E instructional framework improves engagement and learning compared with traditional teaching in an English grammar course. Taken together, these studies suggest that the most defensible multi-agent configurations treat the teacher as one of the agents, not as an outside observer of an autonomous machine conversation. AutoGen's explicit support for human inputs within agent conversations makes that design technically straightforward (Wu et al., 2023).

The strongest technical argument for using several agents rather than one comes from work on deliberation between models. Du and colleagues (2023) had multiple language model instances propose and debate their individual responses and reasoning over several rounds before converging on a common final answer. They present this as a way to improve factuality and reasoning, complementary to verification, self-consistency and scratchpad prompting. A Rubric-Critic Agent that challenges a tutor's draft feedback before the learner sees it is one educational application of the idea. A peer simulator that argues with the tutor in front of the learner, demonstrating disagreement and resolution, is another and arguably more pedagogically interesting one.

These two lines of evidence pull in different directions. Du and colleagues report improvement from structured debate, while Cemri and colleagues (2025) start from the observation that multi-agent gains on benchmarks are often minimal. The two findings need not contradict each other. Debate among equivalent instances aimed at a single answer is a narrower, better-controlled arrangement than heterogeneous role-based pipelines with complex handoffs. Still,

an educator cannot assume that a positive debate result carries over to a four-role tutoring system. A second caution follows from the design itself. Debate is built to reach a common answer, and agreement among instances of similar models is not the same as correctness. In education, a confidently agreed misconception may do more harm than a hesitant single response.

A separate research tradition also uses the term multi-agent, and it should not be confused with orchestration of language models. Multi-agent reinforcement learning trains policies through interaction. Examples include Ma and Liu's (2026) model for collaborative skill transfer in physical education, which integrates video, skeleton and kinematic streams; the biometric dimensions of such work are addressed elsewhere (see Q326). Coordination research in this tradition still offers conceptual lessons. Rother and colleagues (2025) study ad hoc teamwork, in which agents must cooperate without prior coordination or communication, and they note that many approaches struggle in open environments where settings change during deployment. Bredell, Engelbrecht and Schoeman (2025) show that Hanabi tests cooperation under partial observability and limited communication. They argue that conventions added to the action space can improve cooperation without the computational cost of complex architectures. Liu and colleagues (2026) incorporate suboptimal human knowledge into large-population learning in the spirit of human-on-the-loop control. Dasgupta and Musolesi (2025) examine how direct punishment shapes whether cooperation emerges. None of these studies involves classrooms or language models. What they offer is a coherent hypothesis: agents that see only part of the learner state and communicate through thin channels coordinate better when explicit conventions govern their exchanges, and educational orchestration likely needs the equivalent in the form of typed handoffs and shared learner-state records.

Compounding error is the central risk, and it takes recognizable forms in educational pipelines. The failure taxonomy of Cemri and colleagues (2025) was built from general-purpose frameworks, not tutoring systems, but its premise that failures cluster into identifiable patterns transfers directly. Consider the four-agent system in the question. If the Socratic Tutor misdiagnoses the learner's error, the Peer-Simulator may build its staged misconception on that wrong diagnosis. The Rubric-Critic may then score the learner's response against criteria that never applied, and the Safety-Monitor, tuned for harmful content, has no reason to flag a pedagogically wrong but inoffensive exchange. Each agent behaves correctly given its input,

yet the system as a whole teaches badly. The four agents are not independent checks. They share upstream context and often a common underlying model, so their errors are correlated.

A second family of risks involves role conflict and erosion. A Peer-Simulator told to make errors can be mistaken for an authority, especially by younger or less confident learners. A Tutor told to withhold answers can be undercut when a Critic agent explains the solution while justifying a score. A Safety-Monitor with authority to interrupt can cut off a productive struggle it misreads as distress. Conflicts of this kind are coordination failures, and they become more likely as conversation topologies grow more flexible, which is the very property frameworks such as AutoGen are designed to provide (Wu et al., 2023). Arithmetic and symbolic errors present a particular case. A critic that is itself a language model cannot reliably catch a computational mistake made by the tutor. Delegating such checks to deterministic tools, discussed elsewhere (see Q347), is therefore better treated as a precondition for any rubric-critic role in STEM subjects than as an optional enhancement.

The Rubric-Critic Agent deserves separate scrutiny because its outputs drift easily from formative feedback into consequential judgment. Tolsgaard and colleagues (2026) observe a paradox in medical education. AI used in clinical care faces formal scrutiny for safety, performance and monitoring, whereas AI used to generate, score and interpret assessments informing learner progression is adopted in a largely unregulated environment. They also argue that existing validity frameworks remain useful but may not fully account for AI-specific threats. Multi-agent pipelines add a threat that frameworks built around single scorers seldom anticipate. The evidence behind a score is shaped by what the other agents elicited, so the construct being measured partly reflects the orchestration. A learner who received more Socratic prompting, or was matched with a more error-prone simulated peer, produces a different performance sample. The comparison of LLM rubric scoring with psychometric automated essay scoring, and the case for human calibration, is developed elsewhere (see Q345). The multi-agent point is that calibration must cover the whole elicitation chain, not only the final scoring agent.

Equity concerns also grow with architectural complexity. Autenrieth, Schluchter and Schulz (2026) argue conceptually that exclusion in AI-mediated education arises not only from unequal access or skills but also from differential capacities to perceive, interpret and mobilize AI-mediated affordances. They name these an AI divide and an ability divide, and they link them to techno-ableist design. A system with several voices, each playing a distinct role and

some deliberately unreliable, places heavy demands on exactly these interpretive capacities. A learner who cannot tell the fallible peer from the authoritative tutor gains nothing from the peer and may be misled. Abedin and colleagues (2026) likewise pair the opportunities they identify with challenges, which is a reminder that the benefits of generative AI are not evenly distributed. Role legibility, meaning clear and consistent signals of which agent is speaking and how far it should be trusted, is consequently an equity requirement as well as a usability feature.

Present evidence supports a cautious set of design commitments, while the broader case remains unsettled. Learner state should live in a single authoritative record that every agent reads and writes through defined fields, instead of being reconstructed from conversation history. Handoffs should follow explicit conventions, in line with the coordination findings from reinforcement learning (Bredell et al., 2025; Rother et al., 2025). Verification should rely on deterministic tools wherever the domain allows. Each agent's trace should be logged so that a failure can be attributed to a specific role, the analytic stance that the failure taxonomy of Cemri and colleagues (2025) makes possible. Teachers should have defined points at which they can intervene, as both co-teaching and scaffolding research suggest (Hung & Chuang, 2026; Lee et al., 2026). Whether an institution should build role behavior through prompting, retrieval or fine-tuning is addressed elsewhere (see Q340).

The evidence does not yet show several things. Few studies have compared orchestrated multi-agent tutors against strong single-agent baselines on measured learning, as opposed to benchmark accuracy or engagement. It remains unclear whether simulated peers produce the cognitive benefits associated with human peer interaction, or whether learners discount them as mere machinery. The debate literature reports improved factuality (Du et al., 2023), but how this relates to the minimal benchmark gains noted for multi-agent systems more generally (Cemri et al., 2025) is unresolved for educational tasks. No validity framework has yet been worked out for scores produced inside multi-agent elicitation chains (Tolsgaard et al., 2026). Evaluating these questions properly requires pedagogical benchmarks rather than static ones, a distinction developed elsewhere (see Q346). Until that evidence exists, multi-agent orchestration is best regarded as a promising way to separate pedagogical functions whose reliability has not yet been demonstrated.

Q344 How do quantized Small Language Models (SLMs, 1B–8B parameters) running locally on school hardware or edge servers solve student data-privacy, recurring API cost, and offline equity challenges?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

Quantized small language models address the three problems by relocating inference. When a model of roughly one to eight billion parameters is compressed enough to run on a classroom laptop, a school server or a regional edge box, student prompts need not leave institutional control. Per-query fees to a commercial provider give way to a largely fixed hardware cost. Once the model weights are on site, the system keeps working when internet connectivity is poor or absent. That is the architectural promise. The evidence base supporting it is uneven, however. The engineering claims are well grounded in the compression literature. The educational claims rest mainly on conceptual analysis rather than deployment studies.

The framing has been articulated most directly for primary schooling. Zulfiqar and Iqbal (2026) argue that cloud-dependent large language models raise significant concerns about student data privacy, institutional governance and the affordability of AI infrastructure. They present locally hosted small models as an alternative, but their contribution is explicitly a conceptual analysis rather than an evaluation of outcomes. The compression researchers make the same infrastructural case from the engineering side. Lin and colleagues (2023) state as a design motivation that running models locally on edge devices can reduce cloud computing cost and protect users' privacy. The convergence of these two literatures is real. It is a convergence of rationale, though, not yet of classroom evidence. The rest of this essay separates what the mechanics demonstrate from what remains a plausible but untested educational inference.

Two technical developments make local deployment feasible. The first is the small, capable base model. Abdin and colleagues (2024) report that phi-3-mini, a 3.8 billion parameter model trained on 3.3 trillion tokens, reaches 69% on MMLU and 8.38 on MT-bench. They say its performance rivals models such as Mixtral 8x7B and GPT-3.5, while it remains small enough to deploy on a phone. They attribute this capability to the training data, a scaled-up version of the phi-2 dataset built from heavily filtered public web data and synthetic data. They also report further alignment for robustness, safety and chat format. The broader lesson is that parameter count is no longer a reliable proxy for usefulness. Careful data curation can move a model that fits on consumer hardware into a performance band that recently required data-centre inference.

The second development is post-training quantization. Model weights are normally stored at sixteen-bit precision. Quantization re-encodes them at much lower bit widths so that memory footprint and bandwidth demands fall roughly in proportion. Frantar and colleagues (2022) frame the problem precisely: even inference for large, highly accurate generative transformers may require multiple performant GPUs, and existing compression techniques struggled with the scale and complexity of such models. Their GPTQ method was designed to quantize these models accurately after training, without the cost of retraining. Lin and colleagues (2023) add a key insight with Activation-aware Weight Quantization (AWQ). Not all weights matter equally, and protecting only 1% of salient weights can greatly reduce quantization error. They also show that salient channels should be identified from the activation distribution rather than from the weights themselves. AWQ is described as a hardware-friendly, low-bit, weight-only approach. This matters for schools, whose hardware is commodity rather than specialised.

These methods compound. A deliberately small model, further compressed with activation-aware or second-order quantization, can fit within the memory of machines a district already owns or can buy cheaply. That much is established engineering. The quality cost of compressing a particular small model for a particular pedagogical task is less settled. Aggregate benchmark retention is not the same as preserving the fine-grained behaviours tutoring depends on, such as withholding answers, diagnosing misconceptions and calibrating explanations. These are exactly the behaviours that standard benchmarks fail to capture (see Q346).

The privacy argument is the strongest of the three, because it follows almost directly from architecture. Suppose a model runs on hardware the school controls, with no outbound call to a third-party endpoint. Then the student's essay draft, the record of a struggling reader's attempts, or a disclosure typed into a chatbot never enters a vendor's logging, retention or training pipeline. Zulfiqar and Iqbal (2026) place student data privacy and institutional governance at the centre of their case for local small models in primary education, where learners are youngest and least able to consent meaningfully. Lin and colleagues (2023) list privacy protection among the reasons on-device inference is becoming increasingly important.

Local hosting, however, changes who holds the data; it does not by itself determine how the data are governed. Khodi and Curle (2026) identify governance opacity, which they connect to data capture, as one of three risks that personalization-first generative AI can amplify in language education when deployed without explicit pedagogical and governance constraints. A locally hosted system can still log every interaction, still profile students, and still be configured by staff with little training in data protection. The threat simply moves from a distant vendor to the school's own server room and its own administrators. In some respects that is preferable, since accountability is closer and more contestable. Yet it places obligations on institutions that many lack the capacity to meet. Raptis and Psyrras (2026), surveying 262 primary school leaders in Greece, examined challenges to AI integration alongside attitudes and self-efficacy. Their study is a reminder that adoption depends on leaders' readiness, not only on the technology on offer.

The defensible claim is therefore conditional. Local small models remove one major category of privacy exposure, the transfer of identifiable student data to external commercial processors. Whether they produce better privacy outcomes overall depends on local logging policies, access controls and update practices. Few studies have yet audited these in real school deployments.

The cost argument concerns the structure of spending as much as its size. Cloud access to large models is typically metered by usage. For a school, that means costs scale with exactly what educators want to encourage: more students asking more questions more often. Local inference converts this variable cost into capital expenditure on hardware, plus electricity, maintenance and staff time. Zulfiqar and Iqbal (2026) frame the affordability of AI infrastructure as a central barrier and present local small models as a response. Lin and colleagues (2023) likewise name reduced cloud computing cost as a motivation for on-device deployment. The energy side of this ledger is treated more fully elsewhere in this volume (see Q251).

The economics also extend to adaptation. A school system that wants a model to follow its curriculum, use its terminology or tutor in a regional language must usually fine-tune it, and fine-tuning has historically demanded substantial memory. Work outside education shows how quantized low-rank adaptation lowers that barrier. Toksoz and Isik (2026) start from the high memory cost of fine-tuning billion-parameter models on edge hardware. Their framework allocates adapter ranks in three tiers (8, 16 and 32) by profiling layer-wise activation norms on a 500-sample calibration set. Their domain is industrial fault classification, so the transfer to education is analogical rather than demonstrated. The underlying technique, however, adapting a quantized base model with small trainable adapters, is what would let a ministry or university consortium customise a small model without data-centre resources.

Two caveats temper the cost case. First, no study among those reviewed here reports a total-cost-of-ownership comparison between local and cloud deployment in schools. The savings remain an inference from pricing structures, not a measured result. Hardware ages, models need updating, and technical support is scarce precisely in under-resourced systems. Second, the capability gap matters economically. If a local model performs worse on a task, the apparent saving may be offset by weaker learning or by teacher time spent correcting outputs. Pairing small models with external tools for calculation and verification can narrow some of that gap (see Q347). That design adds its own engineering burden.

The equity argument is the most frequently invoked and the most contested. In its simplest form it runs as follows. Cloud AI presupposes reliable broadband, so students in rural areas, low-income households and countries with limited infrastructure are excluded. A model that runs offline on a school server or shared device extends access to them. Lopez-Gazpio (2025) supports the aspiration, arguing that LLMs can mitigate traditional barriers related to language diversity, learning disabilities, cultural differences and socioeconomic inequalities, and can

personalise instruction to learners' educational and emotional needs. Kilat (2026) notes that generative AI presents distinctive opportunities and challenges in developing and resource-diverse contexts. Kilat studied higher education English teachers in Cebu, responding to limited empirical evidence from Philippine higher education. Offline capability is the precondition for any of these benefits in places where connectivity cannot be assumed.

Access, however, is not the whole of equity. Autenrieth, Schluchter and Schulz (2026) introduce the concepts of an AI divide and an ability divide. They argue that exclusion emerges not only from unequal access or skills but from differential capacities to perceive, interpret and mobilise AI-mediated affordances. On this reading, placing a quantized model on a rural school's server closes the connectivity gap but may leave the deeper divides untouched, or widen them. This happens if advantaged students use the tool to extend their learning while others use it to bypass learning. The same authors' attention to techno-ableist design is a caution against assuming that a smaller, cheaper model will be accessible to learners with disabilities simply because it is local.

There is also a capability asymmetry that equity advocates rarely confront. If well-resourced schools use frontier cloud models while poorly resourced schools receive compressed small models, offline deployment could institutionalise a two-tier system. In that system, students already disadvantaged would systematically receive weaker AI support. Abdin and colleagues' (2024) results suggest the gap on standard benchmarks has narrowed considerably. Whether it has narrowed on pedagogically meaningful tasks, and for languages and cultural contexts underrepresented in training data, remains unclear (see Q243). Offline local models are thus a necessary but insufficient condition for equitable AI in education. They remove a hard infrastructural barrier, but they cannot by themselves guarantee comparable quality or the capacities students need to benefit.

Taken together, the evidence supports a measured conclusion. Quantized small models solve the three challenges at the level of system architecture. The privacy solution is the most direct, the cost solution is plausible but unmeasured, and the equity solution is partial. The engineering foundation is solid. Abdin and colleagues (2024) demonstrate that a 3.8 billion parameter model can reach benchmark performance comparable to much larger systems. Frantar and colleagues (2022) and Lin and colleagues (2023) establish methods for compressing generative transformers to low bit widths with limited accuracy loss. The educational superstructure is

thinner. The most directly relevant analysis, by Zulfiqar and Iqbal (2026), is conceptual, and the equity and governance literatures identify risks that local hosting alone cannot resolve.

Several questions remain open. There is no evidence here that students learn as much from a compressed local model as from a cloud model on the same task. Nor are there audited accounts of how schools actually govern locally stored interaction logs. Studies tracing whether offline deployment changes who benefits from AI are also absent, as opposed to studies of who gains access. Human factors matter too. Liu and colleagues (2026), surveying 161 bilingual or multilingual generative AI scientists, found the technology generally perceived as useful and acceptable for foreign language education, but not as a replacement for teachers. A local deployment strategy that treats the model as infrastructure supporting teachers is more consistent with that view than one that treats it as a substitute. Instructional restraint and Socratic behaviour must still be engineered into small models, just as for large ones (see Q338). Compression may make that alignment harder to preserve.

The practical recommendation for districts follows from this assessment. Local small models are a sound choice where data sovereignty, predictable budgets and offline operation are binding constraints. They should be adopted with explicit governance of local data and with task-specific evaluation rather than reliance on general benchmarks. Districts should also commit to monitoring whether the students the deployment was meant to reach actually benefit.

Q345 How does automated rubric scoring via LLMs compare with traditional psychometric Automated Essay Scoring (AES), and why is human calibration required to prevent construct-irrelevant length and vocabulary bias?

12 citations · 12 sources · 4 cross-references

Claim 1 disputed

Automated rubric scoring with large language models differs from traditional psychometric Automated Essay Scoring (AES) less in its task than in the source of its scoring knowledge. Classical AES learns a statistical mapping from text features to scores that trained human raters assigned to a specific prompt. An LLM scorer is instead instructed through a rubric written in natural language and draws on general linguistic competence acquired in pretraining. That makes it quick to deploy across new tasks, but it leaves its judgements only loosely tied to the construct the rubric names. Human calibration is required because both families of system can reach respectable agreement with human raters while partly rewarding features that are not the construct, such as sheer length and conspicuous vocabulary. These features correlate with quality in ordinary samples of student writing. Only systematic comparison against carefully scored human anchors, broken down by those very features, can reveal how much of a machine's agreement is borrowed from them.

The field arrives at this comparison with a long practical motivation. Ramesh and Sanampudi (2021), reviewing automated essay scoring systematically, framed the problem as one of scale. Rising student-to-teacher ratios make manual evaluation time-consuming and, by their account, of limited reliability, while computer-based assessment had matured mainly for multiple-choice items rather than essays and short answers. Mughal and colleagues (2026) observe that most AES research has concentrated on predicting scores and that comparatively few studies had

integrated AES with LLMs such as GPT and Gemini. The newer paradigm is therefore still being characterised against an older one whose strengths and failure modes are better documented. Debelak and Ziegler (2026) add a measurement caution that frames everything that follows. Essays do not consist of test items, so the standards used to evaluate scores from classical ability tests and questionnaires do not transfer straightforwardly to scores produced by AI models. Whatever an LLM scorer does, its outputs must still earn the evidential status of a test score.

Traditional AES is best understood as supervised psychometric modelling. A developer assembles a set of essays written to one prompt, has trained raters score them against a rubric, and fits a model that predicts those scores from measurable properties of the text. Historically these properties were engineered counts and indices: essay length, error frequencies, lexical diversity, word rarity and the density of discourse markers. Later systems replaced or supplemented hand-built features with learned neural representations. The validity argument for such systems rests on two pillars. The first is agreement with human scores on held-out essays. The second, for feature-based models, is a degree of inspectability, since one can examine which features carry weight and ask whether they correspond to the construct.

That inspectability is exactly what exposed the classic weakness of the paradigm. In most human-scored samples, longer essays and essays with more sophisticated vocabulary tend to receive higher scores, partly because developed arguments take space and skilled writers command a wider lexicon. A regression model rewarded only for predicting human scores will happily exploit these correlations. The model may then be accurate in aggregate while being construct-irrelevant at the margin. It can over-reward padded but shallow writing, under-reward concise and precise answers, and be gamed by students who learn that more words and rarer words pay. Prompt-specific training also means each new task requires a fresh scored sample, which is the cost that the scale problem identified by Ramesh and Sanampudi (2021) makes painful.

The interpretable architecture of classical AES has not lost its value in the LLM era. Walsh, Suresh and Ivan (2026) deliberately retain a traditional regression layer in their scoring system for the Casper open-response situational judgment test. They argue that pairing it with LLM components yields scoring of complex constructs that is both accurate and interpretable. Their design concedes something important. The transparency of a fitted, human-anchored aggregation model is an asset worth keeping, not a relic to be discarded.

LLM rubric scoring inverts the classical workflow. Instead of learning weights from hundreds of scored essays, the system receives the rubric, perhaps a few exemplars, and the student response, and it generates a score, often with a rationale. Mughal and colleagues (2026) explored GPT and Gemini in this role, positioning LLMs as a response to human grading that is susceptible to fatigue, bias and subjectivity. Mendonça, Quintal and Mendonça (2025) compared an open-source model (LLaMA 3.2) and a premium model (GPT-4o) against human evaluators across diverse question types in a computer programming course, using detailed rubrics to assess alignment between LLM-generated and human-assigned grades. The comparison of open and proprietary models bears directly on whether institutions can score locally on their own infrastructure, a trade-off examined elsewhere in this chapter (see Q344).

The architectural frontier is moving beyond a single model reading a fixed rubric. Johnsi and Kumar (2026) argue that reliance on static rubrics and single-model evaluation may limit scoring consistency and adaptability across topics and writing styles. Their Multi-LLM Self-Reflection Iterative Prompt Methodology combines cooperative assessment by several models with iterative rubric optimisation. Such ensembles promise to average out idiosyncratic model judgements. They also introduce the coordination and error-propagation problems of multi-agent pipelines, particularly when one agent acts as a rubric critic for another (see Q343).

Whether LLM scorers are dependable enough to stand alone is where the literature divides. García-Varela and colleagues (2025) present ChatGPT as a candidate stable and fair scoring tool. Yet they ground their study in the observation that discrepancies between human and automated scoring have raised concerns about the reliability of automated tools as standalone evaluators. They also note that the consistency and fairness of LLM feedback remain underexplored. The evidence therefore suggests that LLMs can approximate rubric-based human judgement in some settings. It does not yet show that this approximation holds across prompts, populations and model versions without ongoing human anchoring. The flexibility that frees LLM scoring from prompt-specific training also frees it from the explicit, human-fitted weights that made classical AES auditable.

Agreement statistics are the main reason length and vocabulary bias can hide in plain sight. Both classical and LLM-based systems are conventionally validated with Quadratic Weighted Kappa or correlation against human scores. Zhou (2026) argues that this tethering to aggregate reliability metrics obscures discrimination and rater effects. He applied Signal Detection Theory to eight state-of-the-art LLMs, including Claude 3.5 Haiku, DeepSeek-V3, Gemini 3

Flash, GPT-4o and Grok 4.1, scored against expert human raters across 1,726 essays. By separating a model's ability to discriminate between quality levels from its response criteria, essentially its leniency or severity at each threshold, the analysis offers a diagnostic view that a single kappa conceals.

The relevance to construct-irrelevant bias is direct. A model can achieve a high kappa because essay quality and essay length are correlated in the validation sample, so a length-sensitive scorer and a quality-sensitive scorer produce similar rank orders. The two diverge only on the essays where length and quality come apart: the long, repetitive response and the short, incisive one. These are precisely the cases that aggregate metrics weight least and that matter most for fairness to individual students. A model whose thresholds drift upward for verbose writing could post respectable overall agreement while systematically misclassifying concise writers near a pass boundary. This is a structural limitation of the metric rather than a demonstrated property of any particular model. The same problem appears elsewhere in this chapter, where headline benchmark scores fail to predict whether a system teaches well (see Q346).

Debelak and Ziegler (2026) extend the concern to the full apparatus of testing standards. Because essays lack an item structure, familiar routes to reliability and validity evidence, such as internal consistency or item-level analysis, are unavailable or need reformulation for AI-generated scores. The implication is that evaluating an LLM scorer requires evidence designed for the purpose. That evidence should include analyses showing that scores track the rubric's construct rather than correlated surface properties, not merely that scores coincide with human totals.

There are plausible reasons to expect LLM scorers to inherit, and possibly amplify, length and vocabulary bias, though the direct evidence is thinner than the concern. Pretraining on vast quantities of edited text teaches models that fluent, elaborated, lexically varied prose is typical of skilled writing. When a rubric asks whether an argument is well developed, a model may treat elaboration and register as evidence of development. Generated rationales can make such judgements look principled even when they rest on surface cues. Whether LLMs are more or less susceptible than feature-based AES is genuinely contested. Their holistic reading may let them see through padding that crude word counts reward. Alternatively, their sensitivity to stylistic sophistication may disadvantage multilingual writers and students who write plainly but correctly. The agreement-focused studies discussed above largely leave this question unresolved, and it remains unclear how large such effects are in practice.

Human calibration is the procedural answer, and it has several components. The first is an anchor set of responses scored independently by trained raters, with disagreements adjudicated. This set should be deliberately stratified so that it contains long weak essays, short strong ones, and plainly worded responses of high quality. The second is residual analysis: once machine and human scores are compared, the discrepancies are regressed on length, lexical rarity and writer subgroup. If residuals rise with word count, the system is rewarding length beyond what humans judged warranted. The third is perturbation testing, in which an essay is padded with redundant sentences or has its vocabulary inflated without changing its argument, and the score should not move. The fourth is recalibration whenever the underlying model, prompt or rubric changes, since an LLM scorer's behaviour is not fixed in the way a fitted regression is.

The hybrid design of Walsh and colleagues (2026) illustrates how calibration can be built into the architecture. LLMs-as-judges extract construct-relevant features from text, and traditional regression aggregates them. The aggregation weights are estimated against human scores and can be inspected, so an institution can see what drives a score and exclude features it judges construct-irrelevant. By contrast, iterative rubric optimisation of the kind Johnsi and Kumar (2026) propose raises a caution. If optimisation targets agreement alone, it may quietly converge on whatever proxies best reproduce human totals, length included. Unless the human reference data are constructed to break those proxies, optimisation alone does not guarantee construct fidelity. García-Varela and colleagues' (2025) attention to fairness points in the same direction. Fairness is a property to be demonstrated against human benchmarks, not assumed from stability.

Calibration is not only a statistical procedure. It is also a claim about where judgement should reside, and emerging classroom evidence suggests that teachers already negotiate this boundary. Wei, Zhang and Zhu (2026) followed thirteen second-language writing teachers over nine weeks, analysing 278 interactions with generative AI and 876 feedback instances. They identified three collaboration modes: embedding, which is human-led; copilot, which is interactive; and agent, which is AI-led. A MANOVA indicated that rubric dimensions significantly influenced how often each mode was used. Teachers, in other words, did not delegate uniformly. Their reliance on AI varied with the dimension being judged, which is the intuition that formal calibration makes systematic.

Rubric application by LLMs outside essay scoring tells a similar story. Drinkwater Gregg and colleagues (2025) used an LLM to apply a previously tested feedback-quality rubric to first-

year engineering students' peer comments, explicitly interrogating the reliability of LLMs for rubric-based qualitative analysis rather than presuming it. Rubrics can also discipline the humans who supervise AI. Bilbao-Quintana and colleagues (2026), working with 195 pre-service teachers, reported significant gains in pedagogical judgement ($t = 35.12$, $p < .001$, with a large effect size) under a model built on cognitive oversight rubrics. Legitimacy matters as well. Boduroglu and Yigiter (2025) developed and validated, with 416 participants, a scale measuring students' attitudes towards AI-based scoring. This is a reminder that perceived fairness is itself an outcome institutions can and should measure.

The stakes rise as unsupervised take-home writing loses credibility as evidence of individual mastery and assessment shifts towards supervised writing tasks (see Q303), because scoring validity then carries more weight. The comparison can therefore be stated with some confidence at the level of mechanism. Classical AES offers human-fitted, inspectable but prompt-bound scoring, while LLMs offer flexible rubric interpretation whose basis is opaque and whose behaviour shifts across versions. Several things remain unclear. The evidence does not yet show how large length and vocabulary effects are in current LLM scorers, whether ensembles or hybrids reliably suppress them, or how calibrated systems perform in high-stakes use and over time. Until such evidence accumulates, the defensible position is that LLM scores are provisional measurements, trustworthy only to the extent that they survive regular comparison with stratified human judgement.

Q346 Why do high scores on static academic benchmarks (MMLU, GSM8K, MATH) fail to predict whether a model is an effective teacher—and how do pedagogical benchmarks (like MathDial, Bridge, and Pedagogical Content Knowledge evaluations) measure actual student learning transfer?

11 citations · 11 sources · 4 cross-references

Claim 1 disputed

High scores on static academic benchmarks fail to predict teaching effectiveness because they measure a different construct. MMLU, GSM8K and MATH ask whether a model can produce correct answers to well-posed problems. Teaching asks whether a model can change what another mind knows, and that depends on diagnosis, timing, restraint and adaptation, none of which these instruments sample. Each benchmark was built for a legitimate purpose, and its design shows what it leaves out. Hendrycks and colleagues (2020) introduced MMLU as a test of multitask accuracy across 57 subjects, including elementary mathematics, US history, computer science and law. They argued that high accuracy requires extensive world knowledge and problem-solving ability. Cobbe and colleagues (2021) introduced GSM8K, 8.5K linguistically diverse grade-school word problems, to diagnose why language models struggled with robust multi-step reasoning despite the conceptual simplicity of the problems. Hendrycks, Burns, Kadavath and colleagues (2021) assembled MATH, 12,500 competition problems, each with a full step-by-step solution that can be used to teach models to generate derivations and explanations.

All three are scored at the level of the answer. A model succeeds when its output matches the key, whether through multiple-choice selection or a final numerical result. Nothing in the scoring asks whether the model could recognise a learner's misconception, decide when to hold

back the solution, or judge that a hint landed. The MATH solutions are explanations written for a reader who already follows competition mathematics. They are not explanations designed for a confused fourteen-year-old. Cobbe and colleagues' own remedy shows how far the paradigm is oriented toward the answer. They trained verifiers to judge the correctness of completions, then generated many candidate solutions at test time and kept the one the verifier ranked highest. That approach is valuable for reliability, but it optimises one thing: arriving at a correct product. A tutor's work happens before the product exists, in the student's partial and often wrong reasoning. Benchmark accuracy is therefore at best a necessary condition for teaching mathematics, not a sufficient one, and treating it as a proxy for instructional quality is a category error rather than a measurement error.

The gap becomes concrete once we specify what an effective tutor does that a problem solver does not. The first task is diagnosis: inferring, from a wrong answer or a garbled explanation, which specific misunderstanding produced it. The second is strategy selection: choosing whether to prompt, model, question, or simply wait. The third is calibrated self-knowledge: recognising the limits of one's own understanding before asserting something to a learner who cannot check it. The original MMLU report bears on the third point. Hendrycks and colleagues (2020) observed that models had lopsided performance across tasks and frequently did not know when they were wrong. A system can earn a respectable aggregate score while being confidently mistaken in particular domains. For a solver, that is a reliability problem. For a teacher, it is a pedagogical hazard, because confident error transmitted to a novice is harder to dislodge than acknowledged uncertainty.

Wang and colleagues (2024) give the clearest account of the diagnostic gap. They frame it as the difference between novice and expert human tutors, and so as a target for language models. They note that platforms scaling tutoring often rely on novice tutors who struggle to address student mistakes and therefore miss prime learning opportunities. Their remedy, Bridge, uses cognitive task analysis to make an expert's latent reasoning explicit. Before generating a response, the expert identifies the student's error, selects a remediation strategy, and states an intention. That decomposition is itself an argument about measurement. If expert remediation involves three upstream decisions that never appear in a correct final answer, then no answer-level benchmark can observe whether a model makes them well.

A further mismatch lies in the default behaviour of instruction-tuned models. The LearnLM Team (2024) observe that contemporary generative systems are tuned to present information by

default rather than to engage users in the service of learning as a human tutor would. The mechanics of that default, and the prompting and reinforcement methods used to counter it, are treated elsewhere (see Q338). For present purposes the point is narrower. The capability that static benchmarks reward, fluent delivery of a correct answer, is precisely the behaviour a tutor must often withhold. A model whose benchmark score rises because it answers more completely may be moving in the wrong direction pedagogically.

Pedagogical benchmarks try to measure these upstream behaviours directly, and they differ considerably in what they take as ground truth. Tack and Piech (2022) made one of the earliest explicit attempts. Their AI Teacher Test asked whether generative models such as Blender and GPT-3 could reply to a student in an educational dialogue as a capable teacher would. They were candid that no off-the-shelf solution existed for measuring pedagogical ability and presented their work as a first attempt. The design moved the unit of evaluation from the answer to the conversational turn. A model is judged on what it says next to a particular student in a particular exchange, not on whether it can solve the underlying problem.

Bridge, from Wang and colleagues (2024), refines this by anchoring evaluation in an explicit expert decision model. Responses can be examined against whether the error was correctly identified, whether the chosen strategy suits that error, and whether the response realises the stated intention. Tutoring-dialogue datasets such as MathDial, which the field often groups with Bridge, follow a related logic: they place models in conversations with learners who make errors and assess the quality of the teacher moves. The common principle is that pedagogical competence is a property of situated decisions, so the benchmark must present situations rather than problems.

The LearnLM Team (2024) takes a deliberately pluralist route. Rather than commit to one definition of good pedagogy, they recast the task as pedagogical instruction following. Training and evaluation examples carry system-level instructions describing the pedagogical attributes desired in later model turns, so a teacher or developer can specify the behaviour sought. Evaluation then asks whether the model adheres to the stated pedagogy, which makes the benchmark configurable but also shifts responsibility for defining good teaching onto whoever writes the instruction. Jurenka and colleagues (2024) supply the strategic rationale for this whole family of efforts. They argue that the promise of a personal tutor for every learner has not yet materialised, mainly because pedagogical intuitions are hard to verbalise in prompts and good evaluation practice is lacking, both compounded by the difficulty of defining excellent

pedagogy. Their evaluation-driven approach treats measurement design as the bottleneck for responsible development, not as an afterthought.

These instruments are a real advance, but the claim that they measure actual student learning transfer should be resisted. On the evidence available, it overstates what they do. Most pedagogical benchmarks measure proxies for learning. They capture judgments, by experts, trained raters or model-based evaluators, about whether a tutor's move resembles what good teachers do, or whether it follows a specified pedagogical instruction. That is construct validity at the level of instructional behaviour. It is not evidence that a student who received the move learned more, retained it longer, or transferred it to a new problem. Tack and Piech (2022) framed their test around pedagogical ability in dialogue. Wang and colleagues (2024) framed Bridge around closing the gap between novice and expert remediation decisions. Neither framing, as stated, amounts to measuring downstream learning gains.

The distinction matters because the inferential chain from teacher behaviour to learning outcome has known weak links. An expert-endorsed remediation may fail for a given learner. A turn that a rater judges Socratic may frustrate a student who needed a worked example. Fidelity to an instruction, as in the LearnLM framing, is only as good as the pedagogy the instruction encodes. Jurenka and colleagues (2024) acknowledge this indirectly when they name the difficulty of defining excellent pedagogy as a root problem. If the field cannot agree on what excellent pedagogy is, then a benchmark that scores agreement with any one definition inherits that contestation.

There is also a methodological tension the field has not resolved. Static, rater-scored dialogue benchmarks are reproducible, cheap and comparable across models, which is why they spread. Learning-transfer studies require real learners, pre- and post-assessment, delayed retention and ideally comparison conditions. They are slow, expensive and context-bound, and their results do not transfer neatly into a leaderboard. Some developers treat pedagogical benchmarks as sufficient evidence of educational value. Others insist that only learner outcomes count. Both positions have merit, and few studies to date have tested whether rankings on pedagogical benchmarks predict rankings in learning gains. Until that correlation is examined, it remains unclear how much of the predictive failure of MMLU or GSM8K pedagogical benchmarks actually repair, as opposed to relocate.

The wider empirical literature on AI in education compounds this uncertainty, because much of the outcome evidence relies on perception and self-report rather than measured learning. El Idrissi and Alami (2025) surveyed 392 management students in Morocco and used structural equation modelling to relate chatbot quality, task-technology fit, social influence, perceived usefulness and actual usage to academic productivity. Their design reveals associations among perceived constructs, but it cannot show that any model property caused learning. Vieriu and Petrea (2025) studied 85 purposively sampled second-year students at a Bucharest technical university, focusing on perceptions of how AI affected their learning processes and performance alongside the challenges of adoption. Zhang and Liu (2025) asked whether college students' use of generative AI in an open learning environment could enhance critical thinking. They noted that research on this question in open environments is still scarce, even as other studies report benefits. On the instructor side, Baig and Yadegaridehkordi (2025) modelled academic staff satisfaction and continued use of generative AI with partial least squares methods. Such work illuminates adoption, not instructional efficacy.

None of these studies ties outcomes to a model's benchmark profile, academic or pedagogical, and none was designed to. That is the core problem for anyone hoping to validate benchmarks against learning. On one side sit model-level evaluations that are precise but lack ecological validity. On the other sit learner-level studies that are ecological but blind to the model, often correlational and dependent on self-report. Satisfaction, perceived usefulness and perceived productivity are reasonable things to study, but they are weak stand-ins for learning, and a tool that feels helpful because it supplies answers may score highly on exactly those perceptions. The pattern Jurenka and colleagues (2024) diagnose, a lack of good evaluation practice, holds across both levels. Neither the benchmark community nor the classroom-survey community has yet produced the linked evidence that would show which measurable model behaviours produce which learning outcomes.

A defensible position for the field treats evaluation as a validity chain with three links, each tested separately, rather than looking for a single number. The first link is content correctness. Static benchmarks remain useful here as screening instruments, because a tutor that cannot solve the problem cannot reliably teach it. Cobbe and colleagues (2021) showed that even conceptually simple problems exposed brittle multi-step reasoning, and that weakness can be mitigated architecturally by delegating computation and verification to external tools (see Q347). The second link is instructional behaviour. This is the territory of the AI Teacher Test,

Bridge and pedagogical instruction following: whether the system diagnoses errors, selects suitable strategies and exercises restraint. Benchmarks here need the same discipline already demanded of automated scoring. Model-based judges and human raters must be calibrated against expert consensus and audited for construct-irrelevant preferences such as length or fluency (see Q345). The third link is learning, measured in learners through assessments that capture retention and transfer, and it is the link least often tested.

This framing also clarifies how training choices relate to evaluation. If pedagogical behaviour is shaped through fine-tuning or reinforcement from pedagogical feedback (see Q340), then the reward signal is itself a pedagogical benchmark, and its flaws propagate into the model. Jurenka and colleagues (2024) argue for putting evaluation first for this reason. The LearnLM Team's (2024) refusal to fix one definition of pedagogy is a reasonable hedge against encoding a contested theory into the reward. Yet that hedge leaves open whose pedagogy is being followed and whether it works.

What the evidence does not yet show is decisive. Few studies have demonstrated that gains on pedagogical benchmarks predict measured learning gains in real students. Nor has it been established that remediation patterns judged expert-like in dialogue datasets transfer across age groups, subjects and cultural contexts. The honest summary is that academic benchmarks demonstrably measure the wrong construct for teaching. Pedagogical benchmarks plausibly measure a closer one, but their link to learning transfer remains an empirical hypothesis rather than an established fact.

Q347 How does neuro-symbolic tool-calling (delegating calculations and formal verification to Python, SymPy, Lean 4, or Wolfram Alpha) eliminate arithmetic and symbolic hallucinations in STEM education?

14 citations · 14 sources · 3 cross-references

Claim 1 disputed

Neuro-symbolic tool-calling does not eliminate arithmetic and symbolic hallucinations in STEM education. It relocates them. When a language model hands a calculation to a Python interpreter, an algebraic manipulation to SymPy, a proof obligation to Lean 4, or a query to Wolfram Alpha, the computation itself becomes deterministic and, within the tool's own semantics, correct. The model remains responsible for deciding that a tool is needed, translating the student's informal problem into the tool's formal language, choosing the right arguments, and rendering the result back into pedagogically sound prose. Errors in any of those steps survive delegation intact. The precise claim the field can defend is therefore narrower than the question implies. Tool-calling removes one well-characterised class of error, the internal slip in executing a computation the model has already set up correctly, and leaves a different class of error, the formalisation error, largely untouched.

The founding papers frame the problem in exactly this way. Schick and colleagues (2023) observed a paradox: language models solve novel tasks from a few examples yet struggle with basic functionality such as arithmetic and factual lookup, where much simpler and smaller models excel. Their Toolformer was trained to decide which application programming interfaces to call, when to call them, what arguments to pass, and how to incorporate the results into subsequent token prediction. Each of those four decisions is a site where a model can still

go wrong. Gao and colleagues (2022) located the weakness even more precisely. In chain-of-thought prompting, large language models proved adept at decomposing a problem into steps but often made logical and arithmetic mistakes in the solution part, even when the decomposition was correct. Program-aided language models were built on that diagnosis. The model writes a program expressing its decomposition, and an interpreter, not the model, produces the answer. The architecture is honest about what it fixes. It assumes the decomposition is right and protects only the execution.

Why should an educational system need this at all? Language models do not compute in the way a calculator computes. They generate tokens that are statistically plausible continuations of a context, and a plausible-looking digit string is not a correct one. Two strands of evidence suggest that the problem runs deeper than occasional slips. Mirzadeh and colleagues (2024) questioned whether the improving performance of large language models on GSM8K, a widely used benchmark of grade-school mathematics, reflects genuinely advanced mathematical reasoning. Through a large-scale study of several state-of-the-art open and closed models, they raised concerns about the reliability of the reported metrics. For educators this matters directly, because grade-school word problems are precisely the material that tutoring systems are most often deployed to support. A high benchmark score does not establish that a model will compute reliably on the slightly altered problem a particular student brings (see Q346).

Hersche and colleagues (2026) isolated the reasoning component even more cleanly. They compared large language models with neuro-symbolic approaches on Raven's progressive matrices, abstract reasoning tasks that require understanding mathematical rules such as progression and arithmetic addition. To remove any perceptual confound, they supplied the visual attributes directly as text, effectively assuming an oracle perception module. Even with these compositionally structured representations and advanced prompting techniques, neither GPT-4 nor Llama-3 70B achieved perfect accuracy on the center constellation of the I-RAVEN dataset. The finding is narrow, since it concerns one configuration of one abstract reasoning benchmark. Its direction is nonetheless instructive. The failure persists when perception is solved and the rules are elementary, which points to a limitation in carrying out rule-governed operations reliably, not in understanding the problem. That is exactly the gap symbolic execution is meant to fill.

The two strands do not yet tell us how frequently such errors reach students in authentic tutoring dialogues. Neither do they establish whether newer reasoning-oriented models have

narrowed the gap enough to change the cost-benefit calculation of tool use. What they do support is the design premise. Where exactness matters, the model should not be the component that produces the final number or symbolic form.

The symbolic back-ends differ in what they guarantee, and educators should understand those differences rather than treat "the tool" as a single oracle. A general-purpose Python interpreter guarantees faithful execution of the program it receives. It guarantees nothing about whether that program encodes the intended problem. SymPy, as Meurer and colleagues (2017) describe it, is an open-source computer algebra system written in pure Python and designed for extensibility and ease of use in both interactive and programmatic settings. Those properties have made it a popular symbolic library in the scientific Python ecosystem and a natural target for language models that already generate Python. A computer algebra system can simplify, differentiate, integrate, and solve symbolically, so it can check that a student's or a model's transformation preserves equivalence. Its guarantees are bounded by its algorithms and by the assumptions attached to symbols, for example whether a variable is declared real or positive. A wrongly declared assumption yields an answer that is correct for the stated problem and wrong for the intended one.

Lean 4 offers a categorically stronger form of assurance. De Moura and Ullrich (2021) describe it as a reimplementation of the Lean interactive theorem prover in Lean itself. It is fully extensible, so users can modify the parser, elaborator, tactics, decision procedures, and code generator, and it doubles as an efficient functional programming language. In an interactive theorem prover, a proof is accepted only when the system checks every inferential step against the formal rules. A model that generates a Lean proof which compiles has therefore produced something whose validity does not depend on trusting the model. The guarantee concerns the formal statement, though, not the informal claim the student cares about. A machine-checked proof of a mistranslated theorem is still a proof of the wrong thing.

Wolfram Alpha sits between these poles. It is a curated computational engine that accepts semi-natural queries. That makes it convenient, but the translation from informal to formal is then partly hidden inside a proprietary parser, which makes the formalisation step harder to inspect.

Recent surveys place these configurations within a broader taxonomy. De Boer and colleagues (2025) catalogue design patterns for neuro-symbolic systems built on large language models. They argue that such systems can make explicit use of expert knowledge and can be understood

and inspected by humans, but that the growing variety of approaches makes comparison difficult. Bougzime and colleagues (2026) frame neuro-symbolic artificial intelligence as combining deep learning's capacity with large-scale unstructured data and the structured reasoning of symbolic methods, with the potential to improve generalisation, reasoning, and transparency. The operative word in that framing is potential.

The residual risk concentrates in what may be called the formalisation gap. Every tool call begins with a translation from natural language, often a student's ambiguous or partially incorrect phrasing, into code, a symbolic expression, or a formal proposition. Pease and Thompson (2026) state the underlying difficulty plainly. Human language is often vague and ambiguous, and logic leaves great flexibility in how symbols are defined. Their response was to anchor lexical elements in a formal ontology so that symbol meanings remain stable across discourse, and to train a machine learning system on a large corpus of language-logic pairs generated algorithmically from that ontology. The approach illustrates how much engineering is needed to make translation reliable in a controlled domain. It also implies that an open-ended tutoring dialogue, without such anchoring, offers far weaker assurance.

The formalisation gap produces characteristic failures that tool use cannot catch. The model may set up the wrong equation for a word problem, and SymPy will then solve the wrong equation flawlessly. It may omit a domain restriction, so the computer algebra system returns an extraneous root as a valid solution. It may misread a tool's output, for example confusing a symbolic expression with its numerical approximation. It may also decline to call the tool at all when it should, which is one of the four decisions Toolformer had to learn (Schick et al., 2023). The program-aided design of Gao and colleagues (2022) secures execution only after decomposition, and decomposition is where these errors originate. A further failure belongs specifically to education. A tool may return a correct answer while the model's surrounding explanation reasons toward it incorrectly, producing a correct result attached to a hallucinated derivation. Because students often learn more from the derivation than from the answer, this failure is pedagogically more damaging than an outright arithmetic slip.

Formal verification outside education shows both the value and the limits of the approach. Razzaghi and colleagues (2025) used model checking with Computation Tree Logic to verify whether a machine-learning decision-support tool for runway configuration complied with predefined safety regulations under varying surface-wind conditions. The method was rigorous, yet verification could only confirm compliance with properties someone had first written down

formally. Educational verification inherits the same dependency. A verifier checks what it is asked to check, and specifying what a correct, complete, and pedagogically appropriate solution looks like is itself a substantial human task. Sinha and colleagues (2026) add a practical caution. Neuro-symbolic frameworks still impose a steep learning curve and suffer from a lack of user-friendly tools, libraries, and unifying frameworks. That limits how readily schools and edtech developers can build such pipelines correctly.

For teaching, the more interesting promise of tool-calling may lie less in correctness than in inspectability. A symbolic trace (the generated program, the SymPy expression, the Lean proof state) is an artefact that a teacher or advanced student can read, question, and re-run, in a way the hidden states of a neural network cannot be. Michel-Delétie and Sarker (2026), reviewing recent work at leading conferences, find that neuro-symbolic methods have shown great potential for aspects of trustworthiness, particularly interpretability. Mileo (2025) argues for a neuro-symbolic cycle oriented toward human-centred explainability. Her motivation comes from high-stakes settings such as medical imaging, where black-box opacity hinders adoption, but the argument transfers naturally to classrooms, where a teacher must be able to see why a system marked a step wrong. Confalonieri and Guizzardi (2025) show that explicit knowledge structures such as ontologies can support intelligible explanations through reference modelling, common-sense reasoning, and knowledge refinement. This suggests that tool outputs become pedagogically useful when they are mapped onto a structured representation of the domain, not merely returned as bare results. That mapping is the territory of verifiable tutoring architectures built on knowledge tracing and formal domain graphs (see Q341).

The pedagogical risk runs the other way. A system that always produces verified answers can make answer-giving frictionless, and frictionless answers can undercut the productive struggle that much mathematics instruction depends upon. Verification secures the content of feedback, not its timing or its Socratic restraint. A well-designed system might use the symbolic engine silently, to check a student's work and to keep the model's hints accurate, while withholding the computed answer. In that role the tool becomes a guardrail on the tutor rather than a substitute for the learner. When verification is distributed across several agents, a critic agent that wrongly trusts a misformalised tool call can propagate the error with false authority (see Q343). How students actually respond to visible symbolic traces, whether they read them, learn from them, or simply defer to them, remains unclear. The interpretability benefits documented in general neuro-symbolic research have not yet been demonstrated with learners.

The evidence supports a calibrated position. It is established that language models are unreliable executors of arithmetic and symbolic operations (Schick et al., 2023; Gao et al., 2022). The emerging evidence is that offloading execution to deterministic tools addresses that specific weakness. Mature tools are available for doing so: computer algebra systems such as SymPy (Meurer et al., 2017) and interactive theorem provers such as Lean 4 (de Moura and Ullrich, 2021). The broader framing of benchmark gains is disputed, given concerns that headline scores may overstate genuine mathematical reasoning (Mirzadeh et al., 2024), and residual limits persist even under idealised input conditions (Hersche et al., 2026). The verdict also hinges on what counts as a hallucination. If the term covers only computational slips, tool-calling comes close to eliminating them. If it covers misformalised problems, unwarranted assumptions, and explanations that do not match the verified result, tool-calling eliminates none of these and may make them harder to notice, because they arrive wrapped in the authority of a verified computation.

Several gaps limit any stronger claim. Few studies have measured, in authentic educational dialogues, the rate of formalisation errors relative to computational errors, so the net reduction in student-facing mistakes is unquantified. Few have compared Python, SymPy, Lean, and Wolfram back-ends on the same pedagogical tasks. Learning outcomes, as opposed to answer accuracy, remain largely unmeasured. Practical deployment constraints matter too. The tooling burden noted by Sinha and colleagues (2026) and the absence of comparative standards highlighted by de Boer and colleagues (2025) mean that many deployed systems may implement tool-calling inconsistently.

For designers and adopting institutions, the defensible practice follows from these limits. Route every exact computation through a symbolic engine. Expose the formal translation to inspection. Use assumption-aware computer algebra and, where proof matters, machine-checked verification. Treat the informal-to-formal step as the primary site of residual risk, which calls for its own testing, human review, and, where possible, ontology-anchored constraints of the kind Pease and Thompson (2026) describe. Tool-calling is best understood as a way of moving uncertainty to a place where it can be seen, not as a way of abolishing it.

Q111 What duties do educators have toward students who cannot or will not use AI?

17 citations · 17 sources · 5 cross-references

Claim 1 emerging

Educators owe students who cannot or will not use AI a set of positive duties. It is not enough to tolerate non-use; educators must ensure that non-use never hardens into disadvantage. The question has become pressing as AI shifts from optional tool to assumed infrastructure in schools and universities. The equity and rights frameworks developed by UNESCO and the OECD converge on this position, even where they differ in emphasis.

The first duty is to distinguish two populations, because their claims differ. Some students cannot use AI because of cost, connectivity, disability, language, or institutional policy. They stand on the wrong side of what the OECD's 2024 report on equity and inclusion and the 2024 Frontiers in Education analysis of AI-powered education treat as an emerging AI divide. The duty owed to them is one of equity: the school must not let access to learning depend on access to AI. Other students will not use AI, out of religious, philosophical, or personal conviction. They are exercising a choice, and the duty owed to them is one of respect: the school must not punish or marginalise conscientious refusal. UNESCO's rights-based guidance frames both groups' claims as matters of the right to education itself rather than of technological preference.

Refusal is not a fringe position. Runcan and colleagues (2026) surveyed 675 students across six Romanian universities. Perceived benefits strongly predicted acceptance of AI ($\beta = 0.541$), while skepticism had a modest but significant negative effect ($\beta = -0.113$). The design is correlational, but it indicates that doubt coexists with enthusiasm within the same student body. Aloud, Alotaibi and Al-khalifa (2026) modelled the perceptions of 652 King Saud University students. They treated fear of using generative AI as a construct distinct from awareness and

desire to use, and examined whether these perceptions differ by gender, age, academic major, and level of study. Neither study measures refusal directly, so the size of the conscientious non-user population remains unclear. In practice the two duties overlap: both require the school to maintain non-AI pathways that are genuinely equivalent in educational value, not merely available in name.

The second duty is non-discrimination in assessment. AI use may be rewarded through faster completion, higher grades, or implicit expectations about polish and volume. Where it is, students who cannot or will not use it are systematically disadvantaged, and the assessment ends up measuring access to technology rather than learning. The duty is to design assessment so that it measures the learning outcome, not the means of production. The same principle already governs accommodations for disability: the standard is the outcome, and the pathway is adjusted. Where AI is integral to the curriculum, the school must ensure that non-users can still meet the standard by other means. The disability analogy cuts both ways. Some disabled students find mainstream AI tools inaccessible, while others depend on AI as assistive technology (see Q248).

The burden falls squarely on educators' professional conduct. Chinoracky and Stalmasekova (2025) conducted a thematic review of 42 open-access, peer-reviewed articles published between 2022 and 2025. Drawing on Slovak legislation that defines educators' responsibilities, they classified educators' activities into teaching, scientific research, and other work such as academic management and self-directed professional development. Assessment design sits within the teaching responsibilities that such legislation already assigns. This suggests the duty is an extension of existing obligations rather than a new one.

Evidence on educators' own adoption complicates matters. Bahaw and colleagues (2026) refined the Unified Theory of Acceptance and Use of Technology for entrepreneurship educators. They identified affinity to technology as an individual-level antecedent of adoption and specified boundary conditions under which facilitating conditions lose explanatory power. If teachers' uptake of AI depends partly on personal affinity, their implicit expectations of students may as well. Assessment criteria could then drift toward rewarding AI-assisted products without anyone deciding that they should. Explicit outcome criteria are the safeguard against that drift.

The third duty is to teach AI literacy to all students, including those who will not use AI. UNESCO's rights-based framework treats AI literacy as a universal entitlement. Every student should understand what AI is, how it works, what its risks are, and how to evaluate its outputs, because these are now conditions of participation in society rather than optional skills. A student who declines AI still has to live in a world saturated by it. That student must still be able to recognise AI-generated content, protect personal data, and assess machine-produced claims. The duty is to teach about AI to everyone while requiring use of AI from no one.

Curricula are already being reshaped around AI competence, which makes it important to decouple literacy from use. Adeyemi and colleagues (2025) examined awareness and use of large language models among library and information science undergraduates at Kwara State University. They drew a sample of 306 from a population of 1,479, retrieved 279 questionnaires, and framed their study explicitly in terms of implications for educators. Alemán Ramos and Morales Almeida (2026) ran a mixed-methods study of 49 Social Education undergraduates. They integrated perceived AI use, self-reported learning competencies, and professional knowledge requirements to judge preparedness for AI-mediated practice in a socially oriented profession. Both studies treat competence with AI as something graduates are expected to possess. Neither, as summarised, separates knowing about AI from using it, and that gap is where the duty applies. A course can examine how a language model generates text, why it can fabricate sources, and what happens to data entered into it through demonstration, case analysis, and critique, without requiring each student to operate a tool personally. Miranda's (2025) exploratory survey of 376 teachers, university students, and future educators in the University of Salerno area set AI's promise for personalisation and efficiency against concerns about ethical implications and responsible implementation. That pairing suggests critical understanding is wanted even by those who see value in use. Literacy taught this way serves the refuser and the enthusiast alike.

The fourth duty falls on institutions as much as on individual teachers: if AI is expected, it must be provided. Inside Higher Ed reported in 2025 that half of colleges do not grant students access to AI tools. Where that is the case and coursework nonetheless assumes AI, students are left to secure tools privately. What they can obtain then depends on what they can afford, whether a free tier or a paid subscription, and on whether their devices and connections can support it. The analysis of the new digital divide in education poses the choice starkly, as one between AI as a public capability and AI as a private advantage. When institutions neither

provide tools nor design courses that work without them, they default to the second option without having chosen it. Work on the digital divide in AI education makes the corresponding demand for equal opportunities, which in practice means either institutional provision or genuine independence of the curriculum from privately acquired tools.

Access is not only financial. Tabiri and Jones-Mensah (2026) studied Ghanaian tertiary students' use of AI in language learning, including which languages they use it for and at what stage of their studies they adopted it, guided by the Unified Theory of Acceptance and Use of Technology and constructivist learning theory. Their attention to multilingual learning signals that a student's linguistic background may shape how useful a given tool is to them. Nyaaba and Min (2025) tested text-to-video tools for culturally and linguistically responsive teaching with English Language Learners, assessing their capabilities particularly in freemium modes, which is where budget-constrained teachers and students are most likely to work. The duty that follows is concrete. An institution that builds AI into teaching should supply tools that meet privacy and accessibility standards, check that they serve the languages its students actually use, and keep a non-AI route open for anyone the provision still fails.

The fifth duty concerns the student who will not use AI and is entitled to that position. Respect means more than permitting refusal; it means not making refusal costly in hidden ways. A student who objects to a tool's data practices should not be required to open an account with a commercial provider to complete compulsory work. UNESCO's guidance on protecting learners' rights, together with the overview of AI and the right to education, treats privacy and protection from coercive data collection as part of what learners are owed. Educators should state openly which tasks involve AI, offer an equivalent alternative without requiring the student to justify it at length, and avoid treating refusal as evidence of laziness or technophobia.

Respect also requires candour. Neittaanmäki (2025) surveyed medical students at Gothenburg University about their attitudes toward AI in medicine, its effects on their career plans, and their use of generative AI in their studies. Where a profession is being reshaped by AI, a decision to abstain may carry consequences beyond the classroom, and a teacher who conceals this does the student no favour. The duty is to inform without pressuring: to explain what the field increasingly expects, then leave the decision with the student wherever the curriculum permits. The separation of fear from awareness in the King Saud University model points to a related obligation. Some apparent refusal may be anxiety that better information would ease,

while some is a settled judgement. Educators should offer explanation to the first group without treating the second as a problem to be corrected.

These duties have limits, and stating them guards against overreach. Where competence with AI is itself a stated learning outcome, as in some professional programmes, a school cannot exempt a student from the outcome while still certifying it. The duty then shifts to offering the least intrusive means of demonstrating competence, such as institutionally hosted tools with strong privacy protections, and to explaining the requirement clearly before enrolment so that students can choose with full knowledge. The preparedness agenda described in the Social Education study shows why such programmes exist, but it does not license silently extending AI requirements to courses whose outcomes do not include them. Nor do the duties require identical experiences for users and non-users. They require equivalent opportunity to learn and to be judged fairly.

The evidence base remains thin. Most of the empirical work cited here consists of single-institution surveys of attitudes and use, and none of it measures the educational outcomes of non-users directly. The equity analyses identify risks more clearly than they quantify them. The framing in the digital divide literature, that AI either becomes a shared public capability or entrenches private advantage, nonetheless gives educators a workable test. For any practice involving AI, they can ask whether a student without access, or without the wish to use it, could still learn what is taught and show that learning. If the answer is no, the practice needs redesign before it needs defending.

Q267 How should educational institutions finance AI, and how should they weigh that expenditure against competing educational needs?

13 citations · 13 sources · 8 cross-references

Claim 1 disputed

Institutions should finance AI use by use rather than as a category, and in a fixed order of reasoning. First, decide what educational or operational problem a tool is meant to solve and what non-AI alternatives could solve it. Second, match the funding source to the nature of the cost, so that recurring commitments are paid from recurring money and experiments from temporary money. Only then should they ask whether the expenditure is a better use of scarce resources than the alternatives it displaces.

There is no single correct way to fund educational AI, but this order is defensible. The available evidence does not establish that AI spending, in general, produces more educational value per dollar than spending on teachers, tutoring, disability support or materials. Nor does it establish the opposite. What it does establish is that the value of AI depends on the specific use, the design and the setting. Financing decisions must therefore be made tool by tool and purpose by purpose.

This answer concerns publicly funded schools and universities. Most examples come from the United States and England, where funding rules and published evidence are most accessible. That focus carries a bias the wider literature has begun to name. Lakhno's (2026) PRISMA-guided systematic review of scholarship from 2022 to 2024 argues that debates on AI in higher education remain dominated by evidence from high-income contexts. Those debates often assume institutional capacity and robust infrastructure, whereas in low-income countries structural constraints profoundly condition both the opportunities and the risks of adoption [SRC-2057]. Readers in such systems should treat the financing logic below as transferable and the cost figures as not.

Two terms are used throughout. "Financing" means the choice of money used to pay for AI. "Weighing" means the comparison of AI spending with other uses of the same money. The full cost to be financed is set out elsewhere (see Q266), as is the evidence on what AI returns (see Q268). The costs that fall on households and students are examined in Q270 and Q271.

Funding rules differ across jurisdictions, and nothing here should be read as legal advice on the use of any particular fund.

The most common financing error happens before money is discussed at all: a product is chosen, and a budget is then sought for it. A defensible process runs the other way.

It begins by naming the problem, such as teacher planning load, tutoring capacity, feedback turnaround or administrative backlog. It then names the outcome that would show the problem has been reduced. It identifies at least one non-AI way of addressing the same problem, together with the option of doing nothing. Only then does it ask whether an AI tool is likely to do better.

This sequence matters financially. It converts an open-ended technology purchase into a bounded comparison between alternatives, each with a cost and an expected effect. Katsamakas, Pavlov and Saklad (2024) make a related conceptual point. They map the causal feedback mechanisms of AI transformation in a typical higher education institution as a causal loop diagram, arguing that the literature had lacked a systems view of its structure and dynamics [SRC-2469]. For financing, a systems view means that a purchase sets off reinforcing and balancing effects across staffing, teaching and administration, rather than acting as a single line item.

Institutions typically draw on several kinds of money, and each suits a different kind of cost.

Grants, philanthropic gifts and short-term programme funds are temporary or one-time money. They suit costs that end: pilots, evaluation, implementation and initial training. In the United States, the Department of Education's July 2025 guidance confirms that federal formula and discretionary grant funds may be used for AI-based instructional materials, tutoring and advising, provided programme requirements are met and privacy law is respected [SRC-1673]. That guidance creates a lawful route; it does not create new money. Every dollar of an existing grant spent on AI is a dollar not spent on that grant's other allowable uses.

Ongoing licences, support and refresher training are permanent commitments and belong in the recurring operating budget. This is where trade-offs are sharpest, because recurring funds also pay salaries.

Vendor-subsidised or bundled access includes free tiers, discounted introductory pricing and AI features folded into existing platforms. These lower the initial cost, but price, data rights and dependence remain, and pricing can change at renewal.

Tuition and mandatory fees offer another route, particularly in higher education, where AI costs can be built into tuition or technology fees. This spreads costs across all students, including those who never use the tool.

Finally, institutions can impose user charges by requiring individuals to buy their own access. The California State University's own analysis presented this as the alternative to systemwide purchase. The next-closest provider "would need to be supported by campus resources or a user fee" [SRC-1675]. User charges move costs from the institution to students and households, with the equity consequences examined in Q270 and Q271.

The most common structural error is financing recurring obligations with temporary money. A pilot funded by a one-year grant or a vendor discount creates users, habits and expectations. When the grant ends, the institution faces a costly choice either way. It can find recurring money under pressure, or it can withdraw a tool that staff and students now rely on.

The safer rule is that temporary money may start something only if the institution has identified, in advance, how it will end. That means naming either the recurring money that will continue the tool or the conditions under which it will be stopped. Institutions that adopted technology with time-limited pandemic-era funds faced this problem at scale, and the same risk applies to AI.

How money is distributed within a system matters as much as where it comes from. A district or university that funds AI through individual school or departmental budgets will see uneven adoption. Better-resourced units can afford licences, training and support, while others cannot. Two remedies protect against that drift: allocating AI funding by a per-student or per-staff formula, or providing core tools centrally. Both come at the cost of buying access for units that may not use it.

The book's equity chapter shows how readily technology spending widens existing gaps, including between rural and urban schools (Q190), and which interventions have reduced them (Q193). Lakhno's (2026) review points to the same dynamic between countries. Where infrastructure and institutional capacity cannot be assumed, diffusion follows the contours of

existing constraint [SRC-2057]. A financing plan should therefore state how much will be spent, how access will be distributed and how that distribution will be checked.

Some national systems have chosen central capital investment over unit-level purchasing. Gopi and Agarwal (2026) note that India's 2025–26 budget committed ₹500 crore to establish Centres of Excellence in education, framed as a strategic investment in academic innovation and infrastructure [SRC-2470]. Such allocations address capacity rather than licences, and their educational return remains unclear.

Initial adoption receives most scrutiny, but renewal is where most AI money is committed. A renewal should be treated as a new decision rather than an administrative continuation. Has the tool been used, and by whom? With what measured effect, and at what cost per active user? What would the money buy instead?

Renewals approved during budget reductions deserve particular attention, because they signal that AI spending has been protected while other spending has been cut. That may be justified, but the justification should be explicit. Contract terms that allow annual cancellation, of the kind CSU negotiated [SRC-1675], make such reviews meaningful. Multi-year commitments without exit options make them largely symbolic.

The California State University's systemwide agreement with OpenAI illustrates both the advantages and the risks of central financing. According to the university, the renewed agreement costs $1.60 per user, against a next-closest bid of $8.00 per user per month. The two figures are not stated in the same unit; dividing the annual contract value by the projected number of users suggests that the $1.60 figure is also a monthly price, but that is the book's inference from the published numbers rather than a disclosed contract term (see Q266). It extends coverage to 675,000 students, staff and recent graduates [SRC-1675]. These are the institution's own figures rather than independently audited ones. On their face, central purchasing achieved a unit price far below consumer list prices and avoided user fees, keeping the cost off students' accounts.

The same agreement created a large recurring commitment from a public budget during a period of financial pressure. EdSource reported that faculty critics opposed the renewal on the grounds that the money was needed elsewhere [SRC-1676].

The dispute is real, and both sides have a coherent case. Supporters can point to price and to equitable access. Critics can point to opportunity cost within a constrained budget. Neither side, however, could point to published outcome data showing what the licence had achieved in its first period.

That absence is the central financing lesson. A recurring commitment of this size should come with a plan to measure what it buys, set before the contract is signed rather than assembled at renewal. The case also shows why the choice between central purchase and user fees is itself a distributional decision. The university avoided pushing costs onto households, but only by drawing on funds that others argued had stronger claims.

Once a funding source is identified, the expenditure must be compared with what else the money could do. The relevant comparison is not between AI and nothing. It is between AI and the next-best use of the same funds: additional tutoring hours, smaller groups, specialist support, curriculum materials or staff time.

The available evidence allows only a partial comparison. The strongest experimental evidence on teacher time comes from the Education Endowment Foundation's trial in English secondary schools. Science teachers using ChatGPT with a guide reduced weekly lesson-planning time by about 31 per cent, with no apparent loss of quality in the resources produced [SRC-1650] [SRC-1176]. That is a real but bounded effect, amounting to about 25 minutes a week on one task, in one subject and one phase.

Survey evidence from the United States suggests larger savings, but it is self-reported by regular users. Gallup's research with the Walton Family Foundation found that the roughly three in ten teachers who used AI at least weekly estimated saving about 5.9 hours a week. That is equivalent to about six weeks over a school year [SRC-1286] [SRC-1679]. These are estimates from adopters rather than measured effects, and they should not be treated as equivalent to the trial result. The gap between the two sources is wide. It reflects differences in method, sample and task, not a settled finding.

Walton also reported that teachers in schools with an AI policy reported larger time savings than those in schools without one [SRC-1679]. This is a correlation and may reflect differences between the schools themselves. Even so, it suggests that the return on AI spending depends partly on the spending around it: on guidance, training and policy.

Perception studies outside the Anglo-American context point in the same direction. Alsuhaymi and Eltantawy (2026) surveyed 173 principals, supervisors and teachers in public schools providing special education services in Riyadh. They examined whether views on AI-supported administrative decision-making differed by professional role, experience and AI-related training [SRC-2147]. Al-Raimi (2026) surveyed 280 faculty members and academic leaders in Yemeni university health education institutions. That questionnaire covered not only AI use and educational quality but also the challenges and requirements for effective implementation [SRC-2272].

Both studies are descriptive surveys of perceptions. Neither measures learning outcomes or costs. Their value for financing lies in treating training and implementation conditions as variables in their own right. The licence is only part of what must be paid for.

None of these studies converts time saved into money saved, and none compares AI directly with an alternative use of the same budget. Whether reclaimed teacher time reduces staffing costs, improves teaching or is absorbed by other duties is a separate question (see Q269). The wider body of systematic reviews leaves effect sizes contested (see Q263). An institution weighing AI against a teaching post, a tutoring programme or disability support must therefore make an explicit judgement using local evidence. It should not appeal to a general finding that AI "pays for itself".

Financing decisions are also judged by the public and by staff. Survey evidence shows a teaching workforce divided between regular users, occasional users and non-users [SRC-1286]. Any substantial AI expenditure will therefore be seen by part of the workforce as a diversion from priorities they consider more urgent.

The CSU dispute shows how quickly that perception becomes organised opposition when budgets are tight [SRC-1676]. Ocen and colleagues' (2025) review of AI in higher education likewise balances innovation and opportunity against the observation that AI tools, if not used correctly, can be challenging for institutions [SRC-2471]. Spending that buys access without the conditions for appropriate use is unlikely to earn staff support.

A decision process that is transparent about alternatives, costs and expected outcomes is more likely to be accepted than one that presents AI spending as self-evidently modern or efficient.

A defensible financing decision for any AI tool meets seven criteria. It names the problem and the outcome before the product. It compares at least one non-AI alternative and the option of doing nothing. It funds recurring costs from recurring money, and uses temporary money only with a plan for continuation or exit. It costs the full lifecycle, including exit (see Q266). It identifies who bears costs the institution does not pay, whether students, households or staff, and how those costs fall across advantaged and disadvantaged groups. It specifies in advance how effect will be measured and when the decision will be reviewed, so that renewal becomes a genuine choice. And it records the reasoning in board or governing-body papers, so that the choice can be scrutinised and revisited.

None of these criteria presupposes that AI is a good or a bad investment. They exist because the evidence does not yet allow that judgement to be made in general. Each institution must therefore make it openly, case by case, against the real alternatives its money could fund.

- *Could change the conclusions:* independent cost-effectiveness comparisons of AI tutoring with human tutoring; changes in US federal grant priorities (the status of the Department's proposed supplemental AI priority was not verified for this edition); state appropriations; published CSU outcome data.
- *Indicators to monitor:* share of AI spending from temporary versus recurring sources; written alternative-use comparisons in board papers; introduction of AI user fees; AI renewals approved during budget reductions.
- *Related questions:* Q077, Q122, Q190, Q193, Q266, Q268, Q270, Q271.

What changed in this edition: This answer is unchanged in Edition 122. Its most recent revision, in Edition 117: Reorganised into six sections; added international evidence (Lakhno, Gopi and Agarwal, Katsamakas et al., Alsuhaymi and Eltantawy, Al-Raimi, Ocen et al.); clarified correlational and self-reported status of survey findings; added workforce and meta-analysis cross-references. Post-publication review: noted that CSU's

$1.60 and $8.00 figures are stated in different units and that the monthly reading is an inference (see Q266).

Q348 What is the measurable carbon, electricity, and freshwater footprint of scaling generative AI across millions of daily student queries, and how can schools adopt "right-sized compute" policies?

11 citations · 11 sources · 5 cross-references

Claim 1 disputed

The footprint of serving generative AI to millions of students each day is real and measurable in principle. In practice it cannot yet be stated as a reliable per-query figure, because the few rigorous measurements available cover model training or general inference benchmarks rather than educational deployments, and providers rarely disclose the operational data needed to close the gap. What the evidence does establish is the shape of the problem. Energy use scales with model size and with the number of queries served (Luccioni, Jernite and Strubell, 2024). Carbon depends on the electricity grid and the hour at which computation happens (Patterson and colleagues, 2021). Freshwater consumption depends on how data centres are cooled and on the water intensity of the power that feeds them (Li and colleagues, 2023). A school system that multiplies a small per-query cost across hundreds of thousands of learners, several sessions a day and a full academic year is therefore making an environmental decision, whether or not it records one. Right-sized compute means matching the capability of the model to the demands of the task rather than defaulting to the largest available system. It is the most defensible response available to schools now, because it reduces footprint without waiting for perfect measurement.

This answer separates three quantities often blurred in public debate: electricity drawn, carbon emitted, and freshwater withdrawn or consumed. It treats their sum across a school population as an accounting problem in which institutions currently lack most of the inputs. The full lifecycle view, from chip fabrication to device disposal, is addressed elsewhere (see Q250). The focus here is the operational cost of everyday use and the policy levers that operational cost makes available.

The foundational work on computational cost came from training, not use. Strubell, Ganesh and McCallum (2019) argued that accuracy gains in natural language processing depended on exceptionally large computational resources requiring correspondingly substantial energy. They also argued that these models were therefore costly both financially, through hardware, electricity and cloud compute time, and environmentally, through the carbon footprint of the processors that run them. Their paper made energy a legitimate object of methodological scrutiny in machine learning. It also established the norm that researchers should report computational cost alongside accuracy. Patterson and colleagues (2021) then calculated energy use and carbon footprint for several large models, including T5, Meena, GShard, Switch Transformer and GPT-3, and refined earlier estimates for a neural architecture search. Their contribution was partly corrective. Estimating energy cost is difficult without detailed information, and refined calculations can differ from earlier back-of-envelope figures. For education, the lesson is that headline numbers about AI's carbon cost are sensitive to assumptions about hardware, data-centre efficiency and grid mix, and that such numbers should be read as estimates bounded by the information available to their authors.

Training is a one-off cost amortised across every subsequent user, which is why the more relevant quantity for schools is inference, the ongoing cost of answering each query. Luccioni, Jernite and Strubell (2024) offered what they describe as the first systematic comparison of the ongoing inference cost of different categories of machine learning systems. They contrasted task-specific models fine-tuned to do a single job with general-purpose models trained for many tasks. Their framing is direct: the ambition of generality comes at a steep environmental cost, given the energy these systems require and the carbon they emit. This is the key empirical hinge for educational policy. If a general-purpose system is used for a narrow task, such as classifying a short answer, checking spelling or retrieving a definition, a more specialised system may perform that task at much lower energy cost. The exact multiplier depends on the tasks and models compared, and schools should not import a single ratio as though it applied to their own workloads. The direction of the finding, however, is clear: generality carries an energy premium, and that premium is paid on every query.

The scaling arithmetic follows from this. A district's annual inference footprint is approximately the product of per-query energy, the number of queries per student, the number of students and the carbon intensity of the electricity used. Each term is uncertain. Per-query energy varies with model size, response length and whether images or long documents are generated. Query

volume depends on pedagogy and on whether AI is embedded passively in every application or invoked deliberately. Grid intensity varies by region and by hour. Schools almost never observe the first and last terms directly, because they purchase access to remote services. This opacity is not incidental. It follows from the structure of the compute market, in which a few providers control both the infrastructure and the information about it (see Q350).

Freshwater is the least visible of the three footprints and, for many communities, the most locally consequential. Li and colleagues (2023) argued that while AI's carbon footprint has attracted public scrutiny, its water footprint, covering both withdrawal and consumption, has largely remained under the radar. They estimated that training GPT-3 in Microsoft's state-of-the-art United States data centres could directly evaporate 700,000 litres of clean freshwater. They noted that such information had been kept secret rather than disclosed. Looking forward, they projected that global AI demand could account for 4.2 to 6.6 billion cubic metres of water withdrawal in 2027, more than the total annual withdrawal of four to six Denmarks or half of the United Kingdom. These are projections, not measurements, and they depend on assumptions about demand growth and cooling practices. They nonetheless establish that water belongs in any honest accounting of educational AI.

The distinction between withdrawal and consumption matters for school decision-makers. Withdrawn water may be returned to its source; consumed water, largely through evaporation in cooling, is lost to the local basin. Water also follows the location and timing of computation in ways that carbon accounting does not fully capture. A data centre in a water-stressed region during a hot season may impose a heavier local burden than the same workload elsewhere, even where carbon intensity is similar. The two footprints can trade off against each other, and optimising for one does not guarantee improvement in the other. What remains unclear is how much of the water cost of a typical educational query falls on communities near data centres, and how that burden is distributed across regions. Schools that procure AI as an undifferentiated service have no way of knowing whether their students' homework help is drawing on stressed aquifers. That is a strong argument for making water disclosure a procurement requirement rather than a matter of goodwill.

Evidence specific to education is thinner and mostly concerns recognition rather than measurement. Leal Filho and colleagues (2026) combined a bibliometric analysis of 461 peer-reviewed publications indexed in Scopus between 2014 and 2025 with a multiple-case study of selected research-intensive universities. Their premise was that the environmental implications

of AI in higher education remain poorly understood at the institutional level. They also argued that, despite a growing literature on the energy and carbon of AI systems, little is known about how universities recognise or address these concerns. If research-intensive universities, which have sustainability offices and technical expertise, struggle to account for AI's footprint, the challenge for primary and secondary systems with fewer resources is likely greater. Vera Vera and colleagues (2026) conducted a systematic review under PRISMA 2020 using an adapted PICoS framework. They synthesised evidence on the algorithmic carbon footprint of AI tools in environmental education programmes and framed the tension between the pedagogical opportunities AI creates and concerns about data-centre energy and physical infrastructure. That such a review was needed even within environmental education, the field most attuned to these questions, suggests that carbon auditing of educational AI is far from routine practice.

Broader economic evidence points in a direction worth noting but should be interpreted cautiously. Balci, Gürel and Okur (2025) analysed 53,081 firm-year observations from 15 innovation-leading economies between 2003 and 2022 using system GMM. They found that artificial intelligence capability was associated with higher ecological footprint intensity and weakened the footprint-reducing effect of profitability, while education quality was associated with lower intensity and strengthened that channel. These are firm-level associations, not evidence about schools or student queries. They do not show that AI causes higher footprints in any particular setting. They are consistent, however, with the concern that AI adoption without deliberate governance tends to add environmental load rather than subtract it.

The human side of the problem is literacy. Baş and colleagues (2026) examined the relationship between pre-service teachers' AI literacy and their ecological footprint awareness. They observed that these competencies have largely been studied as separate domains, even though both are emphasised in contemporary educational and sustainability frameworks. Fern (2024) argued from more-than-human theory that sustainability, alongside originality and equality, should be part of the dialogue that places students' learning at the centre of generative AI integration. Kalota (2024) offered educators a primer on the underlying concepts of large language models. Such conceptual grounding is a precondition for teachers to understand why model size matters at all. Together these works suggest that right-sized compute is a curricular question as well as a technical one. Teachers who do not understand that a large general model and a small specialised tool differ in cost cannot make informed choices for their classrooms.

A right-sized compute policy turns these findings into institutional rules. It need not wait for precise per-query figures, because its central principle rests on the most robust result available: general-purpose systems carry an energy premium over task-specific ones (Luccioni, Jernite and Strubell, 2024). The policy can be built around five commitments.

The first is task matching. Schools should audit what students and teachers actually use AI for and route each category of task to the least resource-intensive tool that performs it adequately. Spelling and grammar support, vocabulary lookup, simple classification of responses, and retrieval from a curated course library rarely require a frontier general model. Open-ended tutoring dialogue, complex feedback on extended writing, or multimodal accessibility support may justify larger systems. This distinction matters for equity, because some of the most valuable uses, such as alternative representations for learners with disabilities, may legitimately demand more capable models (see Q313). Right-sizing is not uniform minimisation. It is proportionality between educational value and environmental cost.

The second is deliberate invocation. Much query volume comes from AI features embedded by default in learning platforms, generating summaries or suggestions that nobody requested. Turning such features off by default, and invoking AI when a learner or teacher chooses to, reduces the volume term of the scaling equation directly. It also supports students and families who decline AI for principled reasons (see Q111).

The third is disclosure in procurement. Following the reporting norm that Strubell and colleagues (2019) advocated for researchers, and given the secrecy Li and colleagues (2023) documented around water, districts can require vendors to report estimated energy, carbon and water per unit of use. Vendors should also state the regions where computation occurs and the methodology behind their estimates. Patterson and colleagues (2021) showed how sensitive such estimates are to detailed information, so contracts should ask for the assumptions as well as the figures. Collective purchasing across districts strengthens this bargaining position. These costs also belong in the broader financial weighing of AI against competing needs (see Q267).

The fourth is temporal and spatial awareness. Where providers allow it, non-urgent batch tasks such as generating question banks or processing assessment data can be scheduled for times and places with cleaner electricity and lower water stress. Schools have limited direct control here, but asking the question signals demand.

The fifth is institutional accounting. Following the gap Leal Filho and colleagues (2026) identified, AI use should appear in a school's sustainability reporting even if initial estimates are rough. Documenting estimated usage creates the baseline against which right-sizing can be evaluated.

Several things remain unknown, and honest policy should say so. Few studies have measured the per-query footprint of educational AI as students actually use it, with realistic prompt lengths, response sizes and session patterns. It remains unclear whether efficiency gains in hardware and model design will outpace growth in query volume, or whether cheaper inference will simply invite more use. The firm-level association reported by Balci, Gürel and Okur (2025) hints at the latter risk but cannot settle it. Water projections for 2027 rest on demand assumptions that may prove too high or too low. Nor does the evidence yet show that smaller, task-specific tools deliver equivalent learning outcomes in classrooms. The energy comparison is better supported than the pedagogical one, and right-sizing that degrades learning would be a false economy. These gaps call for paired evaluation: whenever a school substitutes a smaller model for a larger one, it should measure both environmental savings and educational effects.

There is also a conceptual risk. The very notion of what counts as intelligent performance, and therefore what counts as an adequate model, is historically produced and embedded in evaluative infrastructures (Olier, 2026). Benchmarks that reward ever-larger general capability can make right-sized tools appear deficient even when they serve educational purposes well. Schools should define adequacy in terms of learning goals rather than leaderboard rankings. Right-sized compute is ultimately a governance stance. It treats computational capacity as a shared, finite resource whose use must be justified by educational value, and it insists that the electricity, carbon and water behind a student's query are part of the cost of education, not an externality to be ignored.

Q349 Who performs the hidden human labor behind "autonomous" educational AI—from Global South data annotators and RLHF raters to teachers whose unpaid pedagogical artifacts are scraped for training?

16 citations · 16 sources · 4 cross-references

Claim 1 disputed

The hidden human labor behind "autonomous" educational AI is performed by three overlapping groups. The first is outsourced data workers, many recruited through crowdsourcing platforms and business process outsourcing firms in Latin America, South Asia and elsewhere in the Global South, who generate and annotate training data. The second is the raters and verifiers who evaluate model outputs and correct them. The third is the teachers, students and writers whose human-produced texts, judgments and pedagogical habits make up the data these systems learn to imitate. The language of autonomy hides all three. Tubaro, Casilli and Coville (2020) offer the most useful map of this terrain. Drawing on qualitative data from multiple sources, they argue that platform micro-work spans three poles: artificial intelligence preparation, artificial intelligence verification and artificial intelligence impersonation. On this account human workers do more than set up systems that later run unattended. They remain inside the operating loop, labeling inputs, checking outputs and sometimes standing in for the machine itself. The impersonation pole is the most unsettling for

education. When a system marketed as automated in fact relies on people completing or correcting its responses, the boundary between machine tutoring and outsourced human tutoring becomes blurred, and learners may never know which they received.

For education this matters because the sector has largely received generative AI as a finished product: a tutor, a feedback engine, a lesson-planning assistant. Graham, Alyanak and Valente (2025) make the point directly for higher education. University instructors who bring large language models into their teaching, they argue, must face the overlooked labor of cloudworkers and data workers whose contributions make these systems function. Warr and Heath (2025) approach the same fact from the other direction. Because large language models are trained on human data, they carry a "hidden curriculum" of social assumptions that appears objective but is not. Taken together, these accounts move the question away from whether AI replaces human work and toward whose work is being absorbed, under what conditions, and with what recognition.

The best-documented layer is outsourced data annotation. Miceli and Posada (2022) studied three platforms operating in Venezuela and a business process outsourcing company in Argentina. They observe that organizations very often outsource data work, defined as generating and annotating data and evaluating outputs, through such intermediaries. Borrowing Foucault's notion of the dispositif, they describe a "data-production dispositif": an arrangement of discourses, actions and objects strategically disposed to reproduce power/knowledge relations in both data and labor. The framing is analytically important. It treats the conditions of annotation as part of what the data are. The categories a worker applies, the instructions a worker follows and the speed demanded of that worker all shape the dataset, and so they shape the model. The dispositif lens also explains why such arrangements persist. Discourses of efficiency and objectivity present annotation as mechanical, which makes the judgment it requires, and the workers who exercise it, easy to overlook.

Wang, Prabhat and Sambasivan (2022) reach a congruent conclusion for India. Following a grounded approach, they conducted three sets of interviews with 25 annotators, 10 industry experts and 12 ML/AI practitioners. They found that annotators' work is dictated by the interests, priorities and values of others above their station. Their study is also notable for widening the lens. Earlier human-centred research had largely examined annotators' subjectivity, bias and efficiency, treating the annotator as a source of error to be controlled. Wang and colleagues instead ask what annotators aspire to and how industry hierarchies

constrain them. Their title, "Whose AI Dream?", names the asymmetry precisely: the people who make the data are rarely the people whose aspirations the resulting systems serve.

These studies do not concern educational AI specifically, and that limit should be stated plainly. None of the empirical work discussed here traces a particular tutoring product back to a particular annotation workforce. What the evidence does establish is that general-purpose machine learning depends on outsourced data work organized through platforms and intermediaries, frequently located in the Global South. Since most educational generative AI is built on general-purpose models, the inference that education inherits this supply chain is reasonable. The specific composition of that chain for any given classroom tool, however, remains unclear.

A second layer consists of evaluation and verification: the raters who judge whether outputs are accurate, safe or helpful, and whose preferences are used to refine model behavior. In the frameworks above, this work falls under what Tubaro and colleagues (2020) call verification and under the "evaluating outputs" component of data work identified by Miceli and Posada (2022). The educational relevance is direct. A system's pedagogical tone, its willingness to refuse, and its sense of what counts as a good explanation are shaped in part by human judgments made far from any classroom, by workers whose own educational contexts and instructions are seldom disclosed.

Human verification also reappears downstream, inside educational and professional institutions themselves. Marty and colleagues (2025) evaluated GPT-4's patient-level education on benign anorectal conditions against verified online medical literature, using a modified EQIP instrument scored by three independent educated reviewers. ChatGPT achieved a median overall score of 22/36 (61%) across topics. The study's authors frame this as performing well. Read through a labor lens, the study shows something else too. Establishing whether AI-generated educational content can be trusted still required trained human evaluators applying structured criteria. A 61% median score is hardly a level at which educators could responsibly stop checking, which means the verifying work is likely to be continuous rather than a one-off cost. Every institutional audit of AI output, whether by a curriculum office, a teacher checking a generated worksheet, or a lecturer reviewing machine feedback, adds unpaid or under-recognized verification labor to the system's apparent autonomy.

One frontier in this area is the attempt to automate annotation itself. Alostad (2025) evaluated whether open large language models could automate stance detection in the Kuwaiti dialect through zero-shot and few-shot prompting. The work was motivated by the scarcity of annotated datasets and specialized tools for low-resource languages. Work of this kind is sometimes read as evidence that human annotation will become obsolete. It is more accurately read as a shift in where human labor sits. Someone must design prompts, select examples and judge whether model labels are good enough, and the models doing the labeling were themselves built on earlier human-annotated data. Whether such substitution reduces total human labor, relocates it, or degrades quality for low-resource languages is not yet established. Feeding model outputs back into training also raises the recursive risks discussed elsewhere (see Q351).

The third layer, teachers whose pedagogical artifacts become training material, is the least empirically documented and the most politically charged for education. The general mechanism is well understood. Generative models acquire their capacities by learning from large bodies of human-generated content. Nasr and colleagues (2025) describe generative AI as transformative precisely because it can mimic human-generated content. Warr and Heath (2025) show what happens when that human content carries social bias. In their technology audit, large language models scoring student writing assigned lower scores when the student was described as attending an "inner-city school" or as preferring rap music. The point for the present question is that human labor sits behind such behavior. The models learned to grade by absorbing human writing about students, schools and quality, much of it plausibly produced by educators. The labor returns to the classroom stripped of authorship and carrying its prejudices.

The specific claim that teachers' lesson plans, worksheets, rubrics and forum posts are scraped without consent or compensation is widely asserted in public debate. The evidence here does not quantify it. Few studies have traced how much classroom material enters training corpora, and the relevant provenance information is generally not disclosed. Scholars should therefore treat the scale of educator-sourced training data as an open empirical question. What can be said with more confidence concerns how AI redistributes pedagogical work. Mohamed (2026), surveying 270 participants in graphic design education and interviewing 12 academics and practitioners, frames generative AI as redistributing the activities through which disciplinary expertise is learned, practised, demonstrated and assessed. Fern (2024) proposes a "more-than-

human ecology" for higher education built around originality, equality and sustainability, concepts that presuppose attention to whose original work these systems rest on.

Teachers' perceptions point to a related tension. Day (2026) analysed forum contributions from 76 preservice teachers in a postgraduate programme in China, examining their views on whether AI could replace human teachers. Day's participants were themselves future teachers, so their reflections on replacement implicitly concern the value of the very professional knowledge that training data may already contain. Hung and Chuang (2026) studied a human–AI co-teaching model in a quasi-experimental grammar course, positioning instructors and AI as sharing pedagogical roles. Both studies, in different ways, cast AI as a quasi-colleague. Neither addresses the fact that the "colleague" was assembled partly from the uncredited output of teachers as a profession. The co-teaching frame can therefore reproduce the invisibility it might otherwise expose. Which aspects of teaching resist this kind of absorption is a separate question (see Q361).

These layers converge in a political economy in which the Global South often occupies a double position: supplier of low-cost data labor and recipient of AI products designed elsewhere. Several education studies examine the reception side without connecting it to the supply side. Olaniyan, Martins and Al Maqrashi (2026), in semi-structured interviews with ten university students, five from the Global North and five from the Global South, use epistemic justice and postcolonial frameworks to examine how generative AI mediates knowledge hierarchies. With a sample of ten, their findings are suggestive at most. Felix (2026) argues that human capital, a concept of Global North origin, needs reframing for Global South higher education policy in the age of AI. Autenrieth, Schluchter and Schulz (2026) propose "AI divide" and "ability divide" concepts. They argue that exclusion arises from differential capacities to perceive, interpret and mobilize AI-mediated affordances, not only from unequal access or skills. Sozon and Parnther (2025), in a PRISMA-guided review of 60 articles, examine research integrity in the Global South under technological change and institutional pressure. Their review matters here because pressures on research integrity and the arrival of AI tools affect the same institutions that are asked to adopt educational AI responsibly.

Read alongside the labor studies, this work points to an unresolved structural question. The same regions whose workers annotate and verify data may receive systems that encode others' epistemic priorities, a pattern Wang and colleagues (2022) document at the level of the individual annotator. Whether this double position constitutes a durable form of extraction, or a

transitional arrangement that local capacity-building can reverse, is genuinely contested. The available evidence cannot settle it. It also connects to the concentration of compute and model ownership among a few firms (see Q350), which determines who captures the value of this distributed labor.

For educational governance, the practical implication is that procurement and pedagogy cannot treat AI tools as labor-free. Graham, Alyanak and Valente (2025) propose the Fairwork scoring system, developed through Fairwork's cloudwork and AI research, as both a methodology and a heuristic for ethical engagement. They urge instructors and students to advocate for better working conditions in AI supply chains. This gives institutions a concrete lever. Supply-chain labor standards can be added to the evaluation criteria applied to classroom AI, alongside the technical and oversight safeguards discussed elsewhere (see Q087). Miceli and Posada's (2022) analysis suggests a further requirement: transparency about how data were produced, by whom and under what instructions. Data-production conditions shape model behavior, including the kinds of grading bias Warr and Heath (2025) uncovered.

Pedagogically, hidden labor can itself become curriculum. Teacher educators who already audit AI for bias, as Warr and Heath recommend, can extend those audits to the provenance of the systems themselves. Students can ask who labeled, who rated and whose writing was learned, not only what the system outputs. Such exercises need not be abstract. A class might trace a single AI-generated piece of feedback back through the categories, rating rubrics and source texts that probably shaped it, and discuss what each human contribution was worth and who was paid for it.

Several things remain unknown. No study discussed here measures annotators' wages or conditions for educational products specifically. The volume of teacher-authored material in training data is unmeasured. It remains unclear whether automated annotation will reduce or merely displace human labor. Until such evidence exists, the most defensible position is a precautionary one. Educational AI should be described and governed as a sociotechnical system that depends on human work, and institutions adopting it share responsibility for the conditions under which that work is done.

Q350 How does the concentration of frontier AI compute among a handful of hyperscale technology corporations create structural dependency risks for public education systems—and what is the case for sovereign or public-option academic AI infrastructure?

13 citations · 13 sources · 4 cross-references

Claim 1 disputed

The concentration of frontier AI compute in a handful of hyperscale corporations creates structural dependency for public education because a system that adopts generative AI is not buying a tool. It is entering an ongoing relationship with the few firms that control the chips, data centres, model weights, pricing and terms of service on which every student query depends. The case for sovereign or public-option academic infrastructure therefore does not rest on matching frontier capability. It rests on keeping public bargaining power, auditability, environmental accountability and pedagogical self-determination in public hands. That argument is analytically strong, but its empirical base is still thin.

The economic root of concentration was identified early. Strubell, Ganesh and McCallum (2019) showed that the accuracy gains of large language models depend on exceptionally large computational resources. Those resources make the models costly in two ways: financially, through hardware, electricity or cloud compute time, and environmentally, through the carbon footprint of the hardware. When capability scales with capital in this way, the number of actors able to train frontier systems shrinks, and everyone else becomes a renter of capability. Patterson and colleagues (2021) estimated the energy use and carbon footprint of several large models, including T5, Meena, GShard, Switch Transformer and GPT-3. They stressed that such estimation is challenging without detailed information. That caveat matters for education: the information needed to assess these systems sits largely with their operators.

It helps to separate several layers of dependency that are often run together. Technical lock-in arises when curricula, assessment workflows and teacher practices are built around one provider's interface and model behaviour. Price dependency arises when public budgets absorb per-seat or per-token charges set unilaterally. Governance dependency arises when acceptable-use rules, content filters and data-retention terms are written by vendors rather than education authorities. Epistemic dependency is subtler: the defaults of a commercial model quietly shape what counts as a good explanation, essay or answer for millions of learners. None of these layers is unique to AI. Compute concentration intensifies all of them at once, because the bottleneck sits below the level of any single application.

The closest empirical precedent is the platformization of schooling that preceded generative AI. Kerssens and van Dijck (2021) examined online environments in Dutch primary schools. They asked how platformization works as a vehicle for integrating public online education into a private global digital infrastructure. The Netherlands is a deliberately hard case: a traditionally strong public-school system. Even there, the authors found that platformization had substantially affected the precarious balance between private and public interests. They framed the remedy as governance of educational technology at several levels at once, rather than as a choice individual schools could make alone.

That finding carries directly into the AI era. If a well-resourced public system with strong institutions could not keep that balance through school-level procurement, there is little reason to expect better outcomes with frontier AI. Here the provider controls not only data storage and workflow but the generation of instructional content and feedback. A learning management

system holds records of learning. A hosted language model increasingly takes part in the cognitive work itself, which raises the stakes of who owns and configures it.

The pandemic showed how such dependencies form. Williamson, Eynon and Potter (2020) treated the turn to digital technologies and distance education during the coronavirus emergency as a matter of politics as much as pedagogy and practice. The structural lesson is that emergency or hype-driven adoption tends to lock in infrastructural choices before public deliberation catches up. Arrangements adopted as stopgaps then become defaults that are costly to unwind. Generative AI has arrived with a similar sense of urgency. Institutions are under pressure to provide access quickly, and the fastest route is almost always an enterprise agreement with an incumbent hyperscaler or its model partners. How durable those arrangements will prove remains unclear. The platform precedent suggests caution about assuming that exit will be easy later.

Dependency extends to knowledge about one's own environmental impact. Schools and universities increasingly carry sustainability commitments, yet they cannot verify the footprint of services run in data centres they do not own. Li and colleagues (2023) estimated that training GPT-3 in Microsoft's state-of-the-art U.S. data centres could directly evaporate 700,000 litres of clean freshwater. They observed that such information had been kept secret. They also projected that global AI demand could account for 4.2 to 6.6 billion cubic metres of water withdrawal in 2027, more than the total annual withdrawal of four to six Denmarks or half of the United Kingdom. These are projections built on estimation, not measured inventories, and should be read as orders of magnitude. Their point for governance is that the figures had to be reconstructed by outsiders because operators did not disclose them.

Inference matters more for education than training, since student use is a continuous stream of queries rather than a one-time event. Luccioni, Jernite and Strubell (2024) offered what they describe as the first systematic comparison of the ongoing inference cost of different categories of machine learning systems. They contrasted task-specific fine-tuned models with general-purpose multi-task models, and argued that the ambition of generality comes at a steep environmental cost in energy and carbon. Their analysis suggests that much of the footprint of educational AI is a design choice rather than a fixed price of progress. Routing routine tasks such as summarisation or classification through the largest general-purpose model is a habit encouraged by bundled commercial offerings.

An institution dependent on a single frontier provider is poorly placed to make that choice. It typically lacks control over which model answers which request, has no metered visibility into energy or water use, and cannot negotiate siting decisions. The detailed accounting of student-scale footprints and right-sized compute policies is treated elsewhere in this volume (see Q348). The point here is political-economic: under concentrated compute, environmental accountability is outsourced along with the computation itself.

The fast-growing empirical literature on AI in education rarely sees this structural layer. Most studies examine adoption through technology-acceptance frameworks centred on the individual user. Mbona and Msosa (2026) used an extended Technology Acceptance Model to study factors associated with AI adoption among students at one South African university. Sova and colleagues (2024) surveyed Romanian economics students on perceived efficacy, usefulness, access to tools and concerns about AI. Napal Fraile and Badiola (2024) applied a UTAUT2 questionnaire to 60 trainee teachers in two northern Spanish universities. They reported good knowledge and perceived ease of use, but low motivation, intention to use and effective use. Salhab (2025) combined an ethics-attitude scale completed by 88 instructors with interviews of 17 instructors at a Palestinian technical university to map potentials, ethical use and challenges.

These studies are useful, but they tend to treat the AI product as a given and ask whether individuals will accept it. That framing makes it hard to see who owns the infrastructure and on what terms access is granted. The evidence that does touch institutional conditions points towards the dependency problem without naming it. In a non-probability sample of 123 Swiss adult educators, Güler (2026) found active AI use reported by 82.1 percent. Usage frequency was associated mainly with self-reported AI knowledge rather than demographics. The most prominent constraints were privacy and security concerns and limited perceived institutional support. This is a correlational, cross-sectional snapshot. Still, it fits a pattern in which individuals adopt commercial tools faster than institutions can provide governed alternatives, leaving data protection to personal judgement.

Access is the other point where structure becomes visible. When Sova and colleagues (2024) treat access to tools as a variable, they acknowledge that availability is unevenly distributed. Under concentrated compute, that distribution is set by commercial pricing tiers rather than public entitlement. The resulting inequalities between households that can buy premium models and those that cannot are examined in detail elsewhere (see Q334). A public option is one of the

few levers that addresses the problem at the infrastructural level rather than through compensatory classroom measures.

The case for sovereign or public-option academic AI infrastructure can be stated in four parts.

The first is bargaining power. An education system that can credibly run capable models on infrastructure it controls negotiates with commercial providers as a customer with alternatives, not as a captive. This holds even if it continues to buy frontier services for some purposes. Such infrastructure might take the form of shared academic compute, pooled procurement across districts or national systems, or hosting of openly available models.

The second is right-sizing. The comparison by Luccioni, Jernite and Strubell (2024) suggests that task-specific models can carry out bounded functions with a smaller footprint than general-purpose systems. Many core educational workloads are bounded in exactly this way: feedback on structured writing, translation of materials, retrieval over curricular content. A public option designed around such workloads could align sustainability with sovereignty instead of trading one against the other. The early warning by Strubell, Ganesh and McCallum (2019) about the financial and environmental costs of scale applies as much to procurement as to research.

The third is pedagogical configurability. Montebello (2026) argues that generative AI decouples assessment performance from cognitive engagement, so that learners can produce assessment outputs without the cognitive work assessment once implicitly enforced. Responding to that shift requires tools configured around engagement rather than output production: models that scaffold, withhold or prompt reflection by design. Commercial general-purpose assistants are optimised for broad user satisfaction, and education authorities have limited influence over their defaults. Sanche and colleagues (2026) developed an exploratory 23-item item pool on student susceptibility to AI, covering over-reliance, misuse and protective reflective practices. They surveyed 408 students recruited by convenience sampling at six Ghanaian institutions. Instruments like this become far more useful when institutions can connect them to interaction data they lawfully hold. Under vendor-controlled infrastructure, that connection is usually unavailable.

The fourth is democratic governance. Kerssens and van Dijck (2021) concluded that edtech must be governed at multiple levels to serve the public good. Public infrastructure is the condition under which multilevel governance has something to govern. Audit rights, data-retention rules, model-update schedules and environmental disclosure become matters of public

policy rather than contract negotiation. The fiscal side of this choice, including how to weigh such investment against other educational needs, is addressed elsewhere (see Q267).

The counter-case deserves equal weight, and the evidence does not settle the dispute.

Public options may lag frontier capability, possibly leaving publicly served students with weaker tools than those whose families or institutions buy commercial access. That would reproduce the very divide sovereignty was meant to close. Building and maintaining compute is expensive and technically demanding. Smaller or poorer systems may be unable to sustain it without regional pooling. Duplicating data-centre capacity also has its own environmental cost, which the footprint estimates of Patterson and colleagues (2021) and Li and colleagues (2023) make clear. Public ownership is not inherently greener; it is only more accountable.

"Sovereignty" is also politically ambiguous. National control over educational AI can serve public deliberation, but it can equally serve surveillance or ideological steering of curricula. Infrastructure arguments must therefore be paired with independent oversight rather than treated as self-justifying.

What the evidence does not yet show is equally important. Few studies have compared learning outcomes, costs or environmental performance between publicly hosted and commercially hosted educational AI. The adoption literature reviewed above measures individual attitudes in mostly single-site, convenience or non-probability samples. It cannot reveal infrastructural effects. The platformization research documents dependency in prior generations of edtech, but how far its lessons transfer to model-based services remains unclear. The environmental figures available are largely external estimates, precisely because operators have not disclosed primary data.

The most defensible position is therefore conditional. Concentrated compute creates real structural risks for public education: lock-in, price exposure, governance displacement, epistemic homogenisation and unaccountable environmental costs. These risks are serious enough to justify building at least a minimal public capability. Even a modest one can preserve the option to exit, set environmental and pedagogical standards, and anchor negotiations. Whether a fuller sovereign stack is worth its cost will depend on evidence not yet gathered, and on how the wider landscape of AI provision evolves over the coming decade (see Q352).

Q351 What is "model collapse" (the degradation of future AI systems trained on recursively generated synthetic text and imagery), and why does it make the preservation of authentic, human-created educational and scholarly archives an urgent civilization-scale priority?

14 citations · 14 sources · 5 cross-references

Claim 1 disputed

Model collapse is the progressive degradation that occurs when generative models are trained, generation after generation, on text and images produced by earlier models rather than by people, so that each successor learns an increasingly distorted copy of the original human record. It makes authentic, human-created educational and scholarly archives an urgent priority

because, if the effect holds at scale, those archives become the only dependable reference against which machine drift can be detected, measured and corrected. Shumailov and colleagues (2024), writing in Nature, framed the problem around what may happen to "GPT-n" once large language models contribute much of the text found online. Their title states the conclusion plainly: AI models collapse when trained on recursively generated data.

The underlying logic is statistical rather than mysterious. Any generative model is a finite, imperfect approximation of the data it was trained on. Its outputs over-represent what it has learned to treat as probable and under-represent what is rare. When a later model learns from those outputs, it inherits the approximation and adds errors of its own. Repeated across generations, the loop can wear away the unusual, the minority and the idiosyncratic, which are often precisely what scholarship and education most need to preserve. A dialect, a minority scholarly tradition or an uncommon but correct method of solving a problem may appear only rarely in training data. A model that slightly underweights it produces outputs in which it is rarer still, and the next model may lose it entirely.

Alemohammad and colleagues (2023) gave the image-domain version a memorable name, describing such systems as "self-consuming" or autophagous loops that can "go MAD". Their analysis used state-of-the-art generative image models and compared three families of loops. These differed in whether real training data stayed fixed or were refreshed across generations, and in whether samples from earlier models were biased to trade diversity for quality. The design itself carries the central conceptual point. Collapse is not a defect of any single model. It is a property of a data ecology, governed by how much genuine human material keeps entering the cycle.

How inevitable collapse is remains genuinely disputed, and the dispute matters for policy. Gerstgrasser and colleagues (2024) observe that earlier investigations largely assumed new synthetic data replace old data over time. They argue that a more realistic assumption is accumulation, in which synthetic material is added alongside the existing human corpus rather than substituted for it. Under that assumption, as their title puts it, the "curse of recursion" can be broken by accumulating real and synthetic data together. On this reading, the catastrophic trajectory depends on a particular and perhaps avoidable practice: discarding or diluting the human record.

The two positions are less opposed than they first appear. The accumulation argument does not show that synthetic data are harmless. It shows that retaining real data can protect against degradation. Its protective mechanism is the continued availability of authentic human material, which is the same variable that the autophagous-loop framing of Alemohammad and colleagues (2023) treats as decisive. Both lines of work therefore locate the safeguard in the same place.

Nor is the engineering problem settled. Shabgahi and colleagues (2026) state that the causes of model collapse are increasingly understood, yet effective mitigation strategies remain scarce. They offer their own approach to fending off recursive-training failure, a sign that the field treats collapse as a live risk rather than a solved curiosity. What the evidence does not yet show is how these laboratory dynamics translate to the messy, partially curated pipelines actually used to train frontier systems. In those pipelines, the ratio of human to synthetic content is rarely disclosed and may be unknown even to developers. The prudent inference is conditional. Collapse is avoidable chiefly to the extent that real human data are kept, identified and kept accessible.

The urgency comes from the convergence of two trends: a finite stock of public human text, and a rising share of machine-generated material in new data. Villalobos and colleagues (2022) estimated the total stock of public human-generated text and forecast demand from training trends. They concluded that, if current development trends continue, models will be trained on datasets roughly equal in size to that stock between 2026 and 2032, or slightly earlier if models are overtrained. These are forecasts resting on extrapolated trends, not measurements, but their implication is clear. Developers will face pressure to look beyond freshly scraped public human text. The authors themselves explore how progress might continue once human-generated datasets can no longer be scaled.

Synthetic data is the most obvious substitute. Shabgahi and colleagues (2026) cite projections suggesting that most available new training data could be machine-generated by 2030. That figure should be read as a projection reported in the literature, not an observed fact. Even so, it describes an information environment in which the default sample of "recent text" is increasingly synthetic.

The appeal of synthetic data is real and often legitimate, which is why the problem cannot be solved by prohibition. Moëll and Sand Aronsson (2026) prompted a large language model to produce first-person clinical narratives paired with target scores on the PHQ-9, LSAS and PCL-

5. No real patients or clinical notes were used, and the narratives were manually screened for coherence and label alignment. Their stated rationale was a privacy-preserving path for method development when real clinical text is unavailable. Education faces analogous privacy constraints around student writing, so similar strategies will be tempting there.

The distinction that matters is between bounded, transparent uses of synthetic data for prototyping and the unlabelled seepage of synthetic content into the general corpus from which future models learn. The temporal dimension compounds the difficulty. Models trained on ageing human data already struggle with fast-moving topics (see Q240), and a corpus that is both stale and increasingly synthetic would worsen that limitation.

Educational and scholarly archives occupy a distinctive position in this ecology for three reasons. They are dense with careful, verified, often rare knowledge. They carry institutional markers of provenance such as authorship, dates and editorial review. And they are themselves rapidly filling with machine-generated material.

Nitu and Dascalu (2024) state the stakes for libraries directly: ensuring the authenticity of texts within digital libraries has become a paramount concern. They built a corpus of approximately 60,000 Romanian documents comprising human-written samples and texts generated by six distinct large language models using three generation methods. The corpus spans books, news, legal, medical and scientific publications. Their exploratory analysis found differences between human-authored and generated texts in lexical diversity and textual complexity. That finding suggests synthetic text is measurably different, and also that detection is a technical undertaking requiring dedicated resources. The work is especially relevant because it addresses a lower-resourced language. For such languages the human record is smaller, so contamination of the archive is proportionally more consequential.

The educational record is also being reshaped at its point of production. Da Silva (2026) frames generative AI in higher education as creating new challenges for academic integrity, intellectual authorship and the development of critical thinking. That work evaluated a pedagogical intervention with 50 graduate students across three cohorts in Engineering and Business Administration master's programmes between February 2025 and June 2026. Seghier's (2026) PRISMA-guided systematic review of architectural education reports that research on how generative AI affects authorship, assessment and studio culture is limited, and that evidence-

based institutional guidance remains scarce. Jukiewicz (2025) likewise notes emerging concerns about generative AI's effects on educational quality and fundamental academic values.

These studies concern integrity in the classroom, not model training. Their relevance here is that they document a growing uncertainty about who, or what, authored the essays, designs, theses and assessments that institutions archive. Even evaluation is becoming machine-mediated. Kortemeyer (2024) examined how a general-purpose pre-trained model, GPT-4, performs on automated short-answer grading, a task long handled by specially trained models. Bhardwaj and Sharma (2026) compared AI and LLM-based learning systems with traditional methods among 350 students and faculty in Indian institutions, focusing on comprehension, retention, personalization and critical thinking. Such adoption suggests that machine-assisted material will form a growing share of what institutions produce and retain. When student work is drafted with assistance and then assessed by machines, the archive's value as a record of human understanding depends on knowing which parts are which. Integrity policy and archival policy therefore converge on the same requirement: reliable provenance (see Q278 on authentication and impersonation).

If the protective factor identified across the collapse literature is the continued availability of identifiable human data, then preserving that data is a form of infrastructure. Its benefits are collective, long-term and poorly captured by markets. This is why the framing appropriately rises to the civilisational scale without becoming apocalyptic.

The accumulation result of Gerstgrasser and colleagues (2024) implies that what must be protected is not merely the existence of human text somewhere. It is a curated, retained, distinguishable body of it that future developers and researchers can return to. Universities, libraries, examination bodies and education ministries hold exactly such material, much of it dated and attributed in ways that predate generative AI. A corpus of human writing whose provenance can be established is, in this light, a scarce and appreciating asset. The forecasts of Villalobos and colleagues (2022) strengthen that conclusion, since they suggest the supply of fresh public human text is approaching its limits.

Several governance implications follow, though the evidence supporting each is still indirect. First, provenance metadata such as creation dates, authorship attestations and disclosure of AI assistance should be treated as part of the scholarly record rather than administrative overhead. Second, institutions should preserve versioned snapshots of their repositories, so that later

contamination does not overwrite earlier authentic states. Third, detection and characterisation research of the kind Nitu and Dascalu (2024) undertook deserves sustained public funding, particularly for smaller languages.

Fourth, the question of who controls these archives cannot be separated from the political economy of compute. Valuable human corpora held by public institutions could either anchor public-interest models or simply be absorbed by a few firms (see Q350). The teachers, students and scholars who produced the material also have claims that preservation policy must respect (see Q349).

Human-centred frameworks for educational AI already provide a natural home for these commitments. CARE-AI, proposed by Zulfiqar and Iqbal (2026), integrates pedagogical alignment, ethical governance and teacher and learner empowerment within a single socio-technical model for primary education. Stewardship of authentic learner and teacher work fits comfortably within such ethical-governance dimensions. Making it explicit would connect classroom-level responsibility to the system-level sustainability of the knowledge commons. Bellomo and Sun (2026) caution that claims of AI-driven "personalization" are often narrowly and ambiguously framed, contrasting consumer-oriented framings with a personalist tradition emphasising autonomy, dignity and integral human flourishing. That distinction bears on archives too: a record valued only as training fuel is treated as a consumable, whereas a record valued as evidence of human thought is treated as something owed care.

The limits of the present evidence should temper rhetoric without dissolving the case for action. The strongest demonstrations of collapse, including those of Shumailov and colleagues (2024) and Alemohammad and colleagues (2023), come from controlled recursive-training experiments. They do not come from audits of deployed systems. The accumulation critique by Gerstgrasser and colleagues (2024) shows that outcomes depend heavily on whether real data are retained. The finding by Shabgahi and colleagues (2026) that mitigation strategies remain scarce indicates that engineering responses are still immature. It remains unclear how large the synthetic share of real training pipelines already is, how quickly it is growing, and at what proportion degradation becomes practically significant for educational uses such as tutoring, feedback and assessment. Few studies have examined effects on minority languages or specialised disciplinary knowledge, where the human record is thinnest and the loss of rare material would matter most.

The argument for preservation does not, however, require certainty that collapse will occur. Every major line of evidence identifies retained, identifiable human data as the safeguard. Once lost, that data cannot be regenerated, because authentic records of how people reasoned, wrote and taught at a given moment cannot be produced after the fact. The asymmetry favours precaution. If collapse proves manageable, well-curated human archives remain invaluable for scholarship, history and education. If it proves serious, they become indispensable.

Educational institutions are among the few actors with both the material and the mandate to act on this asymmetry. That is why the question belongs in long-term governance alongside compute, energy and sovereignty. The broader catalogue of related risks, including data exhaustion and synthetic-content saturation, is treated elsewhere (see Q161). Here the narrower claim is that the human archive is the reference point all of those risks threaten, and that protecting it is a task for the present generation of educators and librarians.

Q352 Looking across a 10-year horizon (2026–2036), what structural scenarios—from ubiquitous ambient wearables and agentic swarms to a potential "Neo-Classical / Unplugged" schooling bifurcation—should long-term educational planners prepare for?

15 citations · 15 sources · 4 cross-references

Claim 1 disputed

Over the 2026–2036 horizon, long-term educational planners should prepare for a portfolio of at least four interacting structural scenarios rather than a single forecast. The first is an ambient-sensing scenario, in which wearables and immersive devices make continuous biometric and behavioural data a default feature of learning. The second is an agentic scenario, in which AI systems initiate, coordinate and execute multi-step instructional and administrative work. The third is a labour-market recomposition scenario that alters what schooling is understood to prepare young people for. The fourth is a bifurcation scenario, in which deliberately low-technology, 'neo-classical' or 'unplugged' schooling becomes a distinct and possibly stratified alternative to AI-saturated provision. These scenarios do not exclude one another. The most plausible decade is one in which all four advance unevenly, across systems and within them, so planning should rest on robustness and reversibility rather than on a bet about which future arrives.

This framing deliberately resists the forecasting style that dominates much commentary on AI in education. Selwyn (2022) argues that future-oriented discussion should concentrate on 'actually existing' AI rather than oversold speculative technologies. He also asks that it foreground the limits of AI in modelling social contexts and simulating human reckoning, autonomy and emotion, attend to the social harms of AI use, and recognise that claims about AI are value-driven. Scenario planning honours that caution when each scenario is anchored in present evidence and treated as a set of plausible pressures, not a destination. It also has to accept that the actors in schools do not move in step. Barbieri's (2026) five-wave survey of four Australian secondary schools spanning a broad socioeconomic range tracked teachers' and students' technology perceptions from 2021 to 2025, across the arrival of generative AI, and the study frames the result as diverging trajectories. Teachers and students experienced the same technological shock differently, and any ten-year plan that assumes a single 'school community' view of AI will misread its own constituency. A scenario portfolio also clarifies what planners

are actually deciding. Infrastructure, staffing and curriculum commitments made in 2026 will still be in place in the early 2030s, so the relevant test is whether each commitment remains defensible under every scenario, not merely under the one that currently seems most likely.

The ambient-sensing scenario is the least speculative, because its components already exist in research settings. Meini and colleagues (2025) conducted a PRISMA-guided systematic review of 43 studies that combined wearable devices, biometric data and AI algorithms in educational settings. They note that wearables provide reliable biometric measurements across contexts and that AI is increasingly used to analyse those data. The review describes the objectives, data types and methods of this work. It cannot tell planners whether such systems improve learning at scale, or what happens when measurement moves from a bounded study to an all-day, all-year infrastructure. That gap is the central planning problem. A device that is defensible as a research instrument becomes something different when it serves as permanent classroom furniture, feeding inferences about attention, stress or engagement into decisions about individual children.

The equity case for immersive and sensing technologies is real and should not be dismissed. Chimbo, Maguraushe and Ndlovu (2026) argue that many students with special educational needs still face rejection through rigid pedagogies, inaccessible content and limited support, despite commitments under Sustainable Development Goal 4. They contend that virtual reality and agentic AI could move education from episodic accommodation toward empowerment and equal opportunity. This is a conceptual argument rather than an outcome study. It nonetheless identifies the constituency for whom ambient and immersive systems may matter most.

Planners therefore face a genuine tension. The same sensing architecture that could personalise access for a disabled learner could normalise continuous physiological monitoring of every child, which is precisely the category of social harm Selwyn (2022) asks the field to foreground. Ambient systems are also always on, so their energy and data-transfer demands accumulate quietly, in ways that right-sized compute policies must anticipate (see Q348). The prudent preparation is to separate the accessibility function from the surveillance function in procurement and law now, before vendors bundle them into a single product. Such separation would let schools adopt assistive devices for individual learners on clinical or educational grounds without thereby authorising cohort-wide data collection, and it would give parents and regulators a clear line to defend.

The agentic scenario, sometimes described in popular discourse as 'swarms' of cooperating AI agents, poses the most direct challenge to existing governance. Evidence from adjacent professions is instructive. Aristidou (2026) characterises agentic AI in radiology as systems that can initiate, manage and coordinate tasks. She observes that debate has been dominated by two lenses: a displacement approach that predicts which jobs are at risk, and an automation-versus-augmentation approach that sorts tasks within jobs. Her reframing toward the reconfiguration of work is directly transferable to teaching. The useful planning question is how the bundle of teacherly work is reassembled when agents handle scheduling, feedback drafting, differentiation and parent communication, rather than whether teachers will be replaced.

The cognitive risks are clearer in professional education than in schooling. Hayes (2026) argues that as medical imaging moves from episodic decision support to workflow-based agentic architectures, the conventional dual-process account of intuitive and analytic judgement may need to become a 'Tri-System' framework. He names the attendant danger 'cognitive surrender'. This is a theoretical proposal, not a measured effect, but it describes a plausible failure mode for learners whose habits of judgement are still forming.

The security dimension is equally underappreciated. Radanliev, Santos and Maple (2026) argue that adversarial vulnerability must be reconceptualised for agentic systems. Their threat model extends from static input perturbations to autonomy, self-governance and closed-loop decision-making across perceptual, cognitive and executive layers. A school that delegates executive actions to agents inherits these attack surfaces, and dependence on a few external providers compounds the exposure (see Q350).

Evidence on learner response remains thin. Alqurni (2026) proposes an integrated model, drawing on the Technology Acceptance Model, Social Cognitive Theory and Self-Determination Theory, in which perceived AI agency, usefulness, trust, autonomy support and self-efficacy jointly shape self-learning behaviour. Saleem's (2025) bibliometric analysis records a rising trend of publication on agentic AI in business education. Rising publication signals attention, not demonstrated benefit. For school leaders, Kumar and Sarkar (2026) map AI integration onto instructional, managerial, strategic and relational leadership dimensions in a scoping review of 21 sources. That framework suggests agentic adoption is a leadership and institutional-design problem as much as a technical one. Each of these lenses implies a different preparation, from security audits to leadership training to student-facing guidance on when delegation is appropriate.

The labour-market scenario matters because it changes the purpose against which every other scenario is judged. Eloundou and colleagues (2024) estimate that roughly 1.8% of jobs could have over half their tasks affected by large language models with simple interfaces and general training. When likely complementary software developments are included, the share rises to just over 46% of jobs. The width of that range is itself the planning lesson: exposure depends heavily on surrounding tools, which are what the coming decade will build.

The experimental evidence on productivity is comparatively robust within its settings. Noy and Zhang (2023) randomly exposed half of 453 college-educated professionals to ChatGPT on incentivised writing tasks. Average completion time fell by 40%, output quality rose by 18%, and inequality between workers decreased. Brynjolfsson, Li and Raymond (2025) studied the staggered introduction of a conversational assistant among 5,172 customer-support agents. Productivity, measured as issues resolved per hour, rose by 15% on average, with substantial heterogeneity. Less experienced and lower-skilled workers improved in both speed and quality, while the most experienced saw small speed gains and small declines in quality. The authors also report evidence that the assistance facilitated learning and improved English fluency, particularly among international agents. Dell'Acqua and colleagues (2023), in a preregistered experiment with 758 consultants, introduce the concept of a 'jagged technological frontier'. AI assistance improved performance on some tasks and worsened it on others of seemingly similar difficulty within the same workflow.

For education, these findings cut in two directions. They suggest AI can compress novice-to-competent trajectories, which is an argument for integrating it. Yet the jagged frontier implies that learners must develop the judgement to recognise when they have crossed onto the wrong side of it, and that judgement is built through unassisted struggle. Beane's (2018) ethnography of robotic surgery is the sharpest warning here. Across a two-year, five-site comparative study and interviews at 13 teaching hospitals, he found that approved methods of learning through increasing participation worked in open surgery but proved insufficient in robotic practice. Trainees then turned to 'shadow learning' outside sanctioned routes. If AI similarly removes the entry-level tasks through which novices once learned, schools and universities may have to deliberately reconstruct apprenticeship that workplaces no longer supply. The evidence does not yet show how durable these productivity effects are, or whether they hold for adolescents rather than adult professionals. Planners should therefore treat these studies as signals about the

direction of workplace change rather than as forecasts of the specific skills that graduates in 2036 will need.

The 'Neo-Classical / Unplugged' bifurcation is the most contested scenario and the one least directly evidenced. Its logic, however, follows from the preceding sections. If agentic and ambient systems risk cognitive surrender, as Hayes (2026) argues, and if the jagged frontier rewards judgement formed without assistance, as Dell'Acqua and colleagues (2023) imply, then some families and institutions will rationally seek schooling that withholds AI during formative years. Such schooling would emphasise handwriting, oral disputation, memorised canons and craft apprenticeship. Beane's (2018) finding that learners improvise unsanctioned routes when approved pathways fail suggests the demand would not wait for official endorsement. Parents might well build it themselves. Some systems may respond by designating protected device-free periods or phases within mainstream schools, which would blur the bifurcation rather than formalise it.

The planning danger lies less in the existence of unplugged schooling than in the way it is distributed. Two quite different bifurcations are possible. In one, deliberate low-technology provision becomes a premium good, with scarce human attention, small classes and protected deep-reading time purchased by advantaged families, while publicly funded systems lean on agentic automation to contain costs. In the other, 'unplugged' describes not a choice but a deprivation: learners without bandwidth, devices or language coverage are left outside AI-mediated provision entirely, which compounds existing divides (see Q359). These scenarios invert the usual equity assumption, and the same classroom could look identical under either. Educators' duties toward students who cannot or will not use AI (see Q111) will therefore become a structural question for system design, not merely a classroom accommodation.

The disagreement here is genuine. Advocates of immersive and agentic tools, such as Chimbo and colleagues (2026), see technology as the route to equity for marginalised learners. Critics in the tradition Selwyn (2022) represents see value-laden claims and under-acknowledged harms. Barbieri's (2026) diverging trajectories hint that such divisions may already run between teachers and students inside the same schools. What remains unclear is whether unplugged provision produces measurably different long-term capacities, and whether a bifurcated system can be prevented from hardening along socioeconomic lines.

Preparing for this portfolio calls for governance instruments designed for uncertainty. First, planners should identify signposts that reveal which scenario is gaining ground. Useful indicators include the share of instructional decisions delegated to agents, the prevalence of biometric data collection, the disappearance of entry-level tasks in local labour markets, and enrolment patterns in low-technology schools by family income. Second, commitments should be reversible. Short procurement contracts, data-portability requirements and the retention of non-AI pedagogical capacity among teachers allow a system to change course if harms emerge. Third, every scenario has a resource footprint, and long-horizon planning must count energy, water and dependency costs alongside learning claims. Fourth, planners should commission evaluation alongside deployment, so that wearable, agentic and unplugged pilots generate comparable evidence on learning, wellbeing and equity rather than isolated vendor reports.

The leadership dimensions that Kumar and Sarkar (2026) identify, spanning instructional, managerial, strategic and relational work, offer a practical frame for allocating these responsibilities. The expanded threat model of Radanliev and colleagues (2026) argues for treating agentic deployment as a safety-critical decision rather than a software upgrade. Above all, Selwyn's (2022) insistence that AI claims are value-driven implies that scenario choice is ultimately political. Whether a system drifts toward ambient monitoring, agentic automation or protected unplugged spaces will reflect decisions about what education is for, not technological inevitability. The evidence base does not yet show which mix produces the best long-term human outcomes. That uncertainty is the strongest argument for keeping multiple pathways open across the decade.

Living-book maintenance note

- *Could change the conclusions:* Longitudinal outcome studies comparing AI-intensive and deliberately low-technology schooling, or large-scale evaluations of wearable and agentic deployments in schools, would substantially revise these scenarios.

- *Indicators to monitor:* Monitor agentic AI adoption in school administration, biometric data-collection policies, entry-level hiring trends, and enrolment in low-technology schools disaggregated by family income.
- *Related questions:* Q111, Q348, Q350, Q359.

What changed in this edition: This answer is unchanged in Edition 122. Its most recent revision, in Edition 121: New in this edition: a ten-year scenario analysis covering ambient wearables, agentic AI, labour-market recomposition and a possible unplugged schooling bifurcation, with equity risks and uncertainty-robust governance tools. 8. **Three**: Q007, Q023, Q034, Q049, Q050, Q061, Q064, Q068, Q069, Q074, Q075, Q094, Q096, Q161, Q168, Q171, Q187, Q204, Q211, Q227, Q237, Q280
9. **Models**: Q019, Q023, Q069, Q075, Q077, Q094, Q131, Q194, Q207, Q238, Q243, Q251, Q272, Q281, Q317, Q320, Q329, Q334, Q338, Q342, Q344

10. **Educational**: Q094, Q127, Q168, Q170, Q185, Q229, Q239, Q243, Q244, Q248, Q251, Q266, Q267, Q268, Q277, Q339, Q343, Q349, Q360, Q362
11. **Tools**: Q026, Q056, Q058, Q067, Q072, Q073, Q160, Q174, Q195, Q224, Q228, Q248, Q253, Q270, Q287, Q300, Q314, Q321, Q323
12. **Design**: Q030, Q079, Q088, Q185, Q230, Q282, Q283, Q284, Q286, Q288, Q298, Q313, Q328, Q337, Q356, Q359, Q362, Q363
13. **Language**: Q014, Q019, Q035, Q082, Q174, Q176, Q228, Q238, Q242, Q243, Q244, Q272, Q325, Q333, Q338, Q341, Q344, Q359
14. **Professional**: Q022, Q054, Q066, Q076, Q085, Q114, Q126, Q193, Q208, Q214, Q216, Q217, Q254, Q255, Q300, Q316, Q356
15. **Academic**: Q017, Q054, Q075, Q083, Q144, Q183, Q209, Q221, Q252, Q261, Q275, Q278, Q279, Q346, Q355, Q358
16. **Chapter 1: Philosophical Foundations — Why Do We Educate?**: Q001, Q002, Q003, Q004, Q005, Q006, Q007, Q008, Q009, Q010, Q102, Q103, Q104, Q105, Q106, Q258
17. **Chapter 3: Ai's Role In Teaching**: Q021, Q022, Q023, Q024, Q025, Q026, Q027, Q028, Q030, Q114, Q116, Q227, Q230, Q260, Q274, Q355
18. **Assessment**: Q024, Q028, Q074, Q120, Q154, Q202, Q208, Q227, Q230, Q285, Q304, Q306, Q307, Q310, Q311
19. **Chapter 10: Practical Navigation — Guides For Teachers, Students, And Leaders**: Q078, Q079, Q081, Q082, Q083, Q084, Q085, Q086, Q087, Q088, Q147, Q150, Q231, Q265, Q359
20. **Chapter 27: Technical Mechanics Of Educational Ai Systems**: Q011, Q095, Q101, Q266, Q338, Q339, Q340, Q341, Q342, Q343, Q344, Q345, Q346, Q347
21. **Chapter 9: Policy And Governance In Practice**: Q069, Q070, Q071, Q072, Q073, Q074, Q075, Q076, Q077, Q144, Q145, Q264, Q277, Q358
22. **Generated**: Q005, Q033, Q055, Q093, Q114, Q162, Q163, Q164, Q221, Q238, Q241, Q256, Q309, Q351
23. **Chapter 25: Disciplinary Pedagogies Across The Curriculum**: Q226, Q232, Q319, Q320, Q321, Q322, Q323, Q324, Q325, Q326, Q327, Q328, Q329

24. **Chapter 4: The Learner's Experience**: Q031, Q032, Q033, Q034, Q035, Q036, Q037, Q118, Q120, Q121, Q233, Q261, Q356
25. **Current**: Q012, Q047, Q050, Q051, Q059, Q079, Q105, Q170, Q186, Q212, Q262, Q265, Q332
26. **First**: Q007, Q023, Q030, Q049, Q050, Q090, Q147, Q166, Q180, Q216, Q221, Q249, Q267
27. **Suggests**: Q052, Q053, Q059, Q175, Q183, Q228, Q242, Q246, Q248, Q249, Q257, Q258, Q260
28. **System**: Q011, Q082, Q122, Q144, Q147, Q154, Q169, Q182, Q185, Q218, Q252, Q266, Q338
29. **Work**: Q045, Q052, Q071, Q078, Q083, Q102, Q128, Q147, Q165, Q168, Q209, Q275, Q280
30. **Chapter 2: Ethical Dimensions**: Q012, Q013, Q014, Q016, Q017, Q018, Q019, Q020, Q109, Q259, Q353, Q354
31. **Chapter 20: Security, Safety, And Institutional Risk**: Q218, Q220, Q221, Q222, Q223, Q224, Q225, Q256, Q257, Q275, Q276, Q278
32. **Chapter 5: Institutions And Systems**: Q038, Q039, Q040, Q041, Q042, Q043, Q122, Q124, Q126, Q234, Q235, Q279
33. **Chapter 6: Work, Economy, And Society**: Q044, Q045, Q046, Q047, Q048, Q050, Q127, Q128, Q129, Q130, Q131, Q262
34. **Chapter 7: The Evidence Base — What Research Actually Shows**: Q052, Q053, Q054, Q055, Q056, Q057, Q058, Q059, Q060, Q136, Q263, Q273
35. **Institutions**: Q040, Q056, Q062, Q073, Q075, Q085, Q088, Q091, Q126, Q206, Q267, Q312
36. **Show**: Q051, Q054, Q055, Q056, Q058, Q059, Q063, Q188, Q228, Q236, Q249, Q254
37. **Teaching**: Q006, Q025, Q099, Q124, Q162, Q199, Q207, Q209, Q225, Q243, Q269, Q361
38. **Chapter 13: Knowledge Integrity And The Information Environment**: Q162, Q163, Q164, Q165, Q166, Q167, Q168, Q169, Q240, Q241, Q272
39. **Chapter 15: Human Development, Wellbeing, And Mental Health**: Q015, Q178, Q180, Q182, Q183, Q185, Q229, Q245, Q246, Q247, Q362
40. **Chapter 18: Higher Education And Research**: Q202, Q203, Q204, Q205, Q206, Q207, Q208, Q209, Q252, Q253, Q363
41. **Chapter 8: Field Experiences — Case Studies From Real Classrooms**: Q061, Q062, Q063, Q064, Q065, Q066, Q067, Q068, Q236, Q237, Q357

42. **Effects**: Q015, Q032, Q051, Q053, Q058, Q059, Q091, Q092, Q097, Q183, Q245

43. **Machine**: Q008, Q028, Q033, Q039, Q102, Q106, Q114, Q121, Q129, Q167, Q272

44. **Pedagogical**: Q023, Q063, Q094, Q197, Q260, Q284, Q292, Q326, Q340, Q343, Q346

45. **Affect**: Q048, Q057, Q214, Q229, Q243, Q269, Q271, Q281, Q296, Q320

46. **Change**: Q002, Q003, Q005, Q026, Q031, Q103, Q118, Q155, Q176, Q275

47. **Changing**: Q033, Q095, Q099, Q128, Q130, Q203, Q208, Q227, Q232, Q269

48. **Chapter 11: Measurement And Evaluation**: Q089, Q090, Q091, Q092, Q093, Q094, Q154, Q155, Q238, Q239

49. **Chapter 17: Environmental And Material Costs**: Q194, Q195, Q196, Q197, Q198, Q199, Q200, Q201, Q250, Q251

50. **Chapter 23: Authentic Assessment Architecture And The Post-Detection Era**: Q303, Q304, Q305, Q306, Q307, Q308, Q309, Q310, Q311, Q312

51. **Cognitive**: Q015, Q027, Q030, Q053, Q078, Q176, Q303, Q310, Q353, Q357

52. **Digital**: Q193, Q195, Q262, Q291, Q293, Q295, Q299, Q300, Q301, Q359

53. **Educators**: Q026, Q088, Q111, Q230, Q240, Q282, Q294, Q306, Q316, Q328

54. **Learners**: Q035, Q057, Q092, Q233, Q236, Q242, Q302, Q306, Q310, Q315

55. **Must**: Q020, Q104, Q111, Q210, Q266, Q284, Q291, Q309, Q319, Q336

56. **Practice**: Q071, Q079, Q098, Q099, Q103, Q159, Q167, Q217, Q254, Q265

57. **Research**: Q052, Q056, Q100, Q175, Q178, Q203, Q205, Q242, Q253, Q358

58. **Ways**: Q074, Q081, Q130, Q171, Q180, Q208, Q221, Q227, Q270, Q271

59. **Across**: Q061, Q211, Q305, Q313, Q331, Q333, Q348, Q352, Q359

60. **Chapter 14: Language, Culture, And Global Asymmetry**: Q170, Q174, Q175, Q176, Q228, Q242, Q243, Q244, Q361

61. **Chapter 16: Equity, Access, And The New Digital Divide**: Q186, Q187, Q188, Q190, Q191, Q192, Q193, Q248, Q249

62. **Chapter 19: Teacher Formation And The Profession**: Q210, Q211, Q212, Q214, Q215, Q216, Q217, Q254, Q255

53. **Chapter 26: Early Childhood, Developmental Stages, And Parenting In An Ai World**: Q049, Q330, Q331, Q332, Q333, Q334, Q335, Q336, Q337
54. **Development**: Q032, Q041, Q054, Q085, Q126, Q193, Q254, Q258, Q323
55. **Early**: Q054, Q060, Q077, Q086, Q097, Q237, Q261, Q330, Q332
56. **Mainly**: Q099, Q174, Q187, Q215, Q232, Q273, Q288, Q327, Q328
57. **Real**: Q007, Q013, Q025, Q032, Q068, Q085, Q086, Q171, Q233
58. **Studies**: Q055, Q058, Q092, Q238, Q239, Q243, Q252, Q287, Q322
59. **Support**: Q024, Q098, Q116, Q192, Q228, Q242, Q274, Q314, Q336
70. **Chapter 12: Frontiers — Emerging Territories**: Q096, Q097, Q098, Q099, Q100, Q160, Q161, Q360
71. **Classroom**: Q025, Q087, Q101, Q164, Q211, Q231, Q260, Q342
72. **Documented**: Q063, Q068, Q164, Q191, Q205, Q220, Q236, Q244
73. **Exist**: Q069, Q077, Q094, Q145, Q164, Q168, Q199, Q263
74. **Five**: Q078, Q174, Q178, Q210, Q217, Q270, Q307, Q339
75. **Four**: Q077, Q090, Q164, Q200, Q205, Q221, Q224, Q271
76. **Governance**: Q041, Q071, Q073, Q124, Q126, Q231, Q235, Q279
77. **High**: Q057, Q074, Q170, Q233, Q277, Q311, Q346, Q360
78. **Level**: Q116, Q128, Q180, Q231, Q249, Q307, Q334, Q357
79. **Means**: Q002, Q017, Q039, Q047, Q083, Q103, Q185, Q313
80. **Model**: Q038, Q075, Q161, Q187, Q200, Q274, Q346, Q351
81. **Peer**: Q051, Q118, Q121, Q204, Q239, Q252, Q343, Q358
82. **Risks**: Q086, Q161, Q224, Q233, Q326, Q330, Q343, Q350
83. **Single**: Q022, Q038, Q042, Q120, Q144, Q194, Q225, Q311
84. **Technical**: Q066, Q087, Q162, Q168, Q227, Q327, Q333, Q340
85. **Technology**: Q037, Q053, Q105, Q126, Q162, Q218, Q265, Q350
86. **Time**: Q023, Q024, Q122, Q171, Q185, Q212, Q269, Q356

37. **Toward**: Q006, Q020, Q028, Q058, Q104, Q111, Q286, Q356
38. **Universities**: Q040, Q062, Q064, Q207, Q232, Q253, Q277, Q279
39. **Used**: Q053, Q128, Q163, Q171, Q180, Q211, Q224, Q277
40. **Whether**: Q050, Q105, Q145, Q169, Q203, Q268, Q271, Q346
41. **Adoption**: Q058, Q084, Q191, Q216, Q235, Q237, Q269
42. **Arts**: Q095, Q227, Q281, Q283, Q285, Q288, Q289
43. **Capacity**: Q001, Q034, Q041, Q043, Q104, Q105, Q192
44. **Chapter 24: Neurodiversity, Special Education, And Multimodal Accessibility**: Q051, Q171, Q313, Q314, Q315, Q316, Q317
45. **Chapter 28: Environmental Sustainability, Compute Political Economy, And Long-Term Governance**: Q111, Q267, Q348, Q349, Q350, Q351, Q352
46. **Children**: Q015, Q097, Q166, Q178, Q245, Q247, Q333
47. **Conditions**: Q092, Q109, Q126, Q154, Q188, Q192, Q238
48. **Cost**: Q122, Q129, Q200, Q207, Q251, Q266, Q309
49. **Families**: Q094, Q099, Q109, Q168, Q216, Q270, Q336
50. **Govern**: Q042, Q216, Q276, Q288, Q295, Q316, Q358
51. **Integrity**: Q017, Q074, Q075, Q083, Q205, Q221, Q275
52. **Knowledge**: Q003, Q004, Q022, Q039, Q104, Q329, Q341
53. **Less**: Q025, Q036, Q053, Q067, Q121, Q203, Q247
54. **Like**: Q008, Q025, Q036, Q100, Q196, Q254, Q346
55. **Main**: Q074, Q075, Q077, Q094, Q164, Q171, Q180
56. **Outcomes**: Q051, Q089, Q185, Q191, Q237, Q251, Q268
57. **Parents**: Q086, Q099, Q150, Q235, Q270, Q333, Q335
58. **Physical**: Q095, Q232, Q285, Q290, Q297, Q302, Q326
59. **Serve**: Q020, Q083, Q170, Q241, Q293, Q325, Q355
60. **Standard**: Q091, Q101, Q168, Q194, Q217, Q317, Q338

1. **Synthetic**: Q161, Q165, Q278, Q287, Q324, Q336, Q351
2. **Teach**: Q027, Q044, Q169, Q210, Q282, Q287, Q299
3. **Tool**: Q147, Q154, Q186, Q192, Q257, Q273, Q347
4. **Training**: Q026, Q066, Q085, Q122, Q203, Q257, Q282
5. **Treat**: Q014, Q043, Q073, Q169, Q276, Q312, Q359
6. **Tutoring**: Q013, Q051, Q118, Q129, Q245, Q274, Q320
7. **Writing**: Q034, Q054, Q083, Q175, Q272, Q319, Q335
8. **Access**: Q088, Q159, Q186, Q193, Q315, Q334
9. **Analysis**: Q155, Q201, Q283, Q287, Q321, Q326
10. **Assessments**: Q064, Q079, Q238, Q305, Q306, Q311
